$$\left[\frac{\hbar^2}{Mr^2} \left(-\frac{1}{2} \frac{1}{\sin \theta} \frac{d}{d\theta} \sin \theta \frac{d}{d\theta} + \frac{m^2}{2 \sin^2 \theta} \right) + \hbar \partial_\tau \right] (\sin \theta \tau | \sin \theta_a \tau_a)_m = \hbar \delta(\tau - \tau_a) \delta(\cos \theta - \cos \theta_a). \quad (8.196)$$

This follows from the differential equation obeyed by the Legendre polynomials $P_l^m(\cos \theta)$ in (8.87). The new amplitude $(\theta \tau | \theta_a \tau_a)_m$, on the other hand, satisfies the equation [corresponding to that of $\sqrt{\sin \theta} P_l^m(\cos \theta)$ in the footnote to Eq. (8.87)]

$$\left[\frac{\hbar^2}{Mr^2} \left(-\frac{1}{2} \frac{d}{d\theta^2} - \frac{1}{8} + \frac{m^2 - 1/4}{2 \sin^2 \theta} \right) + \hbar \partial_\tau \right] (\theta \tau | \theta_a \tau_a)_m = \hbar \delta(\tau - \tau_a) \delta(\theta - \theta_a). \quad (8.197)$$

8.8.2 Angular Barriers in Four Dimensions

In four dimensions, the angular momentum decomposition reads in terms of Euler angles [see (8.162)]

$$\begin{aligned} (\mathbf{u}_b \tau_b | \mathbf{u}_a \tau_a) &= \sum_{l=0}^{\infty} \exp \left\{ -\frac{\hbar L_2}{2Mr^2} (\tau_b - \tau_a) \right\} \\ &\times \frac{l+1}{2\pi^2} \sum_{m_1 m_2 = -l/2}^{l/2} d_{m_1 m_2}^{l/2}(\theta_b) d_{m_1 m_2}^{l/2}(\theta_a) e^{im_1(\varphi_b - \varphi_a) + im_2(\gamma_b - \gamma_a)}, \end{aligned} \quad (8.198)$$

with

$$L_2 \equiv (l+1)^2 - 1/4 = 4(l/2)(l/2+1) + 3/4 \quad (8.199)$$

and m_1, m_2 running over integers or half-integers depending on $l/2$. We now define the projected amplitudes by the expansion

$$(\mathbf{u}_b \tau_b | \mathbf{u}_a \tau_a) = 8 \sum_{m_1 m_2} (\sin \theta_b \tau_b | \sin \theta_a \tau_a)_{m_1 m_2} \frac{1}{2\pi} e^{im_1(\varphi_b - \varphi_a)} \frac{1}{4\pi} e^{im_2(\gamma_b - \gamma_a)}. \quad (8.200)$$

As in (8.164), it is again convenient to introduce the differently normalized amplitude $(\theta_b\tau_b|\theta_a\tau_a)_m$ defined by

$$(\theta_b\tau_b|\theta_a\tau_a)_{m_1m_2} \equiv \sqrt{\sin\theta_b \sin\theta_a} (\sin\theta_b\tau_b | \sin\theta_a\tau_a)_{m_1m_2}, \quad (8.201)$$

in terms of which the expansion becomes [compare (8.163)]

$$(\mathbf{u}_b\tau_b|\mathbf{u}_a\tau_a) = \sum_m \frac{8}{\sqrt{\sin\theta_b \sin\theta_a}} (\theta_b\tau_b|\theta_a\tau_a)_{m_1m_2} \frac{1}{2\pi} e^{im(\varphi_b-\varphi_a)} \frac{1}{4\pi} e^{im(\gamma_b-\gamma_a)}. \quad (8.202)$$

A comparison with (8.198) gives immediately the projected amplitude

$$\begin{aligned} (\theta_b\tau_b|\theta_a\tau_a)_{m_1m_2} &= \sqrt{\sin\theta_b \sin\theta_a} \\ &\times \sum_l \exp\left\{-\frac{\hbar[(l+1)^2 - 1/4]}{2Mr^2}(\tau_b - \tau_a)\right\} \frac{l+1}{2} d_{m_1m_2}^{l/2}(\theta_b) d_{m_1m_2}^{l/2}(\theta_a), \end{aligned} \quad (8.203)$$

in which l is summed in even steps from the larger value of $|2m_1|, |2m_2|$ to infinity.

Let us write down the time-sliced path integral leading to this amplitude. According to (8.151)–(8.153), it is given by

$$(\mathbf{u}_b\tau_b|\mathbf{u}_a\tau_a) \approx \frac{1}{\sqrt{2\pi\hbar\epsilon/Mr^2}^3} \prod_{n=1}^N \left[\int_0^\pi \int_0^{2\pi} \int_0^{4\pi} \frac{d\theta_n \sin\theta_n d\varphi_n d\gamma_n}{8\sqrt{2\pi\hbar\epsilon/Mr^2}^3} \right] \exp\left(-\frac{1}{\hbar} \mathcal{A}^N\right). \quad (8.204)$$

In each time slice we make use of the addition theorem (8.129) and expand the exponent with (8.6) as

$$\begin{aligned} \exp\left[-\frac{Mr^2}{2\hbar\epsilon}(\mathbf{u}_n - \mathbf{u}_{n-1})^2\right] &= \exp\left[-\frac{Mr^2}{\hbar\epsilon}(1 - \cos\Delta\vartheta_n)\right] \\ &= \exp\left\{-\frac{Mr^2}{2\hbar\epsilon}[1 - \cos(\theta_n/2)\cos(\theta_{n-1}/2) - \sin(\theta_n/2)\sin(\theta_{n-1}/2)]\right\} \\ &\times \frac{1}{\sqrt{2\pi\hbar_n^c}} \frac{1}{\sqrt{4\pi\hbar_n^s}} \sum_{m_1, m_2=-\infty}^{\infty} \tilde{I}_{|m_1+m_2|}^c(\hbar_n^c) \tilde{I}_{|m_1-m_2|}^s(\hbar_n^s) \\ &\times \exp\{im_1(\varphi_n - \varphi_{n-1}) + im_2(\gamma_n - \gamma_{n-1})\}, \end{aligned} \quad (8.205)$$

where \hbar_n^c and \hbar_n^s are given by

$$\hbar_n^c = \frac{Mr^2}{\hbar\epsilon} \cos(\theta_n/2) \cos(\theta_{n-1}/2), \quad \hbar_n^s = \frac{Mr^2}{\hbar\epsilon} \sin(\theta_n/2) \sin(\theta_{n-1}/2). \quad (8.206)$$

By doing successively the φ_n - and γ_n -integrations, we wind up with the path integral for the projected amplitude

$$(\theta_b\tau_b|\theta_a\tau_a)_{m_1m_2} \approx \frac{1}{\sqrt{2\pi\epsilon\hbar/4Mr^2}^N} \prod_{n=1}^N \left[\int_0^\pi \frac{d\theta_n}{\sqrt{2\pi\epsilon\hbar/4Mr^2}} \right] \exp\left\{-\frac{1}{\hbar} \mathcal{A}_{m_1m_2}^N\right\}, \quad (8.207)$$

where $\mathcal{A}_{m_1 m_2}^N$ is the sliced action

$$\mathcal{A}_{m_1 m_2}^N = \sum_{n=1}^{N+1} \left\{ \frac{Mr^2}{\epsilon} [1 - \cos[(\theta_n - \theta_{n-1})/2]] - \hbar \log \tilde{I}_{|m_1+m_2|}(\hbar_n^c) - \hbar \log \tilde{I}_{|m_1-m_2|}(\hbar_n^s) \right\}. \quad (8.208)$$

For small ϵ , this can be approximated (setting $\Delta\theta_n \equiv \theta_n - \theta_{n-1}$) by

$$\mathcal{A}_{m_1 m_2}^N \rightarrow \epsilon \sum_{n=1}^{N+1} \left\{ \frac{Mr^2}{2\epsilon^2} [(\Delta\theta_n/2)^2 - \frac{1}{12}(\Delta\theta_n/2)^4 + \dots] + \frac{\hbar^2}{2Mr^2} \frac{(m_1 + m_2)^2 - 1/4}{\cos(\theta_n/2) \cos(\theta_{n-1}/2)} + \frac{\hbar^2}{2Mr^2} \frac{(m_1 - m_2)^2 - 1/4}{\sin(\theta_n/2) \sin(\theta_{n-1}/2)} \right\}, \quad (8.209)$$

with the continuum limit

$$\mathcal{A}_{m_1 m_2} = \int_{\tau_a}^{\tau_b} d\tau \left(\frac{Mr^2}{8} \dot{\theta}^2 - \frac{\hbar^2}{8Mr^2} + \frac{\hbar^2}{2Mr^2} \frac{|m_1 + m_2|^2 - 1/4}{\cos^2(\theta/2)} + \frac{\hbar^2}{2Mr^2} \frac{|m_1 - m_2|^2 - 1/4}{\sin^2(\theta/2)} \right). \quad (8.210)$$

After introducing the auxiliary mass

$$\mu = M/4 \quad (8.211)$$

and rearranging the potential terms, we can write the action equivalently as

$$\mathcal{A}_{m_1 m_2} = \int_{\tau_a}^{\tau_b} d\tau \left(\frac{\mu r^2}{2} \dot{\theta}^2 - \frac{\hbar^2}{32\mu r^2} + \frac{\hbar^2}{2\mu r^2} \frac{m_1^2 + m_2^2 - 1/4 - 2m_1 m_2 \cos \theta}{\sin^2 \theta} \right). \quad (8.212)$$

Just as in the previous system, this action contains an angular barrier $1/\sin^2 \theta$ at $\theta = 0$, and $\theta = \pi$, so that the amplitude (8.207) with the naively time-sliced action (8.176) does not exist for $m_1 = m_2$ or $m_1 = -m_2$, due to path collapse. Only with the properly time-sliced action (8.208) is the path integral stable and solvable by successive integrations with the result (8.203).

As before, the path integral (8.207) is initially only defined and solved by (8.203) if both m_1 and m_2 have integer or half-integer values. The path integral and its solution can, however, be continued to arbitrary real values of $m_1 = \mu_1 \geq 0$ and its $m_2 = \mu_2 \geq 0$. For this we rewrite (8.203) in the form [4]

$$(\theta_b \tau_b | \theta_a \tau_a)_{\mu_1 \mu_2} = \sqrt{\sin \theta_b \sin \theta_a} \quad (8.213)$$

$$\times \sum_{n=0}^{\infty} \exp \left\{ -\frac{\hbar[(n + \mu_1 + 1)^2 - 1/4]}{2Mr^2} (\tau_b - \tau_a) \right\} \frac{n + \mu_1 + 1}{2} d_{\mu_1 \mu_2}^{n+\mu_1}(\theta_b) d_{\mu_1 \mu_2}^{n+\mu_1}(\theta_a),$$

assuming that $\mu_1 \geq \mu_2$. The products of the rotation functions $d_{\mu_1 \mu_2}^\lambda(\theta)$ have a well-defined analytic continuation to arbitrary real values of the indices μ_1, μ_2, λ , as can be seen by expressing them in terms of Jacobi polynomials via formula (1.446).

To perform the path integral in the analytically continued case, we use the expansion valid for all μ_+, μ_- ,¹³

$$\begin{aligned} \frac{z}{2} J_{\mu_+}(z \cos \alpha \cos \beta) J_{\mu_-}(z \sin \alpha \sin \beta) &= \cos^{\mu_+} \alpha \cos^{\mu_+} \beta \sin^{\mu_-} \alpha \sin^{\mu_-} \beta \\ &\times \sum_{n=0}^{\infty} (-1)^n (\mu_+ + \mu_- + 2n + 1) J_{\mu_+ + \mu_- + 2n + 1}(z) \\ &\times \frac{\Gamma(n + \mu_+ + \mu_- + 1) \Gamma(n + \mu_- + 1)}{n! \Gamma(n + \mu_+ + 1) [\Gamma(\mu_- + 1)]^2} \\ &\times F(-n, n + \mu_+ + \mu_- + 1; \mu_- + 1; \sin^2 \alpha) \\ &\times F(-n, n + \mu_+ + \mu_- + 1; \mu_- + 1; \sin^2 \beta) \end{aligned} \quad (8.214)$$

with $\zeta \equiv Mr^2/\hbar\epsilon$. The hypergeometric functions appearing on the right-hand side have a first argument with a negative integer value. They are therefore proportional to the Jacobi polynomials $P_n^{(\mu_-, \mu_+)}$:

$$P_n^{(\mu_-, \mu_+)}(x) = \frac{1}{n!} \frac{\Gamma(n + \mu_- + 1)}{\Gamma(\mu_- + 1)} F(-n, n + \mu_+ + \mu_- + 1; 1 + \mu_-; (1 - x)/2) \quad (8.215)$$

[recall (1.446) and the identity $P_n^{(\mu_-, \mu_+)}(x) = (-)^n P_n^{(\mu_-, \mu_+)}(-x)$]. Inserting $z = i\zeta$, $\alpha = \theta_n/2$, $\beta = \theta_{n-1}/2$, and expressing the Jacobi polynomials in terms of rotation functions continued to real-valued μ_1, μ_2 , we obtain from (8.214) for $\mu_1 \geq \mu_2$

$$\begin{aligned} I_{\mu_+} \left(\zeta \cos \frac{\theta_n}{2} \cos \frac{\theta_{n-1}}{2} \right) I_{\mu_-} \left(\zeta \sin \frac{\theta_n}{2} \sin \frac{\theta_{n-1}}{2} \right) \\ = \frac{4}{\zeta} \sum_{n=0}^{\infty} I_{2n + \mu_+ + \mu_- + 1}(\zeta) \frac{(n + \mu_1 + \mu_2)! (n + \mu_1 - \mu_2)!}{(n + 2\mu_1)! n!} d_{\mu_1 \mu_2}^{n + \mu_1}(\theta_n) d_{\mu_1 \mu_2}^{n + \mu_1}(\theta_{n-1}). \end{aligned} \quad (8.216)$$

Now we make use of the orthogonality relation [compare (1.455)]

$$\int_{-1}^1 d \cos \theta d_{\mu_1 \mu_2}^{n + \mu_1}(\theta) d_{\mu_1 \mu_2}^{n' + \mu_1}(\theta) = \delta_{nn'} \frac{2}{2n + 1}, \quad (8.217)$$

which for real μ_1, μ_2 follows from the corresponding relation for Jacobi polynomials¹⁴

$$\begin{aligned} \int_{-1}^1 dx (1 - x)^{\mu_-} (1 + x)^{\mu_+} P_n^{(\mu_-, \mu_+)}(x) P_{n'}^{(\mu_-, \mu_+)}(x) \\ = \delta_{nn'} \frac{2^{\mu_+ + \mu_- + 1} \Gamma(\mu_+ + n + 1) \Gamma(\mu_- + n + 1)}{n! (\mu_+ + \mu_- + 1 + 2n) \Gamma(\mu_+ + \mu_- + n + 1)}, \end{aligned} \quad (8.218)$$

¹³G.N. Watson, op. cit., Chapter 11.6, Gl. (11.6), (1).

¹⁴I.S. Gradshteyn and I.M. Ryzhik, op. cit., Formula 7.391.

valid for $\text{Re } \mu_+ > -1$, $\text{Re } \mu_- > -1$. Performing all θ_n -integrations in (8.207) yields the time-sliced amplitude

$$(\theta_b \tau_b | \theta_a \tau_a)_{\mu_1 \mu_2} = \sqrt{\sin \theta_b \sin \theta_a} \sum_{n=0}^{\infty} [\tilde{I}_{2n+\mu_++\mu_-+1}(\zeta)]^{N+1} d_{\mu_1 \mu_2}^{n+\mu_1}(\theta_b) d_{\mu_1 \mu_2}^{n+\mu_1}(\theta_a), \quad (8.219)$$

valid for all real $\mu_1 \geq \mu_2 \geq 0$. In the continuum limit, this becomes

$$(\theta_b \tau_b | \theta_a \tau_a)_{\mu_1 \mu_2} = \sqrt{\sin \theta_b \sin \theta_a} \sum_{n=0}^{\infty} e^{-E_n(\tau_b - \tau_a)/\hbar} d_{\mu_1 \mu_2}^{n+\mu_1}(\theta_b) d_{\mu_1 \mu_2}^{n+\mu_1}(\theta_a), \quad (8.220)$$

with

$$E_n = \frac{\hbar}{2Mr^2} [(2n + \mu_+ + \mu_- + 1)^2 - 1/4], \quad (8.221)$$

which proves (8.213).

Apart from the projected motion of a particle near the surface of the sphere, the amplitude (8.213) describes also a particle moving in the general Pöschl-Teller potential [5]

$$V_{\mathcal{PT}'}(\theta) = \frac{\hbar^2}{2Mr^2} \left[\frac{s_1(s_1+1)}{\sin^2(\theta/2)} + \frac{s_2(s_2+1)}{\cos^2(\theta/2)} \right]. \quad (8.222)$$

Due to the analytic continuation to arbitrary real m_1, m_2 the parameters s_1 and s_2 are arbitrary with the potential strength parameters $s_1 = m_1 + m_2 - 1/2$ and $s_2 = m_1 - m_2 - 1/2$. This will be discussed further in Chapter 14.

Recalling the differential equation (1.454) satisfied by the rotation functions $d_{m_1 m_2}^{l/2}(\theta)$, we see that the original projected amplitude (8.207) obeys the Schrödinger equation

$$\left[\frac{\hbar^2}{2\mu r^2} \left(-\frac{1}{\sin \theta} \frac{d}{d\theta} \sin \theta \frac{d}{d\theta} + \frac{3}{16} + \frac{m_1^2 + m_2^2 - 2m_1 m_2 \cos \theta}{\sin^2 \theta} \right) + \hbar \partial_\tau \right] \times (\sin \theta \tau | \sin \theta_a \tau_a)_{m_1 m_2} = \hbar \delta(\tau - \tau_a) \delta(\cos \theta - \cos \theta_a). \quad (8.223)$$

The extra term $3/16$ is necessary to account for the energy difference between the motion near the surface of a sphere in four dimensions, whose energy is $(\hbar^2/2\mu r^2)[(l/2)(l/2+1) + 3/16]$ [see (8.158)], and that of a symmetric spinning top with angular momentum $L = l/2$ in three dimensions, whose energy is $(\hbar^2/2\mu r^2)(l/2)(l/2+1)$, as shown in the next section in detail.

The amplitude $(\theta_b \tau_b | \theta_a \tau_a)_{m_1 m_2}$ defined in (8.201) satisfies the differential equation

$$\left[\frac{\hbar^2}{2\mu r^2} \left(-\frac{d^2}{d\theta^2} - \frac{1}{16} + \frac{m_1^2 + m_2^2 - 1/4 - 2m_1 m_2 \cos \theta}{\sin^2 \theta} \right) + \hbar \partial_\tau \right] \times (\theta \tau | \theta_a \tau_a)_{m_1 m_2} = \hbar \delta(\tau - \tau_a) \delta(\theta - \theta_a). \quad (8.224)$$

This is, of course, precisely the Schrödinger equation associated with the action (8.212).

8.9 Motion on a Sphere in L Dimensions

The wave functions in the time evolution amplitude *near* the surface of a sphere are also correct for the motion *on* a sphere. This is not true for the energies, for which the amplitude (8.158) gives

$$E_l = \frac{\hbar^2}{2Mr^2}(L_2^2)_l, \quad (8.225)$$

with

$$(L_2^2)_l = (l + D/2 - 1)^2 - 1/4, \quad l = 0, 1, 2, \dots \quad (8.226)$$

As we know from Section 1.14, the energies should be equal to

$$E_l = \frac{\hbar^2}{2Mr^2}(\hat{L}^2)_l, \quad (8.227)$$

where $(\hat{L}^2)_l$ denotes the eigenvalues of the square of the angular momentum operator. In D dimensions, the eigenvalues are known from the Schrödinger theory to be

$$(\hat{L}^2)_l = l(l + D - 2), \quad l = 0, 1, 2, \dots \quad (8.228)$$

Apart from the trivial case $D = 1$, the two energies are equal only for $D = 3$, where $(L_2^2)_l \equiv (\hat{L}^2)_l = l(l + 1)$. For all other dimensions, we shall have to remove the difference

$$\Delta(L_2^2)_l \equiv \hat{L}^2 - L_2^2 = \frac{1}{4} - \left(\frac{D}{2} - 1\right)^2 = -\frac{(D-1)(D-3)}{4}. \quad (8.229)$$

The simplest nontrivial case where the difference appears is for $D = 2$ where the role of l is played by the magnetic quantum number m and $(L_2^2)_m = m^2 - 1/4$, whereas the correct energies should be proportional to $(\hat{L}^2)_m = m^2$.

Two changes are necessary in the time-sliced path integral to find the correct energies. First, the time-sliced action (8.152) must be modified to measure the proper distance on the surface rather than the Euclidean distance in the embedding space. Second, we will have to correct the measure of path integration. The modification of the action is simply

$$\mathcal{A}_{\text{on sphere}}^N = \frac{M}{\epsilon} r^2 \sum_{n=1}^{N+1} \frac{(\Delta\vartheta_n)^2}{2}, \quad (8.230)$$

in addition to

$$\mathcal{A}^N = \frac{M}{\epsilon} r^2 \sum_{n=1}^{N+1} (1 - \cos \Delta\vartheta_n). \quad (8.231)$$

Since the time-sliced path integral was solved exactly with the latter action, it is convenient to expand the true action around the solvable one as follows:

$$\mathcal{A}_{\text{on sphere}}^N = \frac{M}{\epsilon} r^2 \sum_{n=1}^{N+1} \left[(1 - \cos \Delta\vartheta_n) + \frac{1}{24} (\Delta\vartheta_n)^4 - \dots \right]. \quad (8.232)$$

There is no need to go to higher than the fourth order in $\Delta\vartheta_n$, since these do not contribute to the relevant order ϵ . For $D = 2$, the correction of the action is sufficient to transform the path integral *near* the surface of the sphere into one *on* the sphere, which in this reduced dimension is merely a circle. On a circle, $\Delta\vartheta_n = \varphi_n - \varphi_{n-1}$ and the measure of path integration becomes

$$\frac{1}{\sqrt{2\pi\hbar\epsilon/Mr^2}} \prod_{n=1}^{N+1} \int_{-\pi/2}^{\pi/2} \frac{d\varphi_n}{\sqrt{2\pi\hbar\epsilon/Mr^2}}. \quad (8.233)$$

The quartic term $(\Delta\vartheta_n)^4 = (\varphi_n - \varphi_{n-1})^4$ can be replaced according to the rules of perturbation theory by its expectation [see (8.62)]

$$\langle(\Delta\vartheta_n)^4\rangle_0 = 3\frac{\epsilon\hbar}{Mr^2}. \quad (8.234)$$

The correction term in the action

$$\Delta_{\text{qu}}\mathcal{A}^N = \frac{M}{\epsilon}r^2 \sum_{n=1}^{N+1} \frac{1}{24}(\Delta\vartheta_n)^4 \quad (8.235)$$

has, therefore, the expectation

$$\langle\Delta_{\text{qu}}\mathcal{A}^N\rangle_0 = (N+1)\epsilon\frac{\hbar^2/4}{2Mr^2}. \quad (8.236)$$

This supplies precisely the missing term which raises the energy from the *near*-the-surface value $E_m = \hbar^2(m^2 - 1/4)/2Mr^2$ to the proper *on*-the-sphere value $E_m = \hbar^2m^2/2Mr^2$.

In higher dimensions, the path integral near the surface of a sphere requires a second correction. The difference (8.229) between \hat{L}^2 and L_2^2 is negative. Since the expectation of the quartic correction term alone is always positive, it can certainly not explain the difference.¹⁵ Let us calculate first its contribution at arbitrary D . For very small ϵ , the fluctuations near the surface of the sphere lie close to the $D - 1$ -dimensional tangent space. Let $\Delta\mathbf{x}_n$ be the coordinates in this space. Then we can write the quartic correction term as

$$\Delta_{\text{qu}}\mathcal{A}^N \approx \frac{M}{\epsilon} \sum_{n=1}^{N+1} \frac{1}{24r^2}(\Delta\mathbf{x}_n)^4, \quad (8.237)$$

where the components $(\Delta\mathbf{x}_n)_i$ have the correlations

$$\langle(\Delta\mathbf{x}_n)_i(\Delta\mathbf{x}_n)_j\rangle_0 = \frac{\hbar\epsilon}{M}\delta_{ij}. \quad (8.238)$$

¹⁵This was claimed by G. Junker and A. Inomata, in *Path Integrals from meV to MeV*, edited by M.C. Gutzwiller, A. Inomata, J.R. Klauder, and L. Streit (World Scientific, Singapore, 1986), p.333.

Thus, according to the rule (8.62), $\Delta_{\text{qu}}\mathcal{A}^N$ has the expectation

$$\langle \Delta\mathcal{A}^N \rangle_0 = (N+1)\epsilon \frac{\hbar^2}{2Mr^2} \Delta_{\text{qu}}L_2^2, \quad (8.239)$$

where $\Delta_{\text{qu}}L_2^2$ is the contribution of the quartic term to the value L_2^2 :

$$\Delta_{\text{qu}}L_2^2 = \frac{D^2 - 1}{12}. \quad (8.240)$$

This result is obtained using the contraction rules for the tensor

$$\langle \Delta x_i \Delta x_j \Delta x_k \Delta x_l \rangle_0 = \left(\frac{\epsilon \hbar}{M} \right)^2 (\delta_{ij} \delta_{kl} + \delta_{ik} \delta_{jl} + \delta_{il} \delta_{jk}), \quad (8.241)$$

which follow from the integrals (8.63).

Incidentally, the same result can also be derived in a more pedestrian way: The term $(\Delta \mathbf{x}_n)^4$ can be decomposed into $D-1$ quartic terms of the individual components Δx_{ni} , and $(D-1)(D-2)$ mixed quadratic terms $(\Delta x_{ni})^2 (\Delta x_{nj})^2$ with $i \neq j$. The former have an expectation $(D-1) \cdot 3(\epsilon \hbar / Mr)^2$, the latter $(D-1)(D-2) \cdot (\epsilon \hbar / Mr)^2$. When inserted into (8.237), they lead to (8.239).

Thus we remain with a final difference in D dimensions:

$$\Delta_f L_2^2 = \Delta L_2^2 - \Delta_{\text{qu}} L_2^2 = -\frac{1}{3}(D-1)(D-2). \quad (8.242)$$

This difference can be removed only by the measure of the path integral. Near the sphere we have used the measure

$$\prod_{n=1}^N \left[\int \frac{d^{D-1} \mathbf{u}_n}{\sqrt{2\pi \hbar \epsilon / Mr^2}^{D-1}} \right]. \quad (8.243)$$

In Chapter 10 we shall argue that this measure is incorrect. We shall find that the measure (8.243) receives a correction factor

$$\prod_{n=1}^N \left[1 + \frac{D-2}{6} (\Delta \vartheta_n)^2 \right] \quad (8.244)$$

[see the factor $(1 + i\Delta \mathcal{A}_j^\epsilon)$ of Eq. (10.151)]. Setting $(\Delta \vartheta_n)^2 = (\Delta \mathbf{x}_n / r)^2$, the expectation of this factor becomes

$$\prod_{n=1}^N \left[1 + \frac{(D-2)(D-1)}{6r^2} \frac{\epsilon \hbar}{M} \right] \quad (8.245)$$

corresponding to a correction term in the action

$$\langle \Delta \mathcal{A}_f^N \rangle_0 = (N+1)\epsilon \frac{\hbar^2}{2Mr^2} \Delta_f L_2^2, \quad (8.246)$$

with $\Delta_f L_2^2$ given by (8.242). This explains the remaining difference between the eigenvalues $(L_2)_l$ and $(\hat{L})_l^2$.

In summary, the time evolution amplitude on the D -dimensional sphere reads [6]

$$(\mathbf{u}_b \tau_b | \mathbf{u}_a \tau_a) = \sum_{l=0}^{\infty} \exp \left[-\frac{\hbar \hat{L}^2}{2Mr^2} (\tau_b - \tau_a) \right] \sum_{\mathbf{m}} Y_{l\mathbf{m}}(\mathbf{u}_b) Y_{l\mathbf{m}}^*(\mathbf{u}_a), \quad (8.247)$$

with

$$\hat{L}^2 = l(l + D - 2), \quad (8.248)$$

which are precisely the eigenvalues of the squared angular momentum operator of Schrödinger quantum mechanics. For $D = 3$ and $D = 4$, the amplitude (8.247) coincides with the more specific representations (8.161) and (8.162), if L_2^2 is replaced by \hat{L}^2 .

Finally, let us emphasize that in contrast to the amplitude (8.158) *near* the surface of the sphere, the normalization of the amplitude (8.247) *on* the sphere is

$$\int d^{D-1} \mathbf{u}_b (\mathbf{u}_b \tau_b | \mathbf{u}_a \tau_a) = 1. \quad (8.249)$$

This follows from the integral

$$\begin{aligned} \int d^{D-1} \mathbf{u}_b \sum_{\mathbf{m}} Y_{l\mathbf{m}}(\mathbf{u}_b) Y_{l\mathbf{m}}^*(\mathbf{u}_a) &= \delta_{l0} \int d^{D-1} \mathbf{u}_b Y_{00}(\mathbf{u}_b) Y_{00}^*(\mathbf{u}_a) \\ &= \delta_{l0} \int d^{D-1} \mathbf{u}_b 1/S_D = \delta_{l0}. \end{aligned} \quad (8.250)$$

This is in contrast to the amplitude near the surface which satisfies

$$\int d^{D-1} \mathbf{u}_b (\mathbf{u}_b \tau_b | \mathbf{u}_a \tau_a) = \exp \left[-\frac{(D/2 - 1)^2 - 1/4}{2\mu r^2} (\tau_b - \tau_a) \right]. \quad (8.251)$$

We end this section with the following observation. In the continuum, the Euclidean path integral on the surface of a sphere can be rewritten as a path integral in flat space with an auxiliary path integral over a Lagrange multiplier $\lambda(\tau)$ in the form¹⁶

$$(\mathbf{x}_b \tau_b | \mathbf{x}_a \tau_a) = \int_{-i\infty}^{i\infty} \int \mathcal{D}^2 x(\tau) \frac{\mathcal{D}\lambda(\tau)}{2\pi i \hbar} \exp \left(-\frac{1}{\hbar} \int_{\tau_a}^{\tau_b} d\tau \left\{ \frac{M}{2} \dot{\mathbf{x}}^2 + \frac{\lambda(\tau)}{2r} [x^2(\tau) - r^2] \right\} \right). \quad (8.252)$$

A naive time slicing of this expression would *not* yield the correct energy spectrum on the sphere. The slicing would lead to the product of integrals

$$(\mathbf{u}_b t_b | \mathbf{u}_a t_a) \approx \prod_{n=1}^N \left[\int d^D x_n \right] \prod_{n=1}^N \left[\int \frac{d\lambda_n}{2\pi i \hbar / \epsilon} \right] \exp \left(\frac{i}{\hbar} \mathcal{A}^N \right), \quad (8.253)$$

¹⁶The field-theoretic generalization of this path integral, in which τ is replaced by a d -dimensional spatial vector \mathbf{x} , is known as the $O(D)$ -symmetric *nonlinear σ -model* in d dimensions. In statistical mechanics it corresponds to the well-studied classical $O(D)$ Heisenberg model in d dimensions.

with $\mathbf{u} \equiv \mathbf{x}/|\mathbf{x}|$ and the time-sliced action

$$\mathcal{A}^N = \sum_{n=1}^{N+1} \left[\frac{M}{2\epsilon} (\mathbf{x}_n - \mathbf{x}_{n-1})^2 + \epsilon \frac{\lambda_n}{2r} (\mathbf{x}_n^2 - r^2) \right]. \quad (8.254)$$

Integrating out the λ_n 's would produce precisely the expression (8.151) with the action (8.152) *near* the surface of the sphere. The δ -functions arising from the λ_n -integrations would force only the intermediate positions \mathbf{x}_n to lie on the sphere; the sliced kinetic terms, however, would not correspond to the geodesic distance. Also, the measure of path integration would be wrong.

8.10 Path Integrals on Group Spaces

In Section 8.3, we have observed that the surface of a sphere in four dimensions is equivalent to the covering group of rotations in three dimensions, i.e., with the group SU(2). Since we have learned how to write down an exactly solvable time-sliced path integral *near* and *on* the surface of the sphere, the equivalence opens up the possibility of performing path integrals for the motion of a mechanical system *near* and *on* the group space of SU(2). The most important system to which the path integral on the group space of SU(2) can be applied is the spinning top, whose Schrödinger quantum mechanics was discussed in Section 1.15. Exploiting the above equivalence we are able to describe the same quantum mechanics in terms of path integrals. The theory to be developed for this particular system will, after a suitable generalization, be applicable to systems whose dynamics evolves on any group space.

First, we discuss the path integral *near* the group space using the exact result of the path integral *near* the surface of the sphere in four dimensions. The crucial observation is the following: The time-sliced action near the surface

$$\mathcal{A}^N = \frac{M}{2\epsilon} r^2 \sum_{n=1}^{N+1} (\mathbf{u}_n - \mathbf{u}_{n-1})^2 = \frac{Mr^2}{\epsilon} \sum_{n=1}^{N+1} (1 - \cos \Delta\vartheta_n) \quad (8.255)$$

can be rewritten in terms of the group elements $g(\varphi, \theta, \gamma)$ defined in Eq. (8.123) as

$$\mathcal{A}^N = \frac{M}{\epsilon} r^2 \sum_{n=1}^{N+1} \left[1 - \frac{1}{2} \text{tr}(g_n g_{n-1}^{-1}) \right], \quad (8.256)$$

with the obvious notation

$$g_n = g(\varphi_n, \theta_n, \gamma_n). \quad (8.257)$$

This follows after using the explicit matrix form for g , which reads

$$\begin{aligned} g(\varphi, \theta, \gamma) &= \exp(i\varphi\sigma_3/2) \exp(i\theta\sigma_2/2) \exp(i\gamma\sigma_3/2) \\ &= \begin{pmatrix} e^{i\varphi/2} & 0 \\ 0 & e^{-i\varphi/2} \end{pmatrix} \begin{pmatrix} \cos(\theta/2) & \sin(\theta/2) \\ -\sin(\theta/2) & \cos(\theta/2) \end{pmatrix} \begin{pmatrix} e^{i\gamma/2} & 0 \\ 0 & e^{-i\gamma/2} \end{pmatrix}. \end{aligned} \quad (8.258)$$

After a little algebra we find

$$\begin{aligned} \frac{1}{2}\text{tr}(g_n g_{n-1}^{-1}) &= \cos(\theta_n/2) \cos(\theta_{n-1}/2) \cos[(\varphi_n - \varphi_{n-1} + \gamma_n - \gamma_{n-1})/2] \\ &+ \sin(\theta_n/2) \sin(\theta_{n-1}/2) \cos[(\varphi_n - \varphi_{n-1} - \gamma_n + \gamma_{n-1})/2], \end{aligned} \quad (8.259)$$

just as in (8.129). The invariant group integration measure is usually defined to be normalized to unity, i.e.,

$$\int dg \equiv \frac{1}{16\pi^2} \int_0^\pi \int_0^{2\pi} \int_0^{4\pi} d\theta \sin\theta d\varphi d\gamma = \frac{1}{2\pi^2} \int d^3\mathbf{u} = 1. \quad (8.260)$$

We shall renormalize the time evolution amplitude $(\mathbf{u}_b \tau_b | \mathbf{u}_a \tau_a)$ near the surface of the four-dimensional sphere accordingly, making it a properly normalized amplitude for the corresponding group elements $(g_b \tau_b | g_a \tau_a)$. Thus we define

$$(\mathbf{u}_b \tau_b | \mathbf{u}_a \tau_a) \equiv \frac{1}{2\pi^2} (g_b \tau_b | g_a \tau_a). \quad (8.261)$$

The path integral (8.151) then turns into the following path integral for the motion near the group space [compare also (8.204)]:

$$(g_b \tau_b | g_a \tau_a) \approx \frac{2\pi^2}{\sqrt{2\pi\hbar\epsilon/Mr^2}^3} \prod_{n=1}^N \left[\int \frac{2\pi^2 dg_n}{\sqrt{2\pi\hbar\epsilon/Mr^2}^3} \right] \exp\left(-\frac{1}{\hbar} \mathcal{A}^N\right). \quad (8.262)$$

Let us integrate this expression within the group space language. For this we expand the exponential as in (8.131):

$$\begin{aligned} \exp\left\{-\frac{Mr^2}{\hbar\epsilon} \left[1 - \frac{1}{2}\text{tr}(g_n g_{n-1}^{-1})\right]\right\} &= \sum_{l=0}^{\infty} \tilde{a}_l(h) \frac{l+1}{2\pi^2} C_l^{(1)}(\cos \Delta\vartheta_n) \\ &= \sum_{l=0}^{\infty} \tilde{a}_l(h) \frac{l+1}{2\pi^2} \sum_{m_1, m_2=-l/2}^{l/2} \mathcal{D}_{m_1 m_2}^{l/2}(\varphi_n, \theta_n, \gamma_n) \mathcal{D}_{m_1 m_2}^{l/2*}(\varphi_{n-1}, \theta_{n-1}, \gamma_{n-1}). \end{aligned} \quad (8.263)$$

In general terms, the right-hand side corresponds to the well-known *character expansion* for the group SU(2):

$$\exp\left[\frac{\hbar}{2}\text{tr}(g_n g_{n-1}^{-1})\right] = \frac{1}{h} \sum_{l=0}^{\infty} (l+1) I_{l+1}(h) \chi^{(l/2)}(g_n g_{n-1}^{-1}). \quad (8.264)$$

Here $\chi^{(l/2)}(g)$ are the so-called *characters*, the traces of the representation matrices of the group element g , i.e.,

$$\chi^{(l/2)}(g) = \mathcal{D}_{mm}^{l/2}(g). \quad (8.265)$$

The relation between the two expansions is obvious if we use the representation properties of the $\mathcal{D}_{m_1 m_2}^{l/2}$ functions and their unitarity to write

$$\chi^{(l/2)}(g_n g_{n-1}^{-1}) = \mathcal{D}_{mm'}^{l/2}(g_n) \mathcal{D}_{mm'}^{l/2*}(g_{n-1}). \quad (8.266)$$

This leads directly to (8.263) [see also the footnote to (8.128)]. Having done the character expansion in each time slice, the intermediate group integrations can all be performed using the orthogonality relations of group characters

$$\int dg \chi^{(L)}(g_1 g^{-1}) \chi^{(L')}(g g_2^{-1}) = \delta_{LL'} \frac{1}{d_L} \chi^{(L)}(g_1 g_2^{-1}). \quad (8.267)$$

The result of the integrations is, of course, the same amplitude as before in (8.162):

$$(g_b \tau_b | g_a \tau_a) = \sum_{l=0}^{\infty} \exp \left[-\frac{\hbar L_2}{2Mr^2} (\tau_b - \tau_a) \right] \times (l+1) \sum_{m_1, m_2 = -l/2}^{l/2} \mathcal{D}_{m_1 m_2}^{l/2}(\varphi_n, \theta_n, \gamma_n) \mathcal{D}_{m_1 m_2}^{l/2*}(\varphi_{n-1}, \theta_{n-1}, \gamma_{n-1}). \quad (8.268)$$

Given this amplitude *near* the group space we can find the amplitude for the motion *on* the group space, by adding to the energy near the sphere $E = \hbar^2[(l/2 + 1)^2 - 1/4]/2Mr^2$ the correction $\Delta E = \hbar^2 \Delta L_2^2 / 2Mr^2$ associated with Eq. (8.229). For $D = 4$, $L_2^2 = (l/2)(l/2+1) + 3/4$ has to be replaced by $\hat{L}^2 = L_2^2 + \Delta L_2^2 = (l/2)(l/2+1)$, and the energy changes by

$$\Delta E = -\frac{3\hbar^2}{8M}. \quad (8.269)$$

Otherwise the amplitude is the same as in (8.268) [6].

Character expansions of the exponential of the type (8.264) and the orthogonality relation (8.267) are general properties of group representations. The above time-sliced path integral can therefore serve as a prototype for the quantum mechanics of other systems moving *near* or *on* more general group spaces than SU(2).

Note that there is no problem in proceeding similarly with noncompact groups [7]. In this case we would start out with a treatment of the path integral *near* and *on* the surface of a hyperboloid rather than a sphere in four dimensions. The solution would correspond to the path integral near and on the group space of the covering group SU(1,1) of the Lorentz group O(2,1). The main difference with respect to the above treatment would be the appearance of hyperbolic functions of the second Euler angle θ rather than trigonometric functions.

An important family of noncompact groups whose path integral can be obtained in this way are the Euclidean groups [8] consisting of rotations and translations. Their *Lie algebra* comprises the momentum operators $\hat{\mathbf{p}}$, whose representation on the spatial wave functions has the Schrödinger form $\hat{\mathbf{p}} = -i\hbar \nabla$. Thus, the canonical commutation rules in a Euclidean space form part of the representation algebra of these groups. Within a Euclidean group, the separation of the path integral into a radial and an azimuthal part is an important tool in obtaining all group representations.

8.11 Path Integral of Spinning Top

We are now also in a position to solve the time-sliced path integral of a spinning top by reducing it to the previous case of a particle moving on the group space $SU(2)$. Only in one respect is the spinning top different: the equivalent “particle” does not move on the covering space $SU(2)$ of the rotation group, but on the rotation group $O(3)$ itself. The angular configurations with Euler angles γ and $\gamma + 2\pi$ are physically indistinguishable. The physical states form a representation space of $O(3)$ and the time evolution amplitude must reflect this. The simplest possibility to incorporate the $O(3)$ topology is to add the two amplitudes leading from the initial configuration $\varphi_a, \theta_a, \gamma_a$ to the two identical final ones $\varphi_b, \theta_b, \gamma_b$ and $\varphi_b, \theta_b, \gamma_b + 2\pi$. This yields the amplitude of the spinning top:

$$\begin{aligned} & (\varphi_b, \theta_b, \gamma_b \tau_b | \varphi_b, \theta_b, \gamma_b \tau_a)_{\text{top}} \\ &= (\varphi_b, \theta_b, \gamma_b \tau_b | \varphi_b, \theta_b, \gamma_b \tau_a) + (\varphi_b, \theta_b, \gamma_b + 2\pi \tau_b | \varphi_b, \theta_b, \gamma_b \tau_a). \end{aligned} \quad (8.270)$$

The sum eliminates all half-integer representation functions $D_{mm'}^{l/2}(\theta)$ in the expansion (8.268) of the amplitude.

Instead of the sum we could have also formed another representation of the operation $\gamma \rightarrow \gamma + 2\pi$, the antisymmetric combination

$$\begin{aligned} & (\varphi_b, \theta_b, \gamma_b \tau_b | \varphi_b, \theta_b, \gamma_b \tau_a)_{\text{fermionic}} \\ &= (\varphi_b, \theta_b, \gamma_b \tau_b | \varphi_b, \theta_b, \gamma_b \tau_a) - (\varphi_b, \theta_b, \gamma_b + 2\pi \tau_b | \varphi_b, \theta_b, \gamma_b \tau_a). \end{aligned} \quad (8.271)$$

Here the expansion (8.268) retains only the half-integer angular momenta $l/2$. As discussed in Chapter 7, half-integer angular momenta are associated with fermions such as electrons, protons, muons, and neutrinos. This is indicated by the subscript “fermionic”. In spite of this, the above amplitude cannot be used to describe a single fermion since this has only one fixed spin $l/2$, while (8.271) contains *all* possible fermionic spins at the same time.

In principle, there is no problem in also treating the non-spherical top. In the formulation *near* the group space, the gradient term in the action,

$$\frac{1}{\epsilon^2} \left[1 - \frac{1}{2} \text{tr}(g_n g_{n-1}^{-1}) \right], \quad (8.272)$$

has to be separated into time-sliced versions of the different angular velocities. In the continuum these are defined by

$$\omega_a = -i \text{tr}(\dot{\sigma}_a g^{-1}), \quad a = \xi, \eta, \zeta. \quad (8.273)$$

The gradient term (8.272) has the symmetric continuum limit $\dot{\omega}_a^2$. With the different moments of inertia I_ξ, I_η, I_ζ , the asymmetric sliced gradient term reads

$$\begin{aligned} & \frac{1}{\epsilon^2} \left\{ I_\xi \left[1 - \frac{1}{2} \text{tr}(g_n \sigma_\xi g_{n-1}^{-1}) \right] + I_\eta \left[1 - \frac{1}{2} \text{tr}(g_n \sigma_\eta g_{n-1}^{-1}) \right] \right. \\ & \quad \left. + I_\zeta \left[1 - \frac{1}{2} \text{tr}(g_n \sigma_\zeta g_{n-1}^{-1}) \right] \right\}, \end{aligned} \quad (8.274)$$

rather than (8.272). The amplitude *near* the top is an appropriate generalization of (8.268). The calculation of the correction term ΔE , however, is more complicated than before and remains to be done, following the rules explained above.

8.12 Path Integral of Spinning Particle

The path integral of a particle on the surface of a sphere contains states of all integer angular momenta $l = 1, 2, 3, \dots$. The path integral on the group space $SU(2)$ contains also all half-integer spins $s = \frac{1}{2}, \frac{3}{2}, \frac{5}{2}, \dots$.

The question arises whether it is possible to set up a path integral which contains only a single spinning particle, for instance of spin $s = 1/2$. Thus we need a path integral which for each time slice spans precisely one irreducible representation space of the rotation group, consisting of the $2s + 1$ states $|s s_3\rangle$ for $s_3 = -s, \dots, s$. In order to sum over paths, we must parametrize this space in terms of a continuous variable. This is possible by selecting a particular spin state, for example the state $|ss\rangle$ pointing in the z -direction, and rotating it into an arbitrary direction $\mathbf{u} = (\sin \theta \cos \varphi, \sin \theta \sin \varphi, \cos \theta)$ with the help of some rotation, for instance

$$|\theta \varphi\rangle \equiv R^s(\theta, \varphi)|ss\rangle \equiv e^{-iS_3\varphi}e^{-iS_2\theta}|ss\rangle, \quad (8.275)$$

where S_i are matrix generators of the rotation group of spin s , which satisfy the commutation rules of the generators \hat{L}_i in (1.414). The states (8.275) are nonabelian versions of the coherent states (7.343). They can be expanded into the $2s + 1$ spin states $|s s_3\rangle$ as follows:

$$|\theta \varphi\rangle = \sum_{s_3=-s}^s |s s_3\rangle \langle s s_3|\hat{R}(\theta, \varphi)|ss\rangle = \sum_{s_3=-s}^s |s s_3\rangle e^{-is_3\varphi} d_{s_3 s}^s(\theta), \quad (8.276)$$

where $d_{mm'}^j(\theta)$ are the representation matrices of $e^{-iS_2\theta}$ with angular momentum j given in Eq. (1.446). For $s = 1/2$, where the matrix $d_{mm'}^j$ has the form (1.447), the states (8.276) are

$$|\theta \varphi\rangle = e^{i\varphi/2} \cos \theta/2 |\frac{1}{2} \frac{1}{2}\rangle - e^{-i\varphi/2} \sin \theta/2 |\frac{1}{2} - \frac{1}{2}\rangle. \quad (8.277)$$

At this point it is useful to introduce the so-called *monopole spherical harmonics* defined by

$$Y_{mq}^j(\theta, \varphi) \equiv \sqrt{\frac{2j+1}{4\pi}} e^{im\varphi} d_{mq}^j(\theta). \quad (8.278)$$

Comparison with Eq. (8.125) shows that these are simply the ultra-spherical harmonics $Y_{jm_q}(\hat{\mathbf{x}})$ with vanishing third Euler angle γ . They satisfy the orthogonality relation

$$\int_{-1}^1 d \cos \theta \int_0^{2\pi} d\varphi Y_{mq}^{j*}(\theta, \varphi) Y_{m'q}^{j'}(\theta, \varphi) = \delta_{jj'} \delta_{mm'}, \quad (8.279)$$

and the completeness relation

$$\sum_{j,m} Y_{mq}^j(\theta, \varphi) Y_{mq}^{j*}(\theta', \varphi') = \delta(\cos \theta - \cos \theta') \delta(\varphi - \varphi'). \quad (8.280)$$

We define now the covariant looking states

$$|\mathbf{u}\rangle \equiv \sqrt{\frac{2j+1}{4\pi}} |\theta \varphi\rangle = \sum_{s_3=-s}^s |s s_3\rangle Y_{s_3 s}^{s*}(\theta, \varphi), \quad (8.281)$$

and write the angular integral as an integral over the surface of the unit sphere:

$$\int_{-1}^1 d \cos \theta \int_0^{2\pi} d\varphi = \int d^3 u \delta(\mathbf{u}^2 - 1) \equiv \int d\mathbf{u}. \quad (8.282)$$

From (8.279) we deduce that the states $|\mathbf{u}\rangle$ are complete in the space of spin- s states:

$$\begin{aligned} \int d\mathbf{u} |\mathbf{u}\rangle \langle \mathbf{u}| &= \sum_{s_3=-s}^s \sum_{s'_3=-s}^s |s s_3\rangle \int_{-1}^1 d \cos \theta \int_0^{2\pi} d\varphi Y_{s_3 s}^{s*}(\theta, \varphi) Y_{s'_3 s}^s(\theta, \varphi) \langle s s'_3| \\ &= \sum_{s_3=-s}^s |s s_3\rangle \langle s s_3| = 1^s. \end{aligned} \quad (8.283)$$

The states are not orthogonal, however. Writing $Y_{s_3 s}^s(\theta, \varphi)$ as $Y_{s_3 s}^s(\mathbf{u})$, we see that

$$\langle \mathbf{u} | \mathbf{u}' \rangle = \sum_{s_3=-s}^s \sum_{s'_3=-s}^s Y_{s_3 s}^s(\mathbf{u}) \langle s s_3 | s s'_3 \rangle Y_{s'_3 s}^s(\mathbf{u}') = \sum_{s_3=-s}^s Y_{s_3 s}^s(\mathbf{u}) Y_{s_3 s}^{s*}(\mathbf{u}'). \quad (8.284)$$

The right-hand side can be calculated as follows:

$$\begin{aligned} \frac{2j+1}{4\pi} \langle s s | e^{i\theta S_2} e^{i\varphi S_3} e^{-i\varphi' S_3} e^{-i\theta' S_2} | s s \rangle &= \frac{2j+1}{4\pi} \langle s s | e^{-isAS_3} e^{-i\beta S_2} | s s \rangle \\ &= \frac{2j+1}{4\pi} e^{-isAS_3} d_{ss}^s(\beta) = \frac{2j+1}{4\pi} e^{-isAS_3} \left(\frac{1 + \mathbf{u} \cdot \mathbf{u}'}{2} \right)^s, \end{aligned} \quad (8.285)$$

where β is the angle between \mathbf{u} and \mathbf{u}' , and $A(\mathbf{u}, \mathbf{u}', \hat{\mathbf{z}})$ is the area of the spherical triangle on the unit sphere formed by the three points in the argument. For a radius R , the area is equal to R^2 time the angular excess E of the triangle, defined as the amount by which the sum of the angles in the triangle is larger than π . An explicit formula for E is the spherical generalization of *Heron's formula* for the area A of a triangle [9]:

$$A = \sqrt{s(s-a)(s-b)(s-c)}, \quad s = (a+b+c)/2 = \text{semiperimeter}. \quad (8.286)$$

The angular excess on a sphere is

$$\tan \frac{E}{4} = \sqrt{\tan \frac{\phi_s}{2} \tan \frac{\phi_s - \phi_a}{2} \tan \frac{\phi_s - \phi_b}{2} \tan \frac{\phi_s - \phi_c}{2}}, \quad (8.287)$$

where ϕ_a, ϕ_b, ϕ_c are the *angular lengths* of the sides of the triangle and

$$\phi_s = (\phi_a + \phi_b + \phi_c)/2 \quad (8.288)$$

is the angular semiperimeter on the sphere.

We can now set up a path integral for the scalar product (8.285):

$$\langle \mathbf{u}_b | \mathbf{u}_a \rangle = \left[\prod_{n=1}^N \int d\mathbf{u}_n \right] \langle \mathbf{u}_b | \mathbf{u}_N \rangle \langle \mathbf{u}_N | \mathbf{u}_{N-1} \rangle \langle \mathbf{u}_{N-1} | \cdots | \mathbf{u}_1 \rangle \langle \mathbf{u}_1 | \mathbf{u}_a \rangle. \quad (8.289)$$

For large N , the intermediate \mathbf{u}_n -vectors will all lie close to their neighbors and we can write approximately

$$\langle \mathbf{u}_n | \mathbf{u}_{n-1} \rangle \approx \frac{2s+1}{4\pi} e^{i\Delta A_n} [1 + \frac{1}{2} \mathbf{u}_n (\mathbf{u}_n - \mathbf{u}_{n-1})]^s \approx \frac{2s+1}{4\pi} e^{i\Delta A_n + \frac{s}{2} \mathbf{u}_n (\mathbf{u}_n - \mathbf{u}_{n-1})}. \quad (8.290)$$

Let us take this expression to the continuum limit. We introduce a time parameter labeling the chain of \mathbf{u}_n -vectors by $t_n = n\epsilon$, and find the small- ϵ approximation

$$\frac{2s+1}{4\pi} \exp \left[i\epsilon s \cos \theta \dot{\varphi} - \frac{s}{4} \epsilon^2 (\dot{\theta}^2 + \sin^2 \theta \dot{\varphi}^2) + \dots \right]. \quad (8.291)$$

The first term is obtained from the scalar product

$$\begin{aligned} \langle \theta \varphi | i\partial_t | \theta \varphi \rangle &= \langle ss | e^{iS_2\theta} e^{iS_3\varphi} i\partial_t e^{-iS_3\varphi} e^{-iS_2\theta} | ss \rangle \\ &= \langle ss | e^{iS_2\theta} e^{iS_3\varphi} (\dot{\varphi} S_3 e^{-iS_3\varphi} e^{-iS_2\theta} + e^{-iS_3\varphi} \dot{\theta} S_2 e^{-iS_2\theta}) | ss \rangle \\ &= \langle ss | (\cos \theta S_3 - \sin \theta S_1) \dot{\varphi} + \dot{\theta} S_2 | ss \rangle = s \cos \theta \dot{\varphi}. \end{aligned} \quad (8.292)$$

This result is actually not completely correct. The reason is that the angular variables in the states (8.275) are cyclic variables. For integer spins, θ and φ are cyclic in 2π , for half-integer spins in 4π . Thus there can be jumps by 2π or 4π in these angles which do not change the states (8.275). In writing down the approximation (8.291) we must assume that we are at a safe distances from such singularities. If we get close to them, we must change the direction of the quantization axis.

Keeping this in mind we can express the scalar product in the limit $\epsilon \rightarrow 0$ by the path integral

$$\langle \mathbf{u}_b | \mathbf{u}_a \rangle = \int \mathcal{D}\mathbf{u} e^{\frac{i}{\hbar} \int_{t_a}^{t_b} dt \hbar s \cos \theta \dot{\varphi}}, \quad (8.293)$$

where $\int \mathcal{D}\mathbf{u}$ is defined by the limit $N \rightarrow \infty$ of the product of integrals

$$\int \mathcal{D}\mathbf{u} \equiv \lim_{N \rightarrow \infty} \left[\frac{2s+1}{4\pi} \prod_{n=1}^N \int d\mathbf{u}_n \right]. \quad (8.294)$$

The path integral fixes the Hilbert space of the spin theory. It is the analog of the zero-Hamiltonian path integral in Eqs. (2.17) and (2.18). Comparing (8.293) with (2.18), we see that $s\hbar \cos \theta$ plays the role of a canonically conjugate momentum of the variable φ .

For a specific spin dynamics we must add, as in (2.15), a Hamiltonian $H(\cos \theta, \varphi)$, and arrive at the general path integral representation for the time evolution amplitude of a spinning particle [10]

$$(\mathbf{u}_b t_b | \mathbf{u}_a t_a) = \int \mathcal{D}\mathbf{u} e^{i \int_{t_a}^{t_b} dt [\hbar s \cos \theta \dot{\varphi} - H(\theta, \varphi)] / \hbar}. \quad (8.295)$$

The above path integral has a remarkable property which is worth emphasizing. For half-integer spins $s = \frac{1}{2}, \frac{3}{2}, \frac{5}{2}, \dots$ it is able to describe the physics of a fermion in terms of a field theory involving a unit vector field \mathbf{u} which describes the direction of the spin state:

$$\langle \mathbf{u} | \hat{\mathbf{S}} | \mathbf{u} \rangle = \langle ss | \hat{R}^{-1}(\theta, \varphi) \hat{\mathbf{S}} \hat{R}(\theta, \varphi) | ss \rangle = R_{ij}(\theta, \varphi) \langle ss | S_j | ss \rangle = s \mathbf{u}. \quad (8.296)$$

This follows from the vector property of the spin matrices $\hat{\mathbf{S}}$. The matrices $R_{ij}(\theta, \varphi)$ are the defining 3×3 matrices of the rotation group (the so-called *adjoint representation*). Thus we describe a fermion in terms of a Bose field.

The above path integral is only the simplest illustration for a more general phenomenon. In 1961, Skyrme pointed out that a certain field configuration of pions is capable of behaving in many respects like a nucleon [11], in particular its fermionic properties.

In two dimensions, Bose field theories are even more powerful and can describe particles with any commutation rule, called anyons in Section 7.5. This will be shown in Chapter 16.

In Chapter 10 we shall see that the action in (8.293) can be interpreted as the action of a particle of charge e on the surface of the unit sphere whose center contains a fictitious magnetic monopole of charge $g = -4\pi\hbar cs/e$. The associated vector potential $\mathbf{A}^{(g)}(\mathbf{u})$ will be given in Eq. (10A.59). Coupling this minimally to a particle of charge e as in Eq. (2.635) on the surface of the sphere yields the action

$$\mathcal{A}_0 = \frac{e}{c} \int_{t_a}^{t_b} \mathbf{A}^{(g)}(\mathbf{u}) \cdot \dot{\mathbf{u}} = \hbar s \int_{t_a}^{t_b} dt \cos \theta \dot{\varphi}, \quad (8.297)$$

where the magnetic flux is supplied to the monopole by two infinitesimally thin flux tubes, the famous *Dirac strings*, one from below and one from above. The field $\mathbf{A}^{(-s)}$ in (8.297) is the average of the two expressions in (10A.61) for $g = -4\pi\hbar cs/e$. We can easily change the supply line to a single string from above, by choosing the states

$$|\theta \varphi\rangle' \equiv \hat{R}(\theta, \varphi) |ss\rangle = e^{-iS_3 \varphi} e^{-iS_2 \theta} e^{iS_3 \varphi} |ss\rangle = |\theta \varphi\rangle e^{is\varphi}, \quad (8.298)$$

rather than $|\theta \varphi\rangle$ of Eq. (8.275) for the construction of the path integral. The physics is the same since the string is an artifact of the choice of the quantization axis.

In terms of Cartesian coordinates, the action (8.297) with a flux supplied from the north pole can also be expressed in terms of the vector $\mathbf{u}(t)$ as [compare (10A.59)]

$$\mathcal{A}_0 = \hbar s \int dt \frac{\hat{\mathbf{z}} \times \mathbf{u}(\mathbf{t})}{1 - u_z(t)} \cdot \dot{\mathbf{u}}(t). \quad (8.299)$$

This expression is singular on the north pole of the unit sphere. The singularity can be rotated into an arbitrary direction \mathbf{n} , leading to

$$\mathcal{A}_0 = \hbar s \int dt \frac{\mathbf{n} \times \mathbf{u}(t)}{1 - \mathbf{n} \cdot \mathbf{u}(t)} \cdot \dot{\mathbf{u}}(t). \quad (8.300)$$

If \mathbf{u} gets close to \mathbf{n} we must change the direction of \mathbf{n} . The action (8.300) is referred to as *Wess-Zumino action*.

In Chapter 10 we shall also calculate the curl of the vector potential $\mathbf{A}^{(g)}$ of a monopole of magnetic charge g and find the radial magnetic field accompanied by a singular string contribution along the direction \mathbf{n} of flux supply [compare (10A.54)]:

$$\mathbf{B}^{(g)} = \nabla \times \mathbf{A}^{(g)} = g \frac{\mathbf{u}}{|\mathbf{u}|} - 4\pi g \int_0^\infty ds \hat{\mathbf{n}} \delta^{(3)}(\mathbf{u} - s \hat{\mathbf{n}}), \quad (8.301)$$

The singular contribution is an artifact of the description of the magnetic field. The line from zero to infinity is called a *Dirac string*. Since the magnetic field has no divergence, the magnetic flux emerging at the origin of the sphere must be imported from somewhere at infinity. In the field (8.302) the field is imported along the straight line in the direction \mathbf{u} . Indeed, we can easily check that the divergence of (8.302) is zero.

For a closed orbit, the interaction (8.297) can be rewritten by Stokes' theorem as

$$\mathcal{A}_0 = \frac{e}{c} \int dt \mathbf{A}^{(g)}(t) \cdot \mathbf{u}(t) = \frac{e}{c} \int d\mathbf{S} \cdot [\nabla \times \mathbf{A}^{(g)}] = \frac{e}{c} \int d\mathbf{S} \cdot \mathbf{B}^{(g)}, \quad (8.302)$$

where $\int d\mathbf{S}$ runs over the surface enclosed by the orbit. This surface may or may not contain the Dirac string of the monopole, in which case \mathcal{A}_0 differ by $4\pi ge/c$. A path integral over closed orbits of the spinning particle

$$Z_{\text{QM}} = \oint d\mathbf{u} e^{i(\mathcal{A}_0 + \mathcal{A})/\hbar}, \quad (8.303)$$

is therefore invariant under changes of the position of the Dirac string if the monopole charge g satisfies the *Dirac charge quantization condition*

$$\frac{ge}{\hbar c} = s, \quad (8.304)$$

with $s = \text{half-integer or integer}$.

Dirac was the first to realize that as a consequence of quantum mechanics, an electrically charged particle whose charge satisfies the quantization condition (8.304) sees only the radial monopole field in (8.302), not the field in the string. The string can run along *any line* L without being detectable. This led him to conjecture that there could exist magnetic monopoles of a specific g , which would explain that all charges in nature are integer multiples of the electron charge [16]. More on this subject will be discussed in Section 16.2.

In Chapter 10 we shall learn how to define a monopole field $\mathbf{A}^{(g)}$ which is free of the artificial string singularity [see Eq. (10A.58)]. With the new definition, the divergence of \mathbf{B} is a δ -function at the origin:

$$\nabla \times \mathbf{B}(\mathbf{u}) = 4\pi g \delta^{(3)}(\mathbf{u}). \quad (8.305)$$

8.13 Berry Phase

This phenomenon has a simple physical basis which can be explained most clearly by means of the following gedanken experiment. Consider a thin rod whose dynamics is described by a unit vector field $\mathbf{u}(t)$ with an action

$$\mathcal{A} = \frac{M}{2} \int dt \left[\dot{\mathbf{u}}^2(t) - V(\mathbf{u}^2(t)) \right], \quad \mathbf{u}^2(t) \equiv 1, \quad (8.306)$$

where $\mathbf{u}(t)$ is a unit vector along the rod. This is the same Lagrangian as for a particle on a sphere as in (8.147) (recall p. 746).

Let us suppose that the thin rod is a solenoid carrying a strong magnetic field, and containing at its center a particle of spin $s = 1/2$. Then (8.306) is extended by the action [13]

$$\mathcal{A}_0 = \int dt \psi^*(t) [i\hbar\partial_t + \gamma\mathbf{u}(t) \cdot \boldsymbol{\sigma}] \psi(t), \quad (8.307)$$

where σ^i are the Pauli spin matrices (1.448). For large coupling strength γ and sufficiently slow rotations of the solenoid, the direction of the fermion spin will always be in the ground state of the magnetic field, i.e., its direction will follow the direction of the solenoid adiabatically, pointing always along $\mathbf{u}(t)$. If we parametrize $\mathbf{u}(t)$ in terms of spherical angles $\theta(t), \phi(t)$ as $\mathbf{n} = (\sin\theta \cos\phi, \sin\theta \sin\phi, \cos\theta)$, the associated wave function satisfies $\mathbf{u}(t) \cdot \boldsymbol{\sigma} \psi(\mathbf{u}(t)) = (1/2)\psi(\mathbf{u}(t))$, and reads

$$\psi(\mathbf{u}(t)) = \begin{pmatrix} e^{-i\phi(t)/2} \cos\theta(t)/2 \\ e^{i\phi(t)/2} \sin\theta(t)/2 \end{pmatrix}. \quad (8.308)$$

Inserting this into (8.307) we obtain [compare (8.292)]

$$\mathcal{A}_0 = \int dt \psi(\mathbf{u}(t)) i\hbar\partial_t \psi(\mathbf{u}(t)) = \hbar \frac{1}{2} \cos\theta(t) \dot{\phi}(t) \equiv \hbar\beta(t). \quad (8.309)$$

The action coincides with the previous expression (8.297). The angle $\beta(t)$ is called *Berry phase* [14].

In this simple model it is obvious why the bosonic theory of the solenoid behaves like a spin-1/2 particle: It simply inherits the physical properties of the enslaved spinor.

The reason why it is a monopole field that causes the spin-1/2 behavior will become clear in another way in Section 14.6. There we shall solve the path integral of a charged particle in a monopole field and show that it behaves like a fermion if its charge e and the monopole charge g have half-integer products $q \equiv eg/\hbar c$.

8.14 Spin Precession

The Wess-Zumino action \mathcal{A}_0 adds an interesting kinetic term to the equation of motion of a solenoid. Extremizing $\mathcal{A}_0 + \mathcal{A}$ yields

$$M \left(\ddot{\mathbf{u}} + \dot{\mathbf{u}}^2 \mathbf{u} \right) = -\partial_{\mathbf{u}} V(\mathbf{u}) - \frac{\delta}{\delta \mathbf{u}(t)} \mathcal{A}_0. \quad (8.310)$$

The functional derivative of \mathcal{A}_0 is most easily calculated starting from the general expression in (8.297)

$$\begin{aligned} \frac{\delta}{\delta u_i(t)} \hbar \int_{t_a}^{t_b} dt \mathbf{A}^{(g)} \cdot \dot{\mathbf{u}} &= \hbar \left(\partial_{u_i} A_j^{(g)} \dot{u}_j - \partial_t A_i^{(g)} \right) = \hbar \left[\left(\partial_{u_i} A_j^{(g)} - \partial_{u_j} A_i^{(g)} \right) \dot{u}_j \right] \\ &= \hbar \left[\left(\nabla \times \mathbf{A}^{(g)} \right) \times \mathbf{u} \right]_i. \end{aligned} \quad (8.311)$$

Inserting here the curl of Eq. (8.302), while staying safely away from the singularity, the last term in (8.310) becomes $\hbar g \mathbf{u} \times \dot{\mathbf{u}}$, and the equation of motion (8.310) turns into

$$M \left(\ddot{\mathbf{u}} + \dot{\mathbf{u}}^2 \mathbf{u} \right) = -\partial_{\mathbf{u}} V(\mathbf{u}) - \hbar g \mathbf{u} \times \dot{\mathbf{u}}. \quad (8.312)$$

Multiplying this vectorially by $\mathbf{u}(t)$ we find [15, 16]

$$M \mathbf{u} \times \ddot{\mathbf{u}} = -\mathbf{u} \times \partial_{\mathbf{u}} V(\mathbf{u}) - \hbar g \left[\mathbf{u} (\mathbf{u} \cdot \dot{\mathbf{u}}) - \dot{\mathbf{u}} \mathbf{u}^2 \right]. \quad (8.313)$$

Since $\mathbf{u}^2 = 1$, this reduces to

$$M \mathbf{u} \times \ddot{\mathbf{u}} - \hbar g \dot{\mathbf{u}} = -\mathbf{u} \times \partial_{\mathbf{u}} V(\mathbf{u}(t)). \quad (8.314)$$

If M is small we obtain for a particle of spin s , where $g = -s$, the so-called *Landau-Lifshitz equation* [17, 18]

$$\hbar s \dot{\mathbf{u}} = -\mathbf{u} \times \partial_{\mathbf{u}} V(\mathbf{u}). \quad (8.315)$$

This is a useful equation for studying magnetization fields in ferromagnetic materials.

The interaction energy of a spinning particle with an external magnetic field has the general form

$$H_{\text{int}} = -\boldsymbol{\mu} \cdot \mathbf{B}, \quad \boldsymbol{\mu} = -\gamma \mathbf{S}, \quad (8.316)$$

where $\boldsymbol{\mu}$ is the magnetic moment, \mathbf{S} the vector of spin matrices, and γ the *gyromagnetic ratio*.

Since \mathbf{u} is the direction vector of the spin, we may identify the magnetic moment of the spin s as

$$\boldsymbol{\mu} = \gamma s \hbar \mathbf{u}, \quad (8.317)$$

so that the interaction energy becomes

$$H_{\text{int}} = -\gamma s \hbar \mathbf{u} \cdot \mathbf{B}. \quad (8.318)$$

Inserting this for $V(\mathbf{u})$ in (8.315) yields the equation of motion

$$\dot{\mathbf{u}} = -\gamma \mathbf{B} \times \mathbf{u}, \quad (8.319)$$

showing a rate of precession $\boldsymbol{\Omega} = -\gamma \mathbf{B}$.

For comparison we recall the derivation of this result in the conventional way from the Heisenberg equation of motion (1.272):

$$\hbar \dot{\mathbf{S}} = i[\hat{H}, \mathbf{S}]. \quad (8.320)$$

Inserting for \hat{H} the interaction energy (8.316) and using the commutation relations (1.414) of the rotation group for the spin matrices \mathbf{S} , this yields the Heisenberg equation for spin precession

$$\dot{\mathbf{S}} = -\gamma \mathbf{B} \times \mathbf{S}, \quad (8.321)$$

in agreement with the Landau-Lifshitz equation (8.315). This shows that the Wess-Zumino term in the action $\mathcal{A}_0 + \mathcal{A}$ has the ability to render quantum equations of motion from a classical action. This allows us, in particular, to mimic systems of half-integer spins, which are fermions, with a theory containing only a bosonic directional vector field $\mathbf{u}(t)$. This has important applications in statistical mechanics where models of interacting quantum spins for ferro- and antiferromagnets à la Heisenberg can be studied by applying field theoretic methods to vector field theories.

Wave Functions

The fundamental quantity obtained by solving a path integral is the time evolution amplitude or propagator of a system $(\mathbf{x}_b t_b | \mathbf{x}_a t_a)$. In Schrödinger quantum mechanics, on the other hand, one has direct access on the energy spectrum and the wave functions of a system [see (1.94)]. This chapter will explain how to extract this information from the time evolution amplitude $(\mathbf{x}_b t_b | \mathbf{x}_a t_a)$. The crucial quantity for this purpose the Fourier transform of $(\mathbf{x}_b t_b | \mathbf{x}_a t_a)$, the fixed-energy amplitude introduced in Eq. (1.317):

$$(\mathbf{x}_b | \mathbf{x}_a)_E = \int_{t_a}^{\infty} dt_b \exp \{iE(t_b - t_a)/\hbar\} (\mathbf{x}_b t_b | \mathbf{x}_a t_a), \quad (9.1)$$

which contains as much information on the system as $(\mathbf{x}_b t_b | \mathbf{x}_a t_a)$, and gives, in particular, a direct access to the energy spectrum and the wave functions of the system. This is done via the spectral decomposition (1.325).

Alternatively, we can work with the causal propagator at imaginary time,

$$(\mathbf{x}_b \tau_b | \mathbf{x}_a \tau_a) = \int \frac{d^D p}{(2\pi\hbar)^D} \exp \left[\frac{i}{\hbar} \mathbf{p}(\mathbf{x}_b - \mathbf{x}_a) - \frac{\mathbf{p}^2}{2M\hbar} (\tau_b - \tau_a) \right], \quad (9.2)$$

and calculate the fixed-energy amplitude by the Laplace transformation

$$(\mathbf{x}_b | \mathbf{x}_a)_E = -i \int_{\tau_a}^{\infty} d\tau_b \exp \{E(\tau_b - \tau_a)/\hbar\} (\mathbf{x}_b \tau_b | \mathbf{x}_a \tau_a). \quad (9.3)$$

9.1 Free Particle in L Dimensions

For a free particle in D dimensions, the fixed-energy amplitude was calculated in Eqs. (1.348) and (1.355). It will be instructive to rederive the same result once more using the development in Section 8.5.1. Here we start directly from the spectral representation (1.325), which for a free particle takes the explicit form Eq. (1.344):

$$(\mathbf{x}_b | \mathbf{x}_a)_E = \int \frac{d^D k}{(2\pi)^D} e^{i\mathbf{k}(\mathbf{x}_b - \mathbf{x}_a)} \frac{i\hbar}{E - \hbar^2 \mathbf{k}^2 / 2M + i\eta}. \quad (9.4)$$

The momentum integral can now be done as follows. The exponential function $\exp(i\mathbf{k}\mathbf{R})$ is written as $\exp(ikR \cos \vartheta)$, where \mathbf{R} is the distance vector $\mathbf{x}_b - \mathbf{x}_a$ and ϑ the angle between \mathbf{k} and \mathbf{R} . Then we use formula (8.100) with the coefficients (8.101) and the hyperspherical harmonics $Y_{l\mathbf{r}}(\hat{\mathbf{x}})$ of Eq. (8.126) and expand

$$e^{i\mathbf{k}\mathbf{R}} = \sum_{l=0}^{\infty} a_l(ikR) \sum_{\mathbf{r}} Y_{l\mathbf{r}}(\hat{\mathbf{k}}) Y_{l\mathbf{r}}^*(\hat{\mathbf{R}}). \quad (9.5)$$

The integral over \mathbf{k} follows now directly from the decomposition into size and direction $d^D k = dk d\hat{\mathbf{k}}$, and the orthogonality property (8.115) of the hyperspherical harmonics, according to which

$$\int d\hat{\mathbf{k}} Y_{l\mathbf{r}}(\hat{\mathbf{k}}) = \delta_{l0} \delta_{\mathbf{r}0} \sqrt{S_D}, \quad (9.6)$$

with S_D of Eq. (1.558). Since $Y_{00}(\hat{\mathbf{x}}) = 1/\sqrt{S_D}$, we obtain

$$(\mathbf{x}_b|\mathbf{x}_a)_E = -\frac{2Mi}{(2\pi)^D} \int_0^{\infty} dk k^{D-1} \frac{1}{k^2 + \kappa^2} a_0(ikR), \quad (9.7)$$

where

$$\kappa \equiv \sqrt{-2ME/\hbar^2}, \quad (9.8)$$

as in (1.346). Inserting $a_0(ikR)$ from (8.101),

$$a_0(ikR) = (2\pi)^{D/2} J_{D/2-1}(kR)/(kR)^{D/2-1}, \quad (9.9)$$

we find

$$(\mathbf{x}_b|\mathbf{x}_a)_E = -\frac{2Mi}{(2\pi)^{D/2}} R^{1-D/2} \int_0^{\infty} dk k^{D/2} \frac{1}{k^2 + \kappa^2} J_{D/2-1}(kR). \quad (9.10)$$

The integral

$$\int_0^{\infty} dk \frac{k^{\nu+1}}{(k^2 + a^2)^{\mu+1}} J_{\nu}(kb) = \frac{a^{\nu-\mu} b^{\mu}}{2^{\mu} \Gamma(\mu + 1)} K_{\nu-\mu}(ab) \quad (9.11)$$

yields once more the fixed-energy amplitude (1.347).

In two dimensions, the amplitude (1.347) becomes [recall (1.350)]

$$(\mathbf{x}_b|\mathbf{x}_a)_E = -\frac{iM}{\pi\hbar} K_0(\kappa|\mathbf{x}_b - \mathbf{x}_a|). \quad (9.12)$$

It can be decomposed into partial waves by inserting

$$|\mathbf{x}_b - \mathbf{x}_a| = \sqrt{r_b^2 + r_a^2 - 2r_a r_b \cos(\varphi_b - \varphi_a)}. \quad (9.13)$$

Then a well-known addition theorem for Bessel functions yields the expansion

$$K_0(\kappa|\mathbf{x}_b - \mathbf{x}_a|) = \sum_{m=-\infty}^{\infty} I_m(\kappa r_{<}) K_m(\kappa r_{>}) e^{im(\varphi_b - \varphi_a)}, \quad (9.14)$$

where $r_<$ and $r_>$ are the smaller and larger values of r_a and r_b , respectively. Hence the fixed-energy amplitude turns into

$$(\mathbf{x}_b|\mathbf{x}_a)_E = -\frac{2iM}{\hbar} \sum_m I_m(\kappa r_<) K_m(\kappa r_>) \frac{1}{2\pi} e^{im(\varphi_b - \varphi_a)}. \quad (9.15)$$

This is an analytic function in the complex E -plane. The parameter κ is real for $E < 0$. For $E > 0$, the square root (9.8) allows for two imaginary solutions, $\kappa^\pm \equiv e^{\mp i\pi/2} k \equiv e^{\mp i\pi/2} \sqrt{2ME}/\hbar$, so that the amplitude has a right-hand cut. Its discontinuity specifies the continuum of free-particle states. On top of the cut, we use the analytic continuation formulas (valid for $-\pi/2 < \arg z \leq \pi$)¹

$$\begin{aligned} I_\mu(e^{-i\pi/2}z) &= e^{-i\pi\mu/2} J_\mu(z), \\ K_\mu(e^{-i\pi/2}z) &= i\frac{\pi}{2} e^{i\pi\mu/2} H_\mu^{(1)}(z), \end{aligned} \quad (9.16)$$

to find the fixed-energy amplitude above the cut

$$(\mathbf{x}_b|\mathbf{x}_a)_{E+i\eta} = \frac{\pi M}{\hbar} \sum_m J_m(kr_<) H_m^{(1)}(kr_>) \frac{1}{2\pi} e^{im(\varphi_b - \varphi_a)}. \quad (9.17)$$

The reflection properties²

$$\begin{aligned} H_\mu^{(1)}(e^{i\pi}z) &= -H_{-\mu}^{(2)}(z) \equiv -e^{-i\pi\mu} H_\mu^{(2)}(z), \\ J_\mu(e^{i\pi}z) &= e^{i\pi\mu} J_\mu(z) \end{aligned} \quad (9.18)$$

yield the amplitude below the cut

$$(\mathbf{x}_b|\mathbf{x}_a)_{E-i\eta} = -\frac{\pi M}{\hbar} \sum_m J_m(kr_<) H_m^{(2)}(kr_>) \frac{1}{2\pi} e^{im(\varphi_b - \varphi_a)}. \quad (9.19)$$

The discontinuity across the cut follows from the relation

$$J_\mu(z) = \frac{1}{2} [H_\mu^{(1)}(z) + H_\mu^{(2)}(z)] \quad (9.20)$$

and reads

$$\text{disc } (\mathbf{x}_b|\mathbf{x}_a)_E = \frac{2\pi M}{\hbar} \sum_{m=-\infty}^{\infty} J_m(kr_b) J_m(kr_a) \frac{1}{2\pi} e^{im(\varphi_b - \varphi_a)}. \quad (9.21)$$

According to (1.330), the integral over the discontinuity yields the completeness relation

$$\begin{aligned} &\int_{-\infty}^{\infty} \frac{dE}{2\pi\hbar} \text{disc } (\mathbf{x}_b|\mathbf{x}_a)_E \\ &= \int_{-\infty}^{\infty} \frac{dE}{2\pi\hbar} \frac{2\pi M}{\hbar} \sum_{m=-\infty}^{\infty} J_m(kr_b) J_m(kr_a) \frac{1}{2\pi} e^{im(\varphi_b - \varphi_a)} = \delta(\mathbf{x}_b - \mathbf{x}_a). \end{aligned} \quad (9.22)$$

¹I.S. Gradshteyn and I.M. Ryzhik, *op. cit.*, Formulas 8.406.1 and 8.407.1.

²*ibid.*, Formulas 8.476.1 and 8.476.8.

After replacing the energy integral by a k -integral,

$$\int_{-\infty}^{\infty} \frac{dE}{2\pi\hbar} \frac{2\pi M}{\hbar} = \int_0^{\infty} dk k, \tag{9.23}$$

we can also write

$$\begin{aligned} \int_{-\infty}^{\infty} \frac{dE}{2\pi\hbar} \text{disc}(\mathbf{x}_b|\mathbf{x}_a)_E &= \int \frac{d^2k}{(2\pi)^2} e^{i\mathbf{k}(\mathbf{x}_b-\mathbf{x}_a)} = \frac{1}{2\pi} \int_0^{\infty} dk k J_0(k|\mathbf{x}_b-\mathbf{x}_a|) \\ &= \sum_{m=-\infty}^{\infty} \int_0^{\infty} dk k J_m(kr_b) J_m(kr_a) \frac{1}{2\pi} e^{im(\varphi_b-\varphi_a)} \\ &= \frac{1}{\sqrt{r_b r_a}} \delta(r_b-r_a) \delta(\varphi_b-\varphi_a). \end{aligned} \tag{9.24}$$

The last two lines exhibit the well-known completeness relation of the radial wave functions of a free particle.³

9.2 Harmonic Oscillator in D Dimensions

The wave functions of the one-dimensional harmonic oscillator have already been derived in Section 2.6 from a spectral decomposition of the time evolution amplitude. This was possible with the help of Mehler’s formula. In D dimensions, the fixed-energy amplitude is the best starting point for determining the wave functions. We take the radial propagator (8.142) obtained from the angular momentum decomposition (8.141) or, for the sake of greater generality, the radial amplitude (8.144) with an additional centrifugal barrier, continue it to imaginary time $\tau = it$, and go over to its Laplace transform

$$\begin{aligned} (r_b|r_a)_{E,l} &= -i\sqrt{M\omega/\hbar}\sqrt{M\omega r_b r_a/\hbar} \int_{\tau_a}^{\infty} d\tau_b e^{E(\tau_b-\tau_a)/\hbar} \frac{1}{\sin[\omega(\tau_b-\tau_a)]} \\ &\quad \times e^{-\frac{1}{\hbar} \frac{M\omega}{2} \coth[\omega(\tau_b-\tau_a)](r_b^2+r_a^2)} I_{\mu} \left(\frac{M\omega r_b r_a}{\hbar \sinh[\omega(\tau_b-\tau_a)]} \right). \end{aligned} \tag{9.25}$$

To evaluate the τ -integral we make use of a standard integral formula for Bessel functions⁴

$$\begin{aligned} \int_0^{\infty} dx [\coth(x/2)]^{2\nu} e^{-\beta \cosh x} J_{\mu}(\alpha \sinh x) \\ = \frac{\Gamma((1+\mu)/2-\nu)}{\alpha \Gamma(\mu+1)} W_{\nu,\mu/2} \left(\sqrt{\alpha^2+\beta^2} + \beta \right) M_{-\nu,\mu/2} \left(\sqrt{\alpha^2+\beta^2} - \beta \right), \end{aligned} \tag{9.26}$$

where $W_{\nu,\mu/2}(z)$, $M_{-\nu,\mu/2}(z)$ are the Whittaker functions. The formula is valid for

$$\text{Re } \beta > |\text{Re } \alpha|, \quad \text{Re}(\mu/2-\nu) > -\frac{1}{2}.$$

³Compare with Eqs. (3.112) and (3.139) in J.D. Jackson, *Classical Electrodynamics*, John Wiley & Sons, New York, 1975.

⁴I.S. Gradshteyn and I.M. Ryzhik, *op. cit.*, Formula 6.669.1.

By a change of variables

$$\sqrt{\alpha^2 + \beta^2} \pm \beta = t\alpha_{b,a},$$

and

$$\sinh x = (\sinh y)^{-1}, \quad \cosh x = \coth y, \quad \coth(x/2) = e^y, \quad \coth x = \cosh y,$$

with

$$dx = dy / \sinh y,$$

Eq. (9.26) goes over into

$$\begin{aligned} & \int_0^\infty \frac{dy}{\sinh y} e^{2\nu y} \exp[-\tfrac{1}{2}t(\alpha_b - \alpha_a) \coth y] J_\mu \left(t \frac{\sqrt{\alpha_b \alpha_a}}{\sinh y} \right) \\ &= \frac{\Gamma((1+\mu)/2 - \nu)}{t\sqrt{\alpha_b \alpha_a} \Gamma(\mu + 1)} W_{\nu, \mu/2}(t\alpha_b) M_{-\nu, \mu/2}(-t\alpha_a). \end{aligned} \quad (9.27)$$

Using the identity

$$M_{-\nu, \mu/2}(z) \equiv e^{-i(\mu+1)\pi/2} M_{\nu, \mu/2}(-z) \quad (9.28)$$

and changing the sign of α_a in (9.27), this can be turned into

$$\begin{aligned} & \int_0^\infty \frac{dy}{\sinh y} e^{2\nu y} \exp[-\tfrac{1}{2}t(\alpha_b + \alpha_a) \coth y] I_\mu \left(\frac{t\sqrt{\alpha_b \alpha_a}}{\sinh y} \right) \\ &= \frac{\Gamma((1+\mu)/2 - \nu)}{t\sqrt{\alpha_b \alpha_a} \Gamma(\mu + 1)} W_{\nu, \mu/2}(t\alpha_b) M_{\nu, \mu/2}(t\alpha_a), \end{aligned} \quad (9.29)$$

with the range of validity

$$\begin{aligned} & \alpha_b > \alpha_a > 0, \quad \operatorname{Re}[(1+\mu)/2 - \nu] > 0, \\ & \operatorname{Re} t > 0, \quad |\arg t| < \pi. \end{aligned} \quad (9.30)$$

Setting

$$y = \omega(t_b - t_a), \quad \alpha_b = \frac{M}{\hbar} \omega r_b^2, \quad \alpha_a = \frac{M\omega}{\hbar} r_a^2, \quad \nu = E/2\omega\hbar \quad (9.31)$$

in (9.29) brings the radial amplitude (9.25) to the form (valid for $r_b > r_a$)

$$(r_b|r_a)_{E,l} = -i \frac{1}{\omega} \frac{1}{\sqrt{r_b r_a}} \frac{\Gamma((1+\mu)/2 - \nu)}{\Gamma(\mu + 1)} W_{\nu, \mu/2} \left(\frac{M\omega}{\hbar} r_b^2 \right) M_{\nu, \mu/2} \left(\frac{M\omega}{\hbar} r_a^2 \right). \quad (9.32)$$

The Gamma function has poles at

$$\nu = \nu_r \equiv (1+\mu)/2 + n_r \quad (9.33)$$

for integer values of the so-called radial quantum number of the system $n_r = 0, 1, 2, \dots$. The poles have the form

$$\Gamma((1+\mu)/2 - \nu) \underset{\nu \sim \nu_r}{\sim} -\frac{(-1)^{n_r}}{n_r!} \frac{1}{\nu - \nu_r}. \quad (9.34)$$

Inserting here the particular value of the parameter μ for the D -dimensional oscillator which is $\mu = D/2 + l - 1$, and remembering that $\nu = E/2\omega\hbar$, we find the energy spectrum

$$E = \hbar\omega (2n_r + l + D/2). \quad (9.35)$$

The principal quantum number is defined by

$$n \equiv 2n_r + l \quad (9.36)$$

and the energy depends on it as follows:

$$E_n = \hbar\omega(n + D/2). \quad (9.37)$$

For a fixed principal quantum number $n = 2n_r + l$, the angular momentum runs through $l = 0, 2, \dots, n$ for even, and $l = 1, 3, \dots, n$ for odd n . There are $d_n = (n + D - 1)! / (D - 1)! n!$ degenerate levels. From the residues $1/(\nu - \nu_r) \sim 2\hbar\omega / (E - E_n)$, we extract the product of radial wave functions at given n_r, l :

$$\begin{aligned} R_{n_r l}(r_b) R_{n_r l}(r_a) &= \frac{1}{\sqrt{r_b r_a}} \frac{2(-1)^{n_r}}{\Gamma(\mu + 1)n_r!} \\ &\times W_{(1+\mu)/2+n_r, \frac{\mu}{2}}(M\omega r_b^2/\hbar) M_{(1+\mu)/2+n_r, \frac{\mu}{2}}(M\omega r_a^2/\hbar). \end{aligned} \quad (9.38)$$

It is now convenient to express the Whittaker functions in terms of the confluent hypergeometric or Kummer functions:⁵

$$W_{(1+\mu)/2+n_r, \frac{\mu}{2}}(z) = e^{-z/2} z^{(1+\mu)/2} U(-n_r, 1 + \mu, z), \quad (9.39)$$

$$M_{(1+\mu)/2+n_r, \frac{\mu}{2}}(z) = e^{-z/2} z^{(1+\mu)/2} M(-n_r, 1 + \mu, z). \quad (9.40)$$

The latter equation follows from the relation

$$M_{-(1+\mu)/2-n_r, \frac{\mu}{2}}(z) = e^{-z/2} z^{(1+\mu)/2} M(1 + \mu + n_r, 1 + \mu, z), \quad (9.41)$$

after replacing $n_r \rightarrow -n_r - \mu - 1$.

For completeness, we also mention the identity

$$M(a, b, z) = e^z M(b - a, b, -z), \quad (9.42)$$

so that

$$M(1 + \mu + n_r, 1 + \mu, z) = e^z M(-n_r, 1 + \mu, -z). \quad (9.43)$$

This permits us to rewrite (9.41) as

$$M_{-(1+\mu)/2-n_r, \frac{\mu}{2}}(z) = e^{z/2} z^{(1+\mu)/2} M(-n_r, 1 + \mu, -z), \quad (9.44)$$

which turns into (9.40) by using (9.28) and appropriately changing the indices.

⁵I.S. Gradshteyn and I.M. Ryzhik, *op. cit.*, Formula 9.220.2.

The Kummer function $M(a, b, z)$ has the power series

$$M(a, b, z) \equiv {}_1F_1(a; b; z) = 1 + \frac{a}{b}z + \frac{a(a+1)}{b(b+1)}\frac{z^2}{2!} + \dots, \quad (9.45)$$

showing that $M_{(1+\mu)/2+n_r, \frac{\mu}{2}}(M\omega r_a^2/2\hbar)$ is an exponential $e^{-M\omega r_a^2/\hbar}$ times a polynomial in r_a of order $2n_r$. A similar expression is obtained for the other factor $W_{(1+\mu)/2+n_r, \frac{\mu}{2}}(M\omega r_b^2/\hbar)$ of Eq. (9.39). Indeed, the Kummer function $U(a, b, z)$ is related to $M(a, b, z)$ by⁶

$$U(a, b, z) = \frac{\pi}{\sin \pi b} \left[\frac{M(a, b, z)}{\Gamma(1+a-b)\Gamma(b)} - z^{1-b} \frac{M(1+a-b, 2-b, z)}{\Gamma(a)\Gamma(2-b)} \right]. \quad (9.46)$$

Since $a = -n_r$ with integer n_r and $1/\Gamma(a) = 0$, we see that only the first term in the brackets is present. Then the identity

$$\Gamma(-\mu)\Gamma(1+\mu) = \pi/\sin[\pi(1+\mu)]$$

leads to the relation

$$U(-n_r, 1+\mu, z) = \frac{\Gamma(-\mu)}{\Gamma(-n_r-\mu)} M(-n_r, 1+\mu, z), \quad (9.47)$$

which is a polynomial in z of order n_r . Thus we have the useful formula

$$W_{(1+\mu)/2+n_r, \frac{\mu}{2}}(z_b) M_{(1+\mu)/2+n_r, \frac{\mu}{2}}(z_a) = \frac{\Gamma(-\mu)}{\Gamma(-n_r-\mu)} e^{-(z_b+z_a)/2} \times (z_b z_a)^{(1+\mu)/2} M(-n_r, 1+\mu, z_b) M(-n_r, 1+\mu, z_a). \quad (9.48)$$

We can therefore re-express Eq. (9.38) as

$$R_{n_r l}(r_b) R_{n_r l}(r_a) = \sqrt{\frac{M\omega}{\hbar}} \frac{2(-)^{n_r} \Gamma(-\mu)}{\Gamma(-n_r-\mu)\Gamma(1+\mu) n_r!} \times e^{-M\omega(r_b^2+r_a^2)/2\hbar} (M\omega r_b r_a/\hbar)^{1/2+\mu} \times M(-n_r, 1+\mu, M\omega r_b^2/\hbar) M(-n_r, 1+\mu, M\omega r_a^2/\hbar). \quad (9.49)$$

We now insert

$$\frac{(-)^{n_r} \Gamma(-\mu)}{\Gamma(-n_r-\mu)} = \frac{\Gamma(n_r+1+\mu)}{\Gamma(1+\mu)}, \quad (9.50)$$

setting $\mu = D/2 + l - 1$, and identify the wave functions as

$$R_{n_r l}(r) = C_{n_r l} (M\omega/\hbar)^{1/4} (M\omega r^2/\hbar)^{l/2+(D-1)/4} \times e^{-M\omega r^2/2\hbar} M(-n_r, l+D/2, M\omega r^2/\hbar), \quad (9.51)$$

⁶M. Abramowitz and I. Stegun, *Handbook of Mathematical Functions*, Dover, New York, 1965, Formula 13.1.3.

with the normalization factor

$$C_{n_r l} = \frac{\sqrt{2}}{\Gamma(1 + \mu)} \sqrt{\frac{(n_r + \mu)!}{n_r!}}. \quad (9.52)$$

By introducing the Laguerre polynomials⁷

$$L_n^\mu(z) \equiv \frac{(n + \mu)!}{n! \mu!} M(-n, \mu + 1, z), \quad (9.53)$$

and using the integral formula⁸

$$\int_0^\infty dz e^{-z} z^\mu L_n^\mu(z) L_{n'}^\mu(z) = \delta_{nn'} \frac{(n + \mu)!}{n!}, \quad (9.54)$$

we find that the radial wave functions satisfy the orthonormality relation

$$\int_0^\infty dr R_{n_r l}(r) R_{n'_r l}(r) = \delta_{n_r n'_r}. \quad (9.55)$$

The radial imaginary-time evolution amplitude has now the spectral representation

$$(r_b \tau_b | r_a \tau_a)_l = \sum_{n_r=0}^\infty R_{n_r l}(r_b) R_{n_r l}(r_a) e^{-E_n(\tau_b - \tau_a)/\hbar}, \quad (9.56)$$

with the energies

$$E_n = \hbar\omega(n + D/2) = \hbar\omega(2n_r + l + D/2). \quad (9.57)$$

The full causal propagator is given, as in (8.91), by

$$(\mathbf{x}_b \tau_b | \mathbf{x}_a \tau_a) = \frac{1}{(r_b r_a)^{(D-1)/2}} \sum_{l=0}^\infty (r_b \tau_b | r_a \tau_a)_l \sum_m Y_{lm}(\hat{\mathbf{x}}_b) Y_{lm}^*(\hat{\mathbf{x}}_a). \quad (9.58)$$

From this, we extract the wave functions

$$\psi_{n_r l m}(\mathbf{x}) = \frac{1}{r^{(D-1)/2}} R_{n_r l}(r) Y_{lm}(\hat{\mathbf{x}}). \quad (9.59)$$

They have the threshold behavior r^l near the origin.

The one-dimensional oscillator may be viewed as a special case of these formulas. For $D = 1$, the partial wave expansion amounts to a separation into even and odd wave functions. There are two “spherical harmonics”,

$$Y_{e,\phi}(\hat{x}) = \frac{1}{\sqrt{2}} (\Theta(x) \pm \Theta(-x)), \quad (9.60)$$

⁷I.S. Gradshteyn and I.M. Ryzhik, op. cit., Formula 8.970 (our definition differs from that in L.D. Landau and E.M. Lifshitz, *Quantum Mechanics*, Pergamon, London, 1965, Eq. (d.13). The relation is $L_n^\mu = (-)^\mu / (n + \mu)! L_{n+\mu}^{L, L, \mu}$.

⁸ibid., Formula 7.414.3.

and the amplitude has the decomposition

$$(x_b \tau_b | x_a \tau_a) = (r_b \tau_b | r_a \tau_a)_e Y_e(\hat{x}_b) Y_e(\hat{x}_a) + (r_b \tau_b | r_a \tau_a)_\phi Y_\phi(\hat{x}_b) Y_\phi(\hat{x}_a), \quad (9.61)$$

with the “radial” amplitudes

$$(r_b \tau_b | r_a \tau_a)_{e,\phi} = (x_b \tau_b | x_a \tau_a) \pm (-x_b \tau_b | x_a \tau_a). \quad (9.62)$$

These are known from Eq. (2.177) to be

$$\begin{aligned} (r_b \tau_b | r_a \tau_a)_{e,\phi} &= \frac{1}{\sqrt{2\pi}} \sqrt{\frac{M\omega/\hbar}{\sinh[\omega(\tau_b - \tau_a)]}} \\ &\times \exp\left[-\frac{M\omega}{2\hbar}(r_b^2 + r_a^2) \cot \omega(\tau_b - \tau_a)\right] 2 \left\{ \begin{array}{l} \cosh \\ \sinh \end{array} \right\} (M\omega r_b r_a / \hbar). \end{aligned} \quad (9.63)$$

The two cases coincide with the integrand of (9.25) for $l = 0$ and 1 , respectively, since $\mu = l + D/2 - 1$ takes the values $\pm 1/2$ and

$$\sqrt{z} I_{\mp \frac{1}{2}}(z) = \frac{2}{2\pi} \left\{ \begin{array}{l} \cosh z \\ \sinh z \end{array} \right. \quad (9.64)$$

The associated energy spectrum (9.35) is

$$E = \begin{cases} \hbar\omega(2n_r + \frac{1}{2}) & \text{even,} \\ \hbar\omega(2n_r + \frac{3}{2}) & \text{odd,} \end{cases} \quad (9.65)$$

with the radial quantum number $n_r = 0, 1, 2, \dots$. The two cases follow the single formula

$$E = \hbar\omega(n + \frac{1}{2}), \quad (9.66)$$

where the principal quantum number $n = 0, 1, 2, \dots$ is related to n_r by $n = 2n_r$ and $n = 2n_r + 1$, respectively. The radial wave functions (9.51) become

$$R_{n_r,e}(r) = (M\omega/\hbar)^{1/4} \sqrt{\frac{2\Gamma(n_r + \frac{1}{2})}{\pi n_r!}} M(-n_r, \frac{1}{2}, M\omega r^2/\hbar), \quad (9.67)$$

$$R_{n_r,\phi}(r) = (M\omega/\hbar)^{1/4} \sqrt{\frac{2\Gamma(n_r + \frac{3}{2})}{(\pi/4)n_r!}} \sqrt{\frac{M\omega r^2}{\hbar}} M(-n_r, \frac{3}{2}, M\omega r^2/\hbar). \quad (9.68)$$

The special Kummer functions appearing here are Hermite polynomials

$$M(-n, \frac{1}{2}, x^2) = \frac{n!}{(2n)!} (-)^n H_{2n}(x), \quad (9.69)$$

$$M(-n, \frac{3}{2}, x^2) = \frac{n!}{(2n+1)!} (-)^n H_{2n+1}(x)/2\sqrt{x}. \quad (9.70)$$

Using the identity

$$\Gamma(z)\Gamma(z + \frac{1}{2}) = (2\pi)^{1/2}2^{-2z+1/2}\Gamma(2z), \tag{9.71}$$

we obtain in either case the radial wave functions [to be compared with the one-dimensional wave functions (2.302)]

$$R_n(r) = N_n\sqrt{2}\lambda_\omega^{-1/2}e^{-r^2/2\lambda_\omega^2}H_n(r/\lambda_\omega), \quad n = 0, 1, 2, \dots \tag{9.72}$$

with

$$\lambda_\omega \equiv \sqrt{\frac{\hbar}{M\omega}}, \quad N_n = \frac{1}{\sqrt{2^n n! \sqrt{\pi}}}. \tag{9.73}$$

This formula holds for both even and odd wave functions with $n_r = 2n$ and $n_r = 2n + 1$, respectively. It is easy to check that they possess the correct normalization $\int_0^\infty dr R_n^2(r) = 1$. Note that the ‘‘spherical harmonics’’ (9.60) remove a factor $\sqrt{2}$ in (9.72), but compensate for this by extending the $x > 0$ integration to the entire x -axis by the ‘‘one-dimensional angular integration’’.

9.3 Free Particle from $\omega \rightarrow 0$ -Limit of Oscillator

The results obtained for the D -dimensional harmonic oscillator in the last section can be used to find the amplitude and wave functions of a free particle in D dimensions in radial coordinates. This is done by taking the limit $\omega \rightarrow 0$ at fixed energy E . In the amplitude (9.32) with $W_{\nu,\mu/2}(z), M_{\nu,\mu/2}(z)$ substituted according to (9.39), we rewrite n_r as $(E/\omega\hbar - l - 1)/2$ and go to the limit $\omega \rightarrow 0$ at a fixed energy E . Replacing $M\omega r^2/\hbar$ by $k^2 r^2/2n_r \equiv z/n_r$ (where $z = k^2 r^2/2$, and using $E = p^2/2M = \hbar^2 k^2/2M$), we apply the limiting formulas⁹

$$\begin{aligned} &\lim_{n_r \rightarrow \infty} \{ \Gamma(1 - n_r - b) U(-a, b, \mp z/n_r) \} \\ &= z^{-\frac{1}{2}(b-1)} \begin{cases} 2K_{b-1}(2\sqrt{z}) \\ -i\pi e^{i\pi b} H_{b-1}^{(1)}(2\sqrt{z}) \end{cases} \quad (\text{Im } z > 0), \end{aligned} \tag{9.74}$$

$$\lim_{n_r \rightarrow \infty} M(-a, b, \mp z/n_r) / \Gamma(b) = z^{-\frac{1}{2}(b-1)} \begin{cases} I_{b-1}(2\sqrt{z}) \\ J_{b-1}(2\sqrt{z}), \end{cases} \tag{9.75}$$

and obtain the radial wave functions directly from (9.51) and (9.75):

$$R_{n_r l}(r) \xrightarrow{n_r \rightarrow \infty} C_{n_r l} (M\omega r^2/\hbar)^{(\mu/2+1/2)} (k^2 r^2/2)^{-\mu/2} \Gamma(1 + \mu) J_\mu(kr), \tag{9.76}$$

where

$$C_{n_r l} \xrightarrow{n_r \rightarrow \infty} \sqrt{2} \left(\frac{E}{2\hbar\omega} \right)^{\mu/2} \frac{1}{\Gamma(1 + \mu)}. \tag{9.77}$$

Hence

$$R_{n_r l}(r) \xrightarrow{n_r \rightarrow \infty} r^{1/2} \sqrt{M\omega/\hbar} \sqrt{2} J_\mu(kr). \tag{9.78}$$

⁹M. Abramowitz and I. Stegun, *op. cit.*, Formulas 13.3.1–13.3.4.

Inserting these wave functions into the radial time evolution amplitude

$$(r_b\tau_b|r_a\tau_a)_l = \sum_{n_r} R_{n_r l}(r_b)R_{n_r l}(r_a)e^{-E_n(\tau_b-\tau_a)/\hbar}, \quad (9.79)$$

and replacing the sum over n_r by the integral $\int_0^\infty dk \hbar k/M\omega$ [in accordance with the $n_r \rightarrow \infty$ limit of $E_{n_r} = \omega\hbar(2n_r + l + D/2) \rightarrow \hbar^2 k^2/2M$], we obtain the spectral representation of the free-particle propagator

$$(r_b\tau_b|r_a\tau_a)_\mu = \sqrt{r_b r_a} \int_0^\infty dk k J_\mu(kr_b)J_\mu(kr_a)e^{-\frac{\hbar k^2}{2M}(\tau_b-\tau_a)}. \quad (9.80)$$

For comparison, we derive the same results directly from the initial spectral representation (9.2) in one dimension

$$(x_b\tau_b|x_a\tau_a) = \int_{-\infty}^\infty \frac{dk}{2\pi} \exp\left[ik(x_b - x_a) - \frac{\hbar k^2}{2M}(\tau_b - \tau_a)\right]. \quad (9.81)$$

Its ‘‘angular decomposition’’ is a decomposition with respect to even and odd wave functions

$$\begin{aligned} (r_b\tau_b|r_a\tau_a)_{e,\theta} &= \int_0^\infty \frac{dk}{\pi} [\cos k(r_b - r_a) \pm \cos k(r_b + r_a)] e^{-\frac{\hbar k^2}{2M}(\tau_b-\tau_a)} \\ &= 2 \int_0^\infty \frac{dk}{\pi} \begin{Bmatrix} \cos kr_b & \cos kr_a \\ \sin kr_b & \sin kr_a \end{Bmatrix} e^{-\frac{\hbar k^2}{2M}(\tau_b-\tau_a)}. \end{aligned} \quad (9.82)$$

In D dimensions we use the expansion (8.100) for $e^{i\mathbf{k}\cdot\mathbf{x}}$ to calculate the amplitude in the radial form

$$\begin{aligned} (\mathbf{x}_b\tau_b|\mathbf{x}_a\tau_a) &= \int \frac{d^D k}{(2\pi)^D} e^{i\mathbf{k}\cdot(\mathbf{x}_b-\mathbf{x}_a)} e^{-\frac{\hbar k^2}{2M}(\tau_b-\tau_a)} \\ &= \frac{1}{(2\pi)^{D/2}} \int_0^\infty dk k^{2\nu} \frac{1}{(kR)^\nu} J_\nu(kR) e^{-\frac{\hbar k^2}{2M}(\tau_b-\tau_a)}, \end{aligned} \quad (9.83)$$

with $\nu \equiv D/2 - 1$. With the help of the addition theorem for Bessel functions¹⁰ (8.188) we rewrite

$$\frac{1}{(kR)^\nu} J_\nu(kR) = \frac{2^\nu \Gamma(\nu)}{(k^2 r_b r_a)^\nu} \sum_{l=0}^\infty (\nu + l) J_{\nu+l}(kr_b) J_{\nu+l}(kr_a) C_l^{(\nu)}(\Delta\vartheta) \quad (9.84)$$

and expand further according to

$$\frac{1}{(kR)^\nu} J_\nu(kR) = \frac{(2\pi)^{D/2}}{(k^2 r_b r_a)^\nu} \sum_{l=0}^\infty J_{\nu+l}(kr_b) J_{\nu+l}(kr_a) \sum_{\mathbf{l}} Y_{l\mathbf{m}}(\hat{\mathbf{x}}_b) Y_{l\mathbf{m}}^*(\hat{\mathbf{x}}_a), \quad (9.85)$$

to obtain the radial amplitude

$$(r_b\tau_b|r_a\tau_a)_l = \sqrt{r_b r_a} \int_0^\infty dk k J_{\nu+l}(kr_b) J_{\nu+l}(kr_a) e^{-\frac{\hbar k^2}{2M}(\tau_b-\tau_a)}, \quad (9.86)$$

¹⁰I.S. Gradshteyn and I.M. Ryzhik, op. cit., Formula 8.532.

just as in (9.80).

For $D = 1$, this reduces to (9.82) using the particular Bessel functions

$$\sqrt{z}J_{\mp 1/2}(z) = \frac{2}{\sqrt{2\pi}} \begin{Bmatrix} \cos z \\ \sin z \end{Bmatrix}. \quad (9.87)$$

9.4 Charged Particle in Uniform Magnetic Field

Let us also find the wave functions of a charged particle in a magnetic field. The amplitude was calculated in Section 2.18. Again we work with the imaginary-time version. Factorizing out the free motion along the direction of the magnetic field, we write

$$(\mathbf{x}_b\tau_b|\mathbf{x}_a\tau_a) = (z_b\tau_b|z_a\tau_a)(\mathbf{x}_b^\perp\tau_b|\mathbf{x}_a^\perp\tau_a), \quad (9.88)$$

with

$$(z_b\tau_b|z_a\tau_a) = \frac{1}{\sqrt{2\pi\hbar(\tau_b - \tau_a)/M}} \exp\left\{-\frac{M(z_b - z_a)^2}{2\hbar(\tau_b - \tau_a)}\right\}, \quad (9.89)$$

and have for the amplitude in the transverse direction

$$(\mathbf{x}_b^\perp\tau_b|\mathbf{x}_a^\perp\tau_a) = \frac{M}{2\pi\hbar(\tau_b - \tau_a)} \frac{\omega(\tau_b - \tau_a)/2}{\sinh[\omega(\tau_b - \tau_a)/2]} \exp\left[-\mathcal{A}_t^\perp/\hbar\right], \quad (9.90)$$

with the classical transverse action

$$\mathcal{A}_t^\perp = \frac{M\omega}{2} \left\{ \frac{1}{2} \coth[\omega(\tau_b - \tau_a)/2] (\mathbf{x}_b^\perp - \mathbf{x}_a^\perp)^2 + \mathbf{x}_a^\perp \times \mathbf{x}_b^\perp \right\}. \quad (9.91)$$

This result is valid if the vector potential is chosen as

$$\mathbf{A} = \frac{1}{2}\mathbf{B} \times \mathbf{x}. \quad (9.92)$$

In the other gauge with

$$\mathbf{A} = (0, Bx, 0), \quad (9.93)$$

there is an extra surface term, and $\mathcal{A}_{\text{cl}}^\perp$ is replaced by

$$\tilde{\mathcal{A}}_{\text{cl}}^\perp = \mathcal{A}_{\text{cl}}^\perp + \frac{M\omega}{2}(x_b y_b - x_a y_a). \quad (9.94)$$

The calculation of the wave functions is quite different in these two gauges. In the gauge (9.93) we merely recall the expressions (2.663) and (2.665) and write down the integral representation

$$(\mathbf{x}_b^\perp\tau_b|\mathbf{x}_a^\perp\tau_a) = \int \frac{dp_y}{2\pi\hbar} e^{ip_y(y_b - y_a)/\hbar} (x_b\tau_b|x_a\tau_a)_{x_0=p_y/M\omega}, \quad (9.95)$$

with the oscillator amplitude in the x -direction

$$(x_b\tau_b|x_a\tau_a)_{x_0} = \sqrt{\frac{M\omega}{2\pi\hbar \sinh[\omega(\tau_b - \tau_a)]}} \exp\left(-\frac{1}{\hbar}\mathcal{A}_{\text{cl}}^{\text{os}}\right), \quad (9.96)$$

and the classical oscillator action centered around x_0

$$\mathcal{A}_{\text{cl}}^{\text{os}} = \frac{M\omega}{2 \sinh[\omega(\tau_b - \tau_a)]} \{ [(x_b - x_0)^2 + (x_a - x_0)^2] \cosh[\omega(\tau_b - \tau_a)] - 2(x_b - x_0)(x_a - x_0) \}. \quad (9.97)$$

The spectral representation of the amplitude (9.96) is then

$$(x_a \tau_b | x_a \tau_a)_{x_0} = \sum_{n=0}^{\infty} \psi_n(x_b - x_0) \psi_n(x_a - x_0) e^{-(n+\frac{1}{2})\omega(\tau_b - \tau_a)}, \quad (9.98)$$

where $\psi_n(x)$ are the oscillator wave functions (2.302). This leads to the spectral representation of the full amplitude (9.88)

$$\begin{aligned} (\mathbf{x}_b \tau_b | \mathbf{x}_a \tau_a) &= \int \frac{dp_z}{2\pi\hbar} \int \frac{dp_y}{2\pi\hbar} e^{ip_z(z_b - z_a)/\hbar} \\ &\times \sum_{n=0}^{\infty} \psi_n(x_b - p_y/M\omega) \psi_n(x_a - p_y/M\omega) e^{-(n+\frac{1}{2})\omega(\tau_b - \tau_a)}. \end{aligned} \quad (9.99)$$

The combination of a sum and two integrals exhibits the complete set of wave functions of a particle in a uniform magnetic field. Note that the energy

$$E_n = (n + \frac{1}{2})\hbar\omega \quad (9.100)$$

is highly degenerate; it does not depend on p_y .

In the gauge $\mathbf{A} = \frac{1}{2}\mathbf{B} \times \mathbf{x}$, the spectral decomposition looks quite different. To derive it, the transverse Euclidean action is written down in radial coordinates [compare Eq. (2.669)] as

$$\mathcal{A}_{\text{cl}}^{\perp} = \frac{M}{2} \left\{ \frac{\omega}{2} \coth[\omega(\tau_b - \tau_a)/2] [r_b^2 + r_a^2 - 2r_b r_a \cos(\varphi_b - \varphi_a)] - i\omega r_b r_a \sin(\varphi_b - \varphi_a) \right\}. \quad (9.101)$$

This can be rearranged to

$$\begin{aligned} \mathcal{A}_{\text{cl}}^{\perp} &= \frac{M\omega}{2} \frac{\omega}{2} \coth[\omega(\tau_b - \tau_a)/2] (r_b^2 + r_a^2) \\ &- \frac{M}{2} \frac{\omega}{\sinh[\omega(\tau_b - \tau_a)/2]} \cos[\varphi_b - \varphi_a - i\omega(\tau_b - \tau_a)/2]. \end{aligned} \quad (9.102)$$

We now expand $e^{-\mathcal{A}_{\text{cl}}^{\perp}/\hbar}$ into a series of Bessel functions using (8.5)

$$\begin{aligned} e^{-\mathcal{A}_{\text{cl}}^{\perp}/\hbar} &= \exp \left\{ -\frac{M\omega}{2\hbar} \frac{\omega}{2} \coth[\omega(\tau_b - \tau_a)/2] (r_b^2 + r_a^2) \right\} \\ &\times \sum_{m=-\infty}^{\infty} I_m \left(\frac{M\omega}{2\hbar} \frac{r_b r_a}{\sinh[\omega(\tau_b - \tau_a)/2]} \right) e^{m\omega(\tau_b - \tau_a)/2} e^{im(\varphi_b - \varphi_a)}. \end{aligned} \quad (9.103)$$

The fluctuation factor is the same as before. Hence we obtain the angular decomposition of the transverse amplitude

$$(\mathbf{x}_b^\perp \tau_b | \mathbf{x}_a^\perp \tau_a) = \frac{1}{\sqrt{r_b r_a}} \sum_m (r_b \tau_b | r_a \tau_a)_m \frac{1}{2\pi} e^{im(\varphi_b - \varphi_a)}, \quad (9.104)$$

where

$$(r_b \tau_b | r_a \tau_a)_m = \sqrt{r_b r_a} \frac{M\omega}{2\hbar\eta} \frac{\eta}{\sinh\eta} \exp\left[-\frac{M\omega}{2\hbar} \frac{\omega}{2} \coth\eta (r_b^2 + r_a^2)\right] I_m\left(\frac{M\omega r_b r_a}{2\hbar \sinh\eta}\right) e^{m\eta}, \quad (9.105)$$

with

$$\eta \equiv \omega(\tau_b - \tau_a)/2. \quad (9.106)$$

To find the spectral representation we go to the fixed-energy amplitude

$$\begin{aligned} (r_b | r_a)_{m,E} &= -i \int_{\tau_a}^{\infty} d\tau_b e^{E(\tau_b - \tau_a)/\hbar} (r_b \tau_b | r_a \tau_a)_m \\ &= -i \sqrt{r_b r_a} \frac{M}{\hbar} \int_0^{\infty} d\eta e^{2\nu\eta} \frac{1}{\sinh\eta} e^{-(M\omega/4\hbar) \coth\eta (r_b^2 + r_a^2)} I_m\left(\frac{M\omega r_b r_a}{2\hbar \sinh\eta}\right). \end{aligned} \quad (9.107)$$

The integral is done with the help of formula (9.29) and yields

$$\begin{aligned} (r_b | r_a)_{m,E} &= -i \sqrt{r_b r_a} \frac{M}{\hbar} \frac{\Gamma\left(\frac{1}{2} - \nu + \frac{|m|}{2}\right)}{(M\omega/2\hbar) r_b r_a \Gamma(|m| + 1)} \\ &\quad \times W_{\nu, |m|/2}\left(\frac{M\omega}{2\hbar} r_b^2\right) M_{\nu, |m|/2}\left(\frac{M\omega}{2\hbar} r_a^2\right), \end{aligned} \quad (9.108)$$

with

$$\nu \equiv \frac{E}{\omega\hbar} + \frac{m}{2}. \quad (9.109)$$

The Gamma function $\Gamma(1/2 - \nu - |m|/2)$ has poles at

$$\nu = \nu_r \equiv n_r + \frac{1}{2} + \frac{|m|}{2} \quad (9.110)$$

of the form

$$\Gamma(1/2 - \nu - |m|/2) \approx -\frac{1}{n_r!} \frac{(-1)^{n_r}}{\nu - \nu_r} \sim -\frac{(-1)^{n_r}}{n_r!} \frac{\omega\hbar}{E - E_{n_r m}}. \quad (9.111)$$

The poles lie at the energies

$$E_{n_r m} = \hbar\omega \left(n_r + \frac{1}{2} + \frac{|m|}{2} - \frac{m}{2} \right). \quad (9.112)$$

These are the well-known Landau levels of a particle in a uniform magnetic field. The Whittaker functions at the poles are (for $m > 0$)

$$M_{-\nu, m/2}(z) = e^{z/2} z^{\frac{1+m}{2}} M(-n_r, 1+m, -z), \quad (9.113)$$

$$W_{\nu, m/2}(z) = e^{-z/2} z^{\frac{1+m}{2}} (-)^{n_r} \frac{(n_r + m)!}{m!} M(-n_r, 1+m, z). \quad (9.114)$$

The fixed-energy amplitude near the poles is therefore

$$(r_b | r_a)_{m, E} \sim \frac{i\hbar}{E - E_{n_r m}} R_{n_r m}(r_b) R_{n_r m}(r_a), \quad (9.115)$$

with the radial wave functions¹¹

$$\begin{aligned} R_{n_r m}(r) &= \sqrt{r} \left(\frac{M\omega}{\hbar} \right)^{1/2} \sqrt{\frac{(n_r + |m|)!}{n_r!} \frac{1}{|m|!}} \\ &\times \exp\left(-\frac{M\omega}{4\hbar} r^2\right) \left(\frac{M\omega}{2\hbar} r^2\right)^{|m|/2} M\left(-n_r, 1 + |m|, \frac{M\omega}{2\hbar} r^2\right). \end{aligned} \quad (9.116)$$

Using Eq. (9.53), they can be expressed in terms of Laguerre polynomials $L_n^\alpha(z)$:

$$\begin{aligned} R_{n_r m} &= \sqrt{r} \left(\frac{M\omega}{\hbar} \right)^{1/2} \sqrt{\frac{n_r!}{(n_r + |m|)!}} \exp\left(-\frac{M\omega}{4\hbar} r^2\right) \\ &\times \left(\frac{M\omega}{2\hbar} r^2\right)^{|m|/2} L_{n_r}^{|m|}\left(\frac{M\omega}{2\hbar} r^2\right). \end{aligned} \quad (9.117)$$

The integral (9.54) ensures the orthonormality of the radial wave functions

$$\int_0^\infty dr R_{n_r m}(r) R_{n'_r m}(r) = \delta_{n_r n'_r}. \quad (9.118)$$

A Laplace transformation of the fixed-energy amplitude (9.108) gives, via the residue theorem, the spectral representation of the radial time evolution amplitude

$$(r_b \tau_b | r_a \tau_a) = \sum_{n_r m} R_{n_r m}(r_b) R_{n_r m}(r_a) e^{-E_{n_r m}(\tau_b - \tau_a)/\hbar}, \quad (9.119)$$

with the energies (9.112). The full wave functions in the transverse subspace are, of course,

$$\psi_{n_r m}(\mathbf{x}) = \frac{1}{\sqrt{r}} R_{n_r m}(r) \frac{e^{im\varphi}}{\sqrt{2\pi}}. \quad (9.120)$$

Comparing the energies (9.112) with (9.100), we identify the principal quantum number n as

$$n \equiv n_r + \frac{|m|}{2} - \frac{m}{2}. \quad (9.121)$$

¹¹Compare with L.D. Landau and E.M. Lifshitz, *Quantum Mechanics*, Pergamon, London, 1965, p. 427.

Note that the infinite degeneracy of the energy levels observed in (9.100) with respect to p_y is now present with respect to m . This energy does not depend on m for $m \geq 0$. The somewhat awkward m -dependence of the energy can be avoided by introducing, instead of m , another quantum number n' related to n, m by

$$m = n' - n. \quad (9.122)$$

The states are then labeled by n, n' with both n and n' taking the values $0, 1, 2, 3, \dots$. For $n' < n$, one has $n' = n_r$ and $m = n' - n < 0$, whereas for $n' \geq n$ one has $n = n_r$ and $m = n' - n \geq 0$. There exists a natural way of generating the wave functions $\psi_{n_r m}(\mathbf{x})$ such that they appear immediately with the quantum numbers n, n' . For this we introduce the Landau radius

$$a = \sqrt{\frac{2\hbar}{M\omega}} = \sqrt{\frac{2\hbar c}{eB}} \quad (9.123)$$

as a length parameter and define the dimensionless transverse coordinates

$$z = (x + iy)/\sqrt{2}a, \quad z^* = (x - iy)/\sqrt{2}a. \quad (9.124)$$

It is then possible to prove that the $\psi_{n_r m}$'s coincide with the wave functions

$$\psi_{n, n'}(z, z^*) = N_{n, n'} e^{z^* z} \left(-\frac{1}{\sqrt{2}} \partial_{z^*} \right)^n \left(-\frac{1}{\sqrt{2}} \partial_z \right)^{n'} e^{-2z^* z}. \quad (9.125)$$

The normalization constants are obtained by observing that the differential operators

$$\begin{aligned} e^{z^* z} \left(-\frac{1}{\sqrt{2}} \partial_{z^*} \right) e^{-z^* z} &= \frac{1}{\sqrt{2}} (-\partial_{z^*} + z), \\ e^{z^* z} \left(-\frac{1}{\sqrt{2}} \partial_z \right) e^{-z^* z} &= \frac{1}{\sqrt{2}} (-\partial_z + z^*) \end{aligned} \quad (9.126)$$

behave algebraically like two independent creation operators

$$\begin{aligned} \hat{a}^\dagger &= \frac{1}{\sqrt{2}} (-\partial_{z^*} + z), \\ \hat{b}^\dagger &= \frac{1}{\sqrt{2}} (-\partial_z + z^*), \end{aligned} \quad (9.127)$$

whose conjugate annihilation operators are

$$\begin{aligned} \hat{a} &= \frac{1}{\sqrt{2}} (\partial_z + z^*), \\ \hat{b} &= \frac{1}{\sqrt{2}} (\partial_{z^*} + z). \end{aligned} \quad (9.128)$$

The ground state wave function annihilated by these is

$$\psi_{0,0}(z, z^*) = \langle z, z^* | 0 \rangle \propto e^{-z^*z}. \quad (9.129)$$

We can therefore write the complete set of wave functions as

$$\psi_{n,n'}(z, z^*) = N_{nn'} \hat{a}^{\dagger n} \hat{b}^{\dagger n'} \psi_{0,0}(z, z^*). \quad (9.130)$$

Using the fact that $\hat{a}^{\dagger*} = \hat{b}^{\dagger}$, $\hat{b}^{\dagger*} = \hat{a}^{\dagger}$, and that partial integrations turn \hat{b}^{\dagger} , \hat{a}^{\dagger} into \hat{a} , \hat{b} , respectively, the normalization integral can be rewritten as

$$\begin{aligned} & \int dx dy \psi_{n_1, n'_1}(z, z^*) \psi_{n_2, n'_2}(z, z^*) \\ &= N_{n_1 n'_1} N_{n_2 n'_2} \int dx dy [(a^\dagger)^{n_1} (b^\dagger)^{n'_1} e^{-z^*z}] [(a^\dagger)^{n_2} (b^\dagger)^{n'_2} e^{-z^*z}] \\ &= N_{n_1 n'_1} N_{n_2 n'_2} \int dx dy e^{-2z^*z} (a^{n_1} b^{n'_1} a^{\dagger n_2} b^{\dagger n'_2}). \end{aligned} \quad (9.131)$$

Here the commutation relations between \hat{a}^\dagger , \hat{b}^\dagger , \hat{a} , \hat{b} serve to reduce the parentheses in the last line to

$$n_1! n_2! \delta_{n_1 n'_1} \delta_{n_2 n'_2}. \quad (9.132)$$

The trivial integral

$$\int dx dy e^{-2z^*z} = \pi \int dr^2 e^{-r^2/a^2} = \pi a^2 \quad (9.133)$$

shows that the normalization constants are

$$N_{n,n'} = \frac{1}{\sqrt{\pi a^2 n! n'}}. \quad (9.134)$$

Let us prove the equality of $\psi_{n_r, m}$ and $\psi_{n, n'}$ up to a possible overall phase. For this we first observe that z, ∂_{z^*} and z^*, ∂_z carry phase factors $e^{i\varphi}$ and $e^{-i\varphi}$, respectively, so that the two wave functions have obviously the azimuthal quantum number $m = n - n'$. Second, we make sure that the energies coincide by considering the Schrödinger equation corresponding to the action (2.643)

$$\frac{1}{2M} \left(-i\hbar \nabla - \frac{e}{c} \mathbf{A} \right)^2 \psi = E\psi. \quad (9.135)$$

In the gauge where

$$\mathbf{A} = (0, Bx, 0),$$

it reads

$$-\frac{\hbar^2}{2M} \left[\partial_x^2 + \left(\partial_y - i\frac{eB}{c}x \right)^2 + \partial_z^2 \right] \psi = E\psi, \quad (9.136)$$

and the wave functions can be taken from Eq. (9.99). In the gauge where

$$\mathbf{A} = (-By/2, Bx/2, 0), \quad (9.137)$$

on the other hand, the Schrödinger equation becomes, in cylindrical coordinates,

$$\left[-\frac{\hbar^2}{2M} \left(\partial_r^2 + \frac{1}{r} \partial_r + \frac{1}{r^2} \partial_\varphi^2 + \partial_z^2 \right) - \frac{ie\hbar B}{2Mc} \partial_\varphi + \frac{e^2 B^2}{8Mc^2} r^2 \right] \psi(r, z, \varphi) = E\psi(r, z, \varphi). \quad (9.138)$$

Employing a reduced radial coordinate $\rho = r/a$ and factorizing out a plane wave in the z -direction, $e^{ip_z z/\hbar}$, this takes the form

$$\left[\partial_\rho^2 + \frac{1}{\rho} \partial_\rho + \frac{a^2}{\hbar^2} (2ME - p_z^2) - \rho^2 - 2i\partial_\varphi - \frac{1}{\rho^2} \partial_\varphi^2 \right] \psi(r, \varphi) = 0. \quad (9.139)$$

The solutions are

$$\psi_{n_r m}(r, \varphi) \propto e^{im\varphi} e^{-\rho^2/2} \rho^{|m|/2} M\left(-n_r, |m| + \frac{1}{2}, \rho\right), \quad (9.140)$$

where the confluent hypergeometric functions $M\left(-n_r, |m| + \frac{1}{2}, \rho\right)$ are polynomials for integer values of the radial quantum number

$$n_r = n + \frac{1}{2}m - \frac{1}{2}|m| - \frac{1}{2}, \quad (9.141)$$

as in (9.116). The energy is related to the principal quantum number by

$$n + \frac{1}{2} \equiv \frac{a^2}{\hbar^2} (2ME - p_z^2). \quad (9.142)$$

Since

$$\frac{2Ma^2}{\hbar^2} = \frac{1}{\hbar\omega}, \quad (9.143)$$

the energy is

$$E = \left(n + \frac{1}{2} \right) \hbar\omega + \frac{p_z^2}{2M}. \quad (9.144)$$

We now observe that the Schrödinger equation (9.139) can be expressed in terms of the creation and annihilation operators (9.127), (9.128) as

$$4 \left[-(a^\dagger a + 1/2) + \frac{1}{\hbar\omega} \left(E - \frac{p_z^2}{2M} \right) \right] \psi(z, z^*) = 0. \quad (9.145)$$

This proves that the algebraically constructed wave functions $\psi_{n,n'}$ in (9.130) coincide with the wave functions $\psi_{n_r m}$ of (9.116) and (9.140), up to an irrelevant phase. Note that the energy depends only on the number of a -quanta; it is independent of the number of b -quanta.

9.5 Dirac δ -Function Potential

For a particle in a Dirac δ -function potential, the fixed-energy amplitudes $(\mathbf{x}_b|\mathbf{x}_a)_E$ can be calculated by performing a perturbation expansion around a free-particle amplitude and summing it up exactly. For any time-independent potential $V(\mathbf{x})$, in addition to a harmonic potential $M\omega^2\mathbf{x}^2/2$, the perturbation expansion in Eq. (3.478) can be Laplace-transformed in the imaginary time via (9.3) to find

$$\begin{aligned} (\mathbf{x}_b|\mathbf{x}_a)_E &= (\mathbf{x}_b|\mathbf{x}_a)_{\omega,E} - \frac{i}{\hbar} \int d^D x_1 (\mathbf{x}_b|\mathbf{x}_1)_{\omega,E} V(\mathbf{x}_1) (\mathbf{x}_1|\mathbf{x}_a)_{\omega,E} \\ &+ -\frac{1}{\hbar^2} \int d^D x_2 \int d^D x_1 (\mathbf{x}_b|\mathbf{x}_2)_{\omega,E} V(\mathbf{x}_2) (\mathbf{x}_2|\mathbf{x}_1)_{\omega,E} V(\mathbf{x}_1) (\mathbf{x}_1|\mathbf{x}_a)_{\omega,E} \\ &+ \dots \end{aligned} \quad (9.146)$$

If the potential is a Dirac δ -function centered around \mathbf{X} ,

$$V(\mathbf{x}) = g \delta^{(D)}(\mathbf{x} - \mathbf{X}), \quad g \equiv \frac{\hbar^2}{Ml^{2-D}}, \quad (9.147)$$

this series simplifies to

$$(\mathbf{x}_b|\mathbf{x}_a)_E = (\mathbf{x}_b|\mathbf{x}_a)_{\omega,E} - \frac{ig}{\hbar} g (\mathbf{x}_b|\mathbf{X})_{\omega,E} (\mathbf{X}|\mathbf{x}_a)_{\omega,E} - \frac{g^2}{\hbar^2} (\mathbf{x}_b|\mathbf{X})_{\omega,E} (\mathbf{X}|\mathbf{X})_{\omega,E} (\mathbf{X}|\mathbf{x}_a)_{\omega,E} + \dots, \quad (9.148)$$

and can be summed up to

$$(\mathbf{x}_b|\mathbf{x}_a)_E = (\mathbf{x}_b|\mathbf{x}_a)_{\omega,E} - i \frac{g}{\hbar} \frac{(\mathbf{x}_b|\mathbf{X})_{\omega,E} (\mathbf{X}|\mathbf{x}_a)_{\omega,E}}{1 + i \frac{g}{\hbar} (\mathbf{X}|\mathbf{X})_{\omega,E}}. \quad (9.149)$$

This is, incidentally, true if a δ -function potential is added to an arbitrary solvable fixed-energy amplitude, not just the harmonic one.

If the δ -function is the only potential, we use formula (9.149) with $\omega = 0$, so that $(\mathbf{x}_b|\mathbf{x}_a)_{0,E}$ reduces to the fixed-energy amplitude (9.12) of a free particle, and obtain directly

$$\begin{aligned} (\mathbf{x}_b|\mathbf{x}_a)_E &= -2i \frac{M}{\hbar} \frac{\kappa^{D-2}}{(2\pi)^{D/2}} \frac{K_{D/2-1}(\kappa R)}{(\kappa R)^{D/2-1}} \\ &- \frac{ig}{\hbar} \frac{i \frac{2M}{\hbar} \frac{\kappa^{D-2}}{(2\pi)^{D/2}} \frac{K_{D/2-1}(\kappa R_b)}{(\kappa R_b)^{D/2-1}} \times i \frac{2M}{\hbar} \frac{\kappa^{D-2}}{(2\pi)^{D/2}} \frac{K_{D/2-1}(\kappa R_a)}{(\kappa R_a)^{D/2-1}}}{1 - \frac{g}{\hbar} \frac{2M}{\hbar} \frac{\kappa^{D-2}}{\pi^{D/2}} \frac{K_{D/2-1}(\kappa \delta)}{(\kappa \delta)^{D/2-1}}}, \end{aligned} \quad (9.150)$$

where $R \equiv |\mathbf{x}_b - \mathbf{x}_a|$ and $R_{a,b} \equiv |\mathbf{x}_{a,b} - \mathbf{X}|$, and δ is an infinitesimal distance regularizing a possible singularity at zero-distance. In $D = 1$ dimension, this reduces to

$$(x_b|x_a)_E = -i \frac{M}{\hbar} \frac{1}{\kappa} e^{-\kappa R} + i \frac{M}{\hbar \kappa} e^{\kappa(R_b+R_a)} \frac{1}{l\kappa + 1}, \quad (9.151)$$

For an attractive potential with $l < 0$, the second term can be written as

$$-i \frac{1}{\kappa l^2} \frac{\hbar}{E + \hbar^2/2Ml^2} e^{\kappa(R_b+R_a)}, \quad (9.152)$$

exhibiting a pole at the bound-state energy $E_B = -\hbar^2/2Ml^2$. In its neighborhood, the pole contribution reads

$$\frac{2}{l} e^{-(R_b+R_a)/l} \frac{i\hbar}{E + \hbar^2/2Ml^2}. \quad (9.153)$$

This has precisely the spectral form (1.325) with the normalized bound-state wave function

$$\psi_B(x) = \sqrt{\frac{2}{l}} e^{-|x-X|/l}. \quad (9.154)$$

In $D = 3$ dimensions, the amplitude (9.150) becomes

$$(\mathbf{x}_b|\mathbf{x}_a)_E = -i \frac{M}{\hbar} \frac{1}{2\pi R} e^{-\kappa R} + i \frac{M}{\hbar} \frac{e^{\kappa R_b}}{2\pi R_b} \frac{e^{\kappa R_a}}{2\pi R_a} \frac{1}{1/l + e^{-\kappa\delta}/2\pi\delta}. \quad (9.155)$$

In the limit $\delta \rightarrow 0$, the denominator requires renormalization. We introduce a renormalized coupling length scale

$$\frac{1}{l_r} \equiv 1 + \frac{1}{2\pi\delta}, \quad (9.156)$$

and rewrite the last factor in (9.155) as

$$\frac{1}{1/l_r - \kappa/2\pi}. \quad (9.157)$$

For $l_r < 0$, this has a pole at the bound-state energy $E_B = -4\pi^2\hbar^2/2Ml_r^2$ of the form

$$-l_r E_B \frac{1}{E - E_B}. \quad (9.158)$$

The total pole term in (9.155) can therefore be written as

$$\psi_B(\mathbf{x}_b)\psi_B^*(\mathbf{x}_a) \frac{i\hbar}{E - E_B}, \quad (9.159)$$

with $\kappa_B = \sqrt{2ME_B}/\hbar = 2\pi/l_r$ and the normalized bound-state wave functions

$$\psi_B(\mathbf{x}) = \left(\frac{\kappa_B^2}{4\pi^2}\right)^{1/4} \frac{e^{-\kappa_B|\mathbf{x}-\mathbf{X}|}}{r}. \quad (9.160)$$

In $D = 2$ dimensions, the situation is more subtle. It is useful to consider the amplitude (9.150) in $D = 2 + \epsilon$ dimensions where one has

$$\begin{aligned}
 (\mathbf{x}_b|\mathbf{x}_a)_E &= -i \frac{M}{\hbar} \frac{1}{\pi} \frac{K_{\epsilon/2}(\kappa R)}{(2\pi\kappa R)^{\epsilon/2}} \\
 &+ i \frac{M^2}{\hbar^2 \pi^2} \frac{1}{(2\pi\kappa R_b)^{\epsilon/2}} \frac{1}{(2\pi\kappa R_a)^{\epsilon/2}} \frac{K_{\epsilon/2}(\kappa R_b) K_{\epsilon/2}(\kappa R_a)}{\hbar} \\
 &\quad + \frac{M}{g} + \frac{M}{\hbar \pi} \frac{1}{(2\pi\kappa\delta)^{\epsilon/2}} K_{\epsilon/2}(\kappa\epsilon). \quad (9.161)
 \end{aligned}$$

Inserting here $K_{\epsilon/2}(\kappa\delta) \approx (1/2)\Gamma(\epsilon/2)(\kappa\delta/2)^{-\epsilon/2}$, the denominator becomes

$$\frac{\hbar}{g} + \frac{M}{2\hbar\pi} \frac{\Gamma(\epsilon/2)}{(\pi\kappa\delta)^{\epsilon/2}} \approx \frac{\hbar}{g} + \frac{M}{2\hbar\pi} \frac{2}{\epsilon} \left[1 - \frac{\epsilon}{2} \log(\pi\kappa\delta) \right]. \quad (9.162)$$

Here we introduce a renormalized coupling constant

$$\frac{1}{g_r} = \frac{1}{g} + \frac{M}{\hbar^2} \frac{1}{\epsilon}, \quad (9.163)$$

and rewrite the right-hand side as

$$\frac{\hbar}{g_r} - \frac{M}{2\hbar\pi} \log \pi\kappa\delta. \quad (9.164)$$

This has a pole at

$$\kappa_B = \frac{1}{\pi\delta} e^{2\hbar^2\pi/Mg_r}, \quad (9.165)$$

indicating a bound-state pole of energy $E_B = -\hbar^2\kappa_B^2/2M$.

We can now go to the limit of $D = 2$ dimensions and find that the pole term in (9.161) has the form

$$\psi_B(\mathbf{x}_b)\psi_B^*(\mathbf{x}_a) \frac{i\hbar}{E - E_B}, \quad (9.166)$$

with the normalized bound-state wave function

$$\psi_B(\mathbf{x}) = \frac{\kappa_B}{\sqrt{\pi}} K_0(\kappa_B|\mathbf{x} - \mathbf{X}|). \quad (9.167)$$

Notes and References

The wave functions derived in this chapter from the time evolution amplitude should be compared with those given in standard textbooks on quantum mechanics, such as L.D. Landau and E.M. Lifshitz, *Quantum Mechanics*, Pergamon, London, 1965. The charged particle in a magnetic field is treated in §111.

The δ -function potential was studied via path integrals by C. Grosche, Phys. Rev. Letters, **71**, 1 (1993).

10

Spaces with Curvature and Torsion

The path integral of a free particle in spherical coordinates has taught us an important lesson: In a Euclidean space, we were able to obtain the correct time-sliced amplitude in curvilinear coordinates by setting up the sliced action in Cartesian coordinates x^i and transforming them to the spherical coordinates $q^\mu = (r, \theta, \phi)$. It was crucial to do the transformation at the level of the *finite* coordinate differences, $\Delta x^i \rightarrow \Delta q^\mu$. This produced higher-order terms in the differences Δq^μ which had to be included up to the order $(\Delta q)^4/\epsilon$. They all contributed to the relevant order ϵ . It is obvious that as long as the space is Euclidean, the same procedure can be used to find the path integral in an arbitrary curvilinear coordinate system q^μ , if we ignore subtleties arising near coordinate singularities which are present in centrifugal barriers, angular barriers, or Coulomb potentials. For these, a special treatment will be developed in Chapters 12–14.

We are now going to develop an entirely nontrivial but quite natural extension of this procedure and define a path integral in an arbitrary metric-affine space with curvature and torsion. It must be emphasized that the quantum theory in such spaces is not uniquely defined by the formalism developed so far. The reason is that also the original Schrödinger theory which was used in Chapter 2 to justify the introduction of path integrals is not uniquely defined in such spaces. In classical physics, the equivalence principle postulated by Einstein is a powerful tool for deducing equations of motion in curved space from those in flat space. At the quantum level, this principle becomes insufficient since it does not forbid the appearance of arbitrary coordinate-independent terms proportional to Planck's quantum \hbar^2 and the scalar curvature R to appear in the Schrödinger equation. We shall set up a simple extension of Einstein's equivalence principle which will allow us to carry quantum theories from flat to curved spaces which are, moreover, permitted to carry certain classes of torsion.

In such spaces, not only the time-sliced action but also the measure of path integration requires a special treatment. To be valid in general it will be necessary to find construction rules for the time evolution amplitude which do not involve the crutch of Cartesian coordinates. The final formula will be purely intrinsic to the general metric-affine space [1].

A crucial test of the validity of the resulting path integral formula will come from applications to systems whose correct operator quantum mechanics is known on the basis of symmetries and group commutation rules rather than canonical commutation rules. In contrast to earlier approaches, our path integral formula will always yield the same quantum mechanics as operator quantum mechanics quantized via group commutation rules.

Our formula can, of course, also be used for an alternative approach to the path integrals solved before in Chapter 8, where a Euclidean space was parametrized in terms of curvilinear coordinates. There it gives rise to a more satisfactory treatment than before, since it involves only the intrinsic variables of the coordinate systems.

10.1 Einstein's Equivalence Principle

To motivate the present study we invoke *Einstein's equivalence principle*, according to which gravitational forces upon a spinless mass point are indistinguishable from those felt in an accelerating local reference.¹ They are independent of the atomic composition of the particle and strictly proportional to the value of the mass, the same mass that appears in the relation between force and acceleration, in Newton's second law. The strict equality between the two masses, gravitational and inertial, is fundamental to Einstein's equivalence principle. Experimentally, the equality holds to an extremely high degree of accuracy. Any possible small deviation can presently be attributed to extra non-gravitational forces. Einstein realized that as a consequence of this equality, all spinless point particles move in a gravitational field along the same orbits which are independent of their composition and mass. This *universality* of orbital motion permits the gravitational field to be attributed to geometric properties of spacetime.

In Newton's theory of gravity, the gravitational forces between mass points are inversely proportional to their distances in a Euclidean space. In Einstein's geometric theory the forces are explained entirely by a curvature of spacetime. In general the spacetime of general relativity may also carry another geometric property, called torsion. Torsion is supposed to be generated by the spin densities of material bodies. Quantitatively, this may have only extremely small effects, too small to be detected by present-day experiments. But this is only due to the small intrinsic spin of ordinary gravitational matter. In exceptional states of matter such as polarized neutron stars or black holes, torsion can become relevant. It is now generally accepted that spacetime should carry a nonvanishing torsion at least locally at those points which are occupied by spinning elementary particles [55]. This follows from rather general symmetry considerations. The precise equations of motion for the torsion field, on the other hand, are still a matter of speculation. Thus it is an open question whether

¹Quotation from his original paper *Über das Relativitätsprinzip und die aus demselben gezogenen Folgerungen*, Jahrbuch der Relativität und Elektonik 4, 411 (1907): "Wir ... wollen daher im folgenden die völlige physikalische Gleichwertigkeit von Gravitationsfeld und entsprechender Beschleunigung des Bezugssystems annehmen".

or not the torsion field is able to propagate into the empty space away from spinning matter.

Even though the effects of torsion are small we shall keep the discussion as general as possible and study the motion of a particle in a metric-affine space with both curvature and torsion. To prepare the grounds let us first recapitulate a few basic facts about classical orbits of particles in a gravitational field. For simplicity, we assume here only the three-dimensional space to have a nontrivial geometry.² Then there is a natural choice of a time variable t which is conveniently used to parametrize the particle orbits.

Starting from the free-particle action we shall then introduce a path integral for the time evolution amplitude in any metric-affine space which determines the quantum mechanics via the quantum fluctuations of the particle orbits.

10.2 Classical Motion of Mass Point in General Metric-Affine Space

On the basis of the equivalence principle, Einstein formulated the rules for finding the classical laws of motion in a gravitational field as a consequence of the geometry of spacetime. Let us recapitulate his reasoning adapted to the present problem of a nonrelativistic point particle in a non-Euclidean geometry.

10.2.1 Equations of Motion

Consider first the action of the particle along the orbit $\mathbf{x}(t)$ in a flat space parametrized with rectilinear, Cartesian coordinates:

$$\mathcal{A} = \int_{t_a}^{t_b} dt \frac{M}{2} (\dot{x}^i)^2, \quad i = 1, 2, 3. \quad (10.1)$$

It is transformed to curvilinear coordinates q^μ , $\mu = 1, 2, 3$, via some functions

$$x^i = x^i(q), \quad (10.2)$$

leading to

$$\mathcal{A} = \int_{t_a}^{t_b} dt \frac{M}{2} g_{\mu\nu}(q) \dot{q}^\mu \dot{q}^\nu, \quad (10.3)$$

where

$$g_{\mu\nu}(q) = \partial_\mu x^i(q) \partial_\nu x^i(q) \quad (10.4)$$

is the *induced metric* for the curvilinear coordinates. Repeated indices are understood to be summed over, as usual.

²The generalization to non-Euclidean spacetime will be obvious after the development in Chapter 19.

The length of the orbit in the flat space is given by

$$l = \int_{t_a}^{t_b} dt \sqrt{g_{\mu\nu}(q) \dot{q}^\mu \dot{q}^\nu}. \quad (10.5)$$

Both the action (10.3) and the length (10.5) are invariant under arbitrary reparametrizations of space $q^\mu \rightarrow q'^\mu$.

Einstein's equivalence principle amounts to the postulate that the transformed action (10.3) describes directly the motion of the particle in the presence of a gravitational field caused by other masses. The forces caused by the field are all a result of the geometric properties of the metric tensor.

The equations of motion are obtained by extremizing the action in Eq. (10.3) with the result

$$\partial_t(g_{\mu\nu}\dot{q}^\nu) - \frac{1}{2}\partial_\mu g_{\lambda\nu}\dot{q}^\lambda\dot{q}^\nu = g_{\mu\nu}\ddot{q}^\nu + \bar{\Gamma}_{\lambda\nu\mu}\dot{q}^\lambda\dot{q}^\nu = 0. \quad (10.6)$$

Here

$$\bar{\Gamma}_{\lambda\nu\mu} \equiv \frac{1}{2}(\partial_\lambda g_{\nu\mu} + \partial_\nu g_{\lambda\mu} - \partial_\mu g_{\lambda\nu}) \quad (10.7)$$

is the Riemann connection or Christoffel symbol of the first kind [recall (1.70)]. With the help of the Christoffel symbol of the second kind [recall (1.71)]

$$\bar{\Gamma}_{\lambda\nu}{}^\mu \equiv g^{\mu\sigma}\bar{\Gamma}_{\lambda\nu\sigma}, \quad (10.8)$$

we can write

$$\ddot{q}^\mu + \bar{\Gamma}_{\lambda\nu}{}^\mu\dot{q}^\lambda\dot{q}^\nu = 0. \quad (10.9)$$

The solutions of these equations are the classical orbits. They coincide with the extrema of the length of a line l in (10.5). Thus, in a curved space, classical orbits are the shortest lines, the *geodesics* [recall (1.72)].

The same equations can also be obtained directly by transforming the equation of motion from

$$\ddot{x}^i = 0 \quad (10.10)$$

to curvilinear coordinates q^μ , which gives

$$\ddot{x}^i = \frac{\partial x^i}{\partial q^\mu}\ddot{q}^\mu + \frac{\partial^2 x^i}{\partial q^\lambda \partial q^\nu}\dot{q}^\lambda\dot{q}^\nu = 0. \quad (10.11)$$

At this place it is again useful to employ the quantities defined in Eq. (1.361), the basis triads and their reciprocals

$$e^i{}_\mu(q) \equiv \frac{\partial x^i}{\partial q^\mu}, \quad e_i{}^\mu(q) \equiv \frac{\partial q^\mu}{\partial x^i}, \quad (10.12)$$

which satisfy the orthogonality and completeness relations (1.362):

$$e_i^\mu e^\nu_i = \delta^\mu_\nu, \quad e_i^\mu e^\mu_j = \delta_i^j. \quad (10.13)$$

The induced metric can then be written as

$$g_{\mu\nu}(q) = e^i_\mu(q) e^i_\nu(q). \quad (10.14)$$

Labeling Cartesian coordinates, upper and lower indices i are the same. The indices μ, ν of the curvilinear coordinates, on the other hand, can be lowered only by contraction with the metric $g_{\mu\nu}$ or raised with the inverse metric $g^{\mu\nu} \equiv (g_{\mu\nu})^{-1}$. Using the basis triads, Eq. (10.11) can be rewritten as

$$\frac{d}{dt}(e^i_\mu \dot{q}^\mu) = e^i_\mu \ddot{q}^\mu + \partial_\nu e^i_\mu \dot{q}^\mu \dot{q}^\nu = 0,$$

or as

$$\ddot{q}^\mu + e_i^\mu \partial_\lambda e^i_\kappa \dot{q}^\kappa \dot{q}^\lambda = 0. \quad (10.15)$$

The quantity in front of $\dot{q}^\kappa \dot{q}^\lambda$ is called the *affine connection*:

$$\Gamma_{\lambda\kappa}^\mu = e_i^\mu \partial_\lambda e^i_\kappa. \quad (10.16)$$

Due to (10.13), it can also be written as [compare (1.370)]

$$\Gamma_{\lambda\kappa}^\mu = -e^i_\kappa \partial_\lambda e_i^\mu. \quad (10.17)$$

Thus we arrive at the transformed flat-space equation of motion

$$\ddot{q}^\mu + \Gamma_{\kappa\lambda}^\mu \dot{q}^\kappa \dot{q}^\lambda = 0. \quad (10.18)$$

The solutions of this equation are called the *straightest lines* or *autoparallels*.

If the coordinate transformation functions $x^i(q)$ are smooth and single-valued, their derivatives commute as required by Schwarz's integrability condition

$$(\partial_\lambda \partial_\kappa - \partial_\kappa \partial_\lambda) x^i(q) = 0. \quad (10.19)$$

Then the triads satisfy the identity

$$\partial_\lambda e^i_\kappa - \partial_\kappa e^i_\lambda = 0, \quad (10.20)$$

implying that the connection $\Gamma_{\lambda\kappa}^\mu$ is symmetric in the lower indices. In fact, it coincides with the Riemann connection, the Christoffel symbol $\bar{\Gamma}_{\lambda\kappa}^\mu$. This follows immediately after inserting $g_{\mu\nu}(q) = e^i_\mu(q) e^i_\nu(q)$ into (10.7) and working out all derivatives using (10.20). Thus, for a space with curvilinear coordinates q^μ which can be reached by an integrable coordinate transformation from a flat space, the autoparallels coincide with the geodesics.

10.2.2 Nonholonomic Mapping to Spaces with Torsion

It is possible to map the x -space locally into a q -space with torsion via an infinitesimal transformation

$$dx^i = e^i_{\mu}(q)dq^{\mu}. \quad (10.21)$$

We merely have to assume that the coefficient functions $e^i_{\mu}(q)$ do not satisfy the property (10.20) which follows from the Schwarz integrability condition (10.19):

$$\partial_{\lambda}e^i_{\kappa}(q) - \partial_{\kappa}e^i_{\lambda}(q) \neq 0, \quad (10.22)$$

implying that second derivatives in front of $x^i(q)$ do not commute as in Eq. (10.19):

$$(\partial_{\lambda}\partial_{\kappa} - \partial_{\kappa}\partial_{\lambda})x^i(q) \neq 0. \quad (10.23)$$

In this case we shall call the differential mapping (10.21) *nonholonomic*, in analogy with the nomenclature for nonintegrable constraints in classical mechanics. The property (10.23) implies that $x^i(q)$ is a multivalued function $x^i(q)$, of which we shall give typical examples below in Eqs. (10.44) and (10.55).

Educated readers in mathematics have been wondering whether such nonholonomic coordinate transformations make any sense. They will understand this concept better if they compare the situation with the quite similar but much simpler creation of magnetic field in a field-free space by *nonholonomic gauge transformations*. More details are explained in Appendix 10A.

From Eq. (10.22) we see that the image space of a nonholonomic mapping carries torsion. The connection $\Gamma_{\lambda\kappa}^{\mu} = e_i^{\mu}e^i_{\kappa,\lambda}$ has a nonzero antisymmetric part, called the *torsion tensor*:³

$$S_{\lambda\kappa}^{\mu} = \frac{1}{2}(\Gamma_{\lambda\kappa}^{\mu} - \Gamma_{\kappa\lambda}^{\mu}) = \frac{1}{2}e_i^{\mu}(\partial_{\lambda}e^i_{\kappa} - \partial_{\kappa}e^i_{\lambda}). \quad (10.24)$$

In contrast to $\Gamma_{\lambda\kappa}^{\mu}$, the antisymmetric part $S_{\lambda\kappa}^{\mu}$ is a proper tensor under general coordinate transformations. The contracted tensor

$$S_{\mu} \equiv S_{\mu\lambda}^{\lambda} \quad (10.25)$$

transforms like a vector, whereas the contracted connection $\Gamma_{\mu} \equiv \Gamma_{\mu\nu}^{\nu}$ does not. Even though $\Gamma_{\mu\nu}^{\lambda}$ is not a tensor, we shall freely lower and raise its indices using contractions with the metric or the inverse metric, respectively: $\Gamma_{\nu}^{\mu\lambda} \equiv g^{\mu\kappa}\Gamma_{\kappa\nu}^{\lambda}$, $\Gamma_{\mu}^{\nu\lambda} \equiv g^{\nu\kappa}\Gamma_{\mu\kappa}^{\lambda}$, $\Gamma_{\mu\nu\lambda} \equiv g_{\lambda\kappa}\Gamma_{\mu\nu}^{\kappa}$. The same thing will be done with $\bar{\Gamma}_{\mu\nu}^{\lambda}$.

In the presence of torsion, the affine connection (10.16) is no longer equal to the Christoffel symbol. In fact, by rewriting $\Gamma_{\mu\nu\lambda} = e_{i\lambda}\partial_{\mu}e^i_{\nu}$ trivially as

$$\begin{aligned} \Gamma_{\mu\nu\lambda} = & \frac{1}{2} \left\{ [e_{i\lambda}\partial_{\mu}e^i_{\nu} + \partial_{\mu}e_{i\lambda}e^i_{\nu}] + [e_{i\mu}\partial_{\nu}e^i_{\lambda} + \partial_{\nu}e_{i\mu}e^i_{\lambda}] - [e_{i\mu}\partial_{\lambda}e^i_{\nu} + \partial_{\lambda}e_{i\mu}e^i_{\nu}] \right\} \\ & + \frac{1}{2} \left\{ [e_{i\lambda}\partial_{\mu}e^i_{\nu} - e_{i\lambda}\partial_{\nu}e^i_{\mu}] - [e_{i\mu}\partial_{\nu}e^i_{\lambda} - e_{i\mu}\partial_{\lambda}e^i_{\nu}] + [e_{i\nu}\partial_{\lambda}e^i_{\mu} - e_{i\nu}\partial_{\mu}e^i_{\lambda}] \right\} \end{aligned} \quad (10.26)$$

³Our notation for the geometric quantities in spaces with curvature and torsion is the same as in J.A. Schouten, *Ricci Calculus*, Springer, Berlin, 1954.

and using $e^i{}_\mu(q)e^i{}_\nu(q) = g_{\mu\nu}(q)$, we find the decomposition

$$\Gamma_{\mu\nu}{}^\lambda = \bar{\Gamma}_{\mu\nu}{}^\lambda + K_{\mu\nu}{}^\lambda, \quad (10.27)$$

where the combination of torsion tensors

$$K_{\mu\nu\lambda} \equiv S_{\mu\nu\lambda} - S_{\nu\lambda\mu} + S_{\lambda\mu\nu} \quad (10.28)$$

is called the *contortion tensor*. It is antisymmetric in the last two indices so that

$$\Gamma_{\mu\nu}{}^\nu = \bar{\Gamma}_{\mu\nu}{}^\nu. \quad (10.29)$$

In the presence of torsion, the shortest and straightest lines are no longer equal. Since the two types of lines play geometrically an equally favored role, the question arises as to which of them describes the correct classical particle orbits. Intuitively, we expect the straightest lines to be the correct trajectories since massive particles possess *inertia* which tend to minimize their deviations from a straight line in space-time. It is hard to conceive how a particle should know which path to take at each instant in time in order to minimize the path length to a distant point. This would contradict the principle of locality which pervades all laws of physics. Only in a spacetime without torsion is this possible, since there the shortest lines happen to coincide with straightest ones for purely mathematical reasons. In Subsection 10.2.3, the straightest lines will be derived from an action principle.

In Einstein's theory of gravitation, matter produces curvature in four-dimensional Minkowski spacetime, thereby explaining the universal nature of gravitational forces. The flat spacetime metric is

$$\eta_{ab} = \begin{pmatrix} 1 & & & \\ & -1 & & \\ & & -1 & \\ & & & -1 \end{pmatrix}_{ab}, \quad a, b = 0, 1, 2, 3. \quad (10.30)$$

The *Riemann-Cartan curvature tensor* is defined as the covariant curl of the affine connection:

$$R_{\mu\nu\lambda}{}^\kappa = \partial_\mu \Gamma_{\nu\lambda}{}^\kappa - \partial_\nu \Gamma_{\mu\lambda}{}^\kappa - [\Gamma_\mu, \Gamma_\nu]_\lambda{}^\kappa, \quad \mu, \nu, \dots = 0, 1, 2, 3. \quad (10.31)$$

The last term is written in a matrix notation for the connection, in which the tensor components $\Gamma_{\mu\lambda}{}^\kappa$ are viewed as matrix elements $(\Gamma_\mu)_\lambda{}^\kappa$. The matrix commutator in (10.31) is then equal to

$$[\Gamma_\mu, \Gamma_\nu]_\lambda{}^\kappa \equiv (\Gamma_\mu \Gamma_\nu - \Gamma_\nu \Gamma_\mu)_\lambda{}^\kappa = \Gamma_{\mu\lambda}{}^\sigma \Gamma_{\nu\sigma}{}^\kappa - \Gamma_{\nu\lambda}{}^\sigma \Gamma_{\mu\sigma}{}^\kappa. \quad (10.32)$$

Expressing the affine connection (10.16) in (10.31) with the help of Eqs. (10.16) in terms of the four-dimensional generalization of the triads (10.12) and their reciprocals (10.12), the tetrads $e^a{}_\mu$ and their reciprocals $e_a{}^\mu$, we obtain the compact formula

$$R_{\mu\nu\lambda}{}^\kappa = e_a{}^\kappa (\partial_\mu \partial_\nu - \partial_\nu \partial_\mu) e^a{}_\lambda. \quad (10.33)$$

For the mapping (10.21), this implies that not only the coordinate transformation $x^a(q)$, but also its first derivatives fail to satisfy Schwarz's integrability condition:

$$(\partial_\mu \partial_\nu - \partial_\nu \partial_\mu) \partial_\lambda x^a(q) \neq 0. \quad (10.34)$$

Such general transformation matrices $e^a{}_\mu(q)$ will be referred to as *multivalued basis tetrads*.

A transformation for which $x^a(q)$ have commuting derivatives, while the first derivatives $\partial_\mu x^a(q) = e^i{}_\mu(q)$ do not, carries a flat-space region into a purely curved one.

Einstein's original theory of gravity assumes the absence of torsion. The space properties are completely specified by the *Riemann curvature tensor* formed from the Riemann connection (the Christoffel symbol)

$$\bar{R}_{\mu\nu\lambda}{}^\kappa = \partial_\mu \bar{\Gamma}_{\nu\lambda}{}^\kappa - \partial_\nu \bar{\Gamma}_{\mu\lambda}{}^\kappa - [\bar{\Gamma}_\mu, \bar{\Gamma}_\nu]_\lambda{}^\kappa. \quad (10.35)$$

The relation between the two curvature tensors is

$$R_{\mu\nu\lambda}{}^\kappa = \bar{R}_{\mu\nu\lambda}{}^\kappa + \bar{D}_\mu K_{\nu\lambda}{}^\kappa - \bar{D}_\nu K_{\mu\lambda}{}^\kappa - [K_\mu, K_\nu]_\lambda{}^\kappa. \quad (10.36)$$

In the last term, the $K_{\mu\lambda}{}^\kappa$'s are viewed as matrices $(K_\mu)_\lambda{}^\kappa$. The symbols \bar{D}_μ denote the *covariant derivatives* formed with the Christoffel symbol. Covariant derivatives act like ordinary derivatives if they are applied to a scalar field. When applied to a vector field, they act as follows:

$$\begin{aligned} \bar{D}_\mu v_\nu &\equiv \partial_\mu v_\nu - \bar{\Gamma}_{\mu\nu}{}^\lambda v_\lambda, \\ \bar{D}_\mu v^\nu &\equiv \partial_\mu v^\nu + \bar{\Gamma}_{\mu\lambda}{}^\nu v^\lambda. \end{aligned} \quad (10.37)$$

The effect upon a tensor field is the generalization of this; every index receives a corresponding additive $\bar{\Gamma}$ contribution.

Note that the Laplace-Beltrami operator (1.371) applied to a scalar field $\sigma(q)$ can be written as

$$\Delta \sigma = g^{\mu\nu} \bar{D}_\mu \bar{D}_\nu \sigma. \quad (10.38)$$

In the presence of torsion, there exists another covariant derivative formed with the affine connection $\Gamma_{\mu\nu}{}^\lambda$ rather than the Christoffel symbol which acts upon a vector field as

$$\begin{aligned} D_\mu v_\nu &\equiv \partial_\mu v_\nu - \Gamma_{\mu\nu}{}^\lambda v_\lambda, \\ D_\mu v^\nu &\equiv \partial_\mu v^\nu + \Gamma_{\mu\lambda}{}^\nu v^\lambda. \end{aligned} \quad (10.39)$$

Note by definition of $\Gamma_{\lambda\kappa}{}^\mu$ in (10.16) and (10.17), the covariant derivatives of $e^i{}_\mu$ and $e_i{}^\mu$ vanish:

$$D_\mu e^i{}_\nu \equiv \partial_\mu e^i{}_\nu - \Gamma_{\mu\nu}{}^\lambda e^i{}_\lambda = 0, \quad D_\mu e_i{}^\nu \equiv \partial_\mu e_i{}^\nu + \Gamma_{\mu\lambda}{}^\nu e_i{}^\lambda = 0. \quad (10.40)$$

This will be of use later.

From either of the two curvature tensors, $R_{\mu\nu\lambda}{}^\kappa$ and $\bar{R}_{\mu\nu\lambda}{}^\kappa$, one can form the once-contracted tensors of rank two, the *Ricci tensor*

$$R_{\nu\lambda} = R_{\mu\nu\lambda}{}^\mu, \quad (10.41)$$

and the *curvature scalar*

$$R = g^{\nu\lambda} R_{\nu\lambda}. \quad (10.42)$$

The celebrated Einstein equation for the gravitational field postulates that the tensor

$$G_{\mu\nu} \equiv R_{\mu\nu} - \frac{1}{2}g_{\mu\nu}R, \quad (10.43)$$

the so-called *Einstein tensor*, is proportional to the symmetric energy-momentum tensor of all matter fields. This postulate was made only for spaces with no torsion, in which case $R_{\mu\nu} = \bar{R}_{\mu\nu}$ and $R_{\mu\nu}$, $G_{\mu\nu}$ are both symmetric. As mentioned before, it is not yet clear how Einstein's field equations should be generalized in the presence of torsion since the experimental consequences are as yet too small to be observed. In this text, we are not concerned with the generation of curvature and torsion but only with their consequences upon the motion of point particles.

It is useful to set up two simple examples for nonholonomic mappings which illustrate the way in which these are capable of generating curvature and torsion from a Euclidean space. The reader not familiar with this subject is advised to consult a textbook on the physics of defects [2], where such mappings are standard and of great practical importance; every plastic deformation of a material can only be described in terms of such mappings.

As a first example consider the transformation in two dimensions

$$dx^i = \begin{cases} dq^1 & \text{for } i = 1, \\ dq^2 + \epsilon \partial_\mu \phi(q) dq^\mu & \text{for } i = 2, \end{cases} \quad (10.44)$$

with an infinitesimal parameter ϵ and the multi-valued function

$$\phi(q) \equiv \arctan(q^2/q^1). \quad (10.45)$$

The triads reduce to dyads, with the components

$$\begin{aligned} e^1{}_\mu &= \delta^1{}_\mu, \\ e^2{}_\mu &= \delta^2{}_\mu + \epsilon \partial_\mu \phi(q), \end{aligned} \quad (10.46)$$

and the torsion tensor has the components

$$e^1{}_\lambda S_{\mu\nu}{}^\lambda = 0, \quad e^2{}_\lambda S_{\mu\nu}{}^\lambda = \frac{\epsilon}{2}(\partial_\mu \partial_\nu - \partial_\nu \partial_\mu)\phi. \quad (10.47)$$

Figure 10.1 Edge dislocation in crystal associated with missing semi-infinite plane of atoms. The nonholonomic mapping from the ideal crystal to the crystal with the dislocation introduces a δ -function type torsion in the image space.

If we differentiate (10.45) formally, we find $(\partial_\mu \partial_\nu - \partial_\nu \partial_\mu)\phi \equiv 0$. This, however, is incorrect at the origin. Using Stokes' theorem we see that

$$\int d^2q (\partial_1 \partial_2 - \partial_2 \partial_1)\phi = \oint dq^\mu \partial_\mu \phi = \oint d\phi = 2\pi \quad (10.48)$$

for any closed circuit around the origin, implying that there is a δ -function singularity at the origin with

$$e^2{}_\lambda S_{12}{}^\lambda = \frac{\epsilon}{2} 2\pi \delta^{(2)}(q). \quad (10.49)$$

By a linear superposition of such mappings we can generate an arbitrary torsion in the q -space. The mapping introduces no curvature.

In defect physics, the mapping (10.46) is associated with a dislocation caused by a missing or additional layer of atoms (see Fig. 10.1). When encircling a dislocation along a closed path C , its counter image C' in the ideal crystal does not form a closed path. The closure failure is called the *Burgers vector*

$$b^i \equiv \oint_{C'} dx^i = \oint_C dq^\mu e^i{}_\mu. \quad (10.50)$$

It specifies the direction and thickness of the layer of additional atoms. With the help of Stokes' theorem, it is seen to measure the torsion contained in any surface S spanned by C :

$$b^i = \oint_S d^2s^{\mu\nu} \partial_\mu e^i{}_\nu = \oint_S d^2s^{\mu\nu} e^i{}_\lambda S_{\mu\nu}{}^\lambda, \quad (10.51)$$

where $d^2s^{\mu\nu} = -d^2s^{\nu\mu}$ is the projection of an oriented infinitesimal area element onto the plane $\mu\nu$. The above example has the Burgers vector

$$b^i = (0, \epsilon). \quad (10.52)$$

A corresponding closure failure appears when mapping a closed contour C in the ideal crystal into a crystal containing a dislocation. This defines a Burgers vector:

$$b^\mu \equiv \oint_{C'} dq^\mu = \oint_C dx^i e_i{}^\mu. \quad (10.53)$$

Figure 10.2 Edge disclination in crystal associated with missing semi-infinite section of atoms of angle Ω . The nonholonomic mapping from the ideal crystal to the crystal with the disclination introduces a δ -function type curvature in the image space.

By Stokes' theorem, this becomes a surface integral

$$\begin{aligned} b^\mu &= \oint_S d^2 s^{ij} \partial_i e_j^\mu = \oint_S d^2 s^{ij} e_i^\nu \partial_\nu e_j^\mu \\ &= - \oint_S d^2 s^{ij} e_i^\nu e_j^\lambda S_{\nu\lambda}^\mu, \end{aligned} \quad (10.54)$$

the last step following from (10.17).

As a second example for a nonholonomic mapping, we generate curvature by the transformation

$$x^i = \delta^i_\mu \left[q^\mu + \frac{\Omega}{2\pi} \epsilon^\mu_{\nu\kappa} q^\nu \phi(q) \right], \quad (10.55)$$

with the multi-valued function (10.45). The symbol $\epsilon_{\mu\nu}$ denotes the antisymmetric Levi-Civita tensor. The transformed metric

$$g_{\mu\nu} = \delta_{\mu\nu} - \frac{\Omega}{\pi} \epsilon_{\mu\lambda} \epsilon_{\nu\kappa} \frac{q^\lambda q^\kappa}{q^\sigma q_\sigma} \quad (10.56)$$

is single-valued and has commuting derivatives. The torsion tensor vanishes since $(\partial_1 \partial_2 - \partial_2 \partial_1) x^{1,2}$ are both proportional to $q^{2,1} \delta^{(2)}(q)$, a distribution identical to zero. The local rotation field $\omega(q) \equiv \frac{1}{2}(\partial_1 x^2 - \partial_2 x^1)$, on the other hand, is equal to the multi-valued function $-\Omega \phi(q)/2\pi$, thus having the noncommuting derivatives:

$$(\partial_1 \partial_2 - \partial_2 \partial_1) \omega(q) = -\Omega \delta^{(2)}(q). \quad (10.57)$$

To lowest order in Ω , this determines the curvature tensor, which in two dimensions possesses only one independent component, for instance R_{1212} . Using the fact that $g_{\mu\nu}$ has commuting derivatives, R_{1212} can be written as

$$R_{1212} = (\partial_1 \partial_2 - \partial_2 \partial_1) \omega(q). \quad (10.58)$$

In defect physics, the mapping (10.55) is associated with a disclination which corresponds to an entire section of angle Ω missing in an ideal atomic array (see Fig. 10.2).

It is important to emphasize that our multivalued basis tetrads $e^a_\mu(q)$ are *not* related to the standard tetrads or *vierbein fields* $h^\alpha_\mu(q)$ used in the theory of gravitation with spinning particles. The difference is explained in Appendix 10B.

10.2.3 New Equivalence Principle

In classical mechanics, many dynamical problems are solved with the help of non-holonomic transformations. Equations of motion are differential equations which remain valid if transformed differentially to new coordinates, even if the transformation is not integrable in the Schwarz sense. Thus we *postulate that the correct equations of motion of point particles in a space with curvature and torsion are the images of the equation of motion in a flat space.* The equations (10.18) for the autoparallels yield therefore the correct trajectories of spinless point particles in a space with curvature and torsion.

This postulate is based on our knowledge of the motion of many physical systems. Important examples are the Coulomb system which will be discussed in detail in Chapter 13, and the spinning top in the body-fixed reference system [3]. Thus the postulate has a good chance of being true, and will henceforth be referred to as a *new equivalence principle*.

10.2.4 Classical Action Principle for Spaces with Curvature and Torsion

Before setting up a path integral for the time evolution amplitude we must find an action principle for the classical motion of a spinless point particle in a space with curvature and torsion, i.e., the movement along autoparallel trajectories. This is a nontrivial task since autoparallels must emerge as the extremals of an action (10.3) involving only the metric tensor $g_{\mu\nu}$. The action is independent of the torsion and carries only information on the Riemann part of the space geometry. Torsion can therefore enter the equations of motion only via some novel feature of the variation procedure. Since we know how to perform variations of an action in the Euclidean x -space, we deduce the correct procedure in the general metric-affine space by transferring the variations $\delta x^i(t)$ under the nonholonomic mapping

$$\dot{q}^\mu = e_i^\mu(q)\dot{x}^i \quad (10.59)$$

into the q^μ -space. Their images are quite different from ordinary variations as illustrated in Fig. 10.3(a). The variations of the Cartesian coordinates $\delta x^i(t)$ are done at fixed endpoints of the paths. Thus they form *closed paths* in the x -space. Their images, however, lie in a space with defects and thus possess a closure failure indicating the amount of torsion introduced by the mapping. This property will be emphasized by writing the images $\delta^S q^\mu(t)$ and calling them *nonholonomic variations*. The superscript indicates the special feature caused by torsion.

Let us calculate them explicitly. The paths in the two spaces are related by the integral equation

$$q^\mu(t) = q^\mu(t_a) + \int_{t_a}^t dt' e_i^\mu(q(t'))\dot{x}^i(t'). \quad (10.60)$$

For two neighboring paths in x -space differing from each other by a variation $\delta x^i(t)$, equation (10.60) determines the nonholonomic variation $\delta^S q^\mu(t)$:

$$\delta^S q^\mu(t) = \int_{t_a}^t dt' \delta^S [e_i^\mu(q(t')) \dot{x}^i(t')]. \quad (10.61)$$

A comparison with (10.59) shows that the variation δ^S and the time derivatives d/dt of $q^\mu(t)$ commute with each other:

$$\delta^S \dot{q}^\mu(t) = \frac{d}{dt} \delta^S q^\mu(t), \quad (10.62)$$

just as for ordinary variations δx^i :

$$\delta \dot{x}^i(t) = \frac{d}{dt} \delta x^i(t). \quad (10.63)$$

Let us also introduce *auxiliary nonholonomic variations* in q -space:

$$\bar{\delta} q^\mu \equiv e_i^\mu(q) \delta x^i. \quad (10.64)$$

In contrast to $\delta^S q^\mu(t)$, these vanish at the endpoints,

$$\bar{\delta} q(t_a) = \bar{\delta} q(t_b) = 0, \quad (10.65)$$

just as the usual variations $\delta x^i(t)$, i.e., they form *closed* paths with the unvaried orbits.

Using (10.62), (10.63), and the fact that $\delta^S x^i(t) \equiv \delta x^i(t)$, by definition, we derive from (10.61) the relation

$$\begin{aligned} \frac{d}{dt} \delta^S q^\mu(t) &= \delta^S e_i^\mu(q(t)) \dot{x}^i(t) + e_i^\mu(q(t)) \frac{d}{dt} \delta x^i(t) \\ &= \delta^S e_i^\mu(q(t)) \dot{x}^i(t) + e_i^\mu(q(t)) \frac{d}{dt} [e^i_\nu(t) \bar{\delta} q^\nu(t)]. \end{aligned} \quad (10.66)$$

After inserting

$$\delta^S e_i^\mu(q) = -\Gamma_{\lambda\nu}^\mu \delta^S q^\lambda e_i^\nu, \quad \frac{d}{dt} e^i_\nu(q) = \Gamma_{\lambda\nu}^\mu \dot{q}^\lambda e^i_\mu, \quad (10.67)$$

this becomes

$$\frac{d}{dt} \delta^S q^\mu(t) = -\Gamma_{\lambda\nu}^\mu \delta^S q^\lambda \dot{q}^\nu + \Gamma_{\lambda\nu}^\mu \dot{q}^\lambda \bar{\delta} q^\nu + \frac{d}{dt} \bar{\delta} q^\mu. \quad (10.68)$$

It is useful to introduce the difference between the nonholonomic variation $\delta^S q^\mu$ and an auxiliary closed nonholonomic variation δq^μ :

$$\delta^S b^\mu \equiv \delta^S q^\mu - \bar{\delta} q^\mu. \quad (10.69)$$

Then we can rewrite (10.68) as a first-order differential equation for $\delta^S b^\mu$:

$$\frac{d}{dt}\delta^S b^\mu = -\Gamma_{\lambda\nu}{}^\mu \delta^S b^\lambda \dot{q}^\nu + 2S_{\lambda\nu}{}^\mu \dot{q}^\lambda \delta q^\nu. \quad (10.70)$$

After introducing the matrices

$$G^\mu{}_\lambda(t) \equiv \Gamma_{\lambda\nu}{}^\mu(q(t))\dot{q}^\nu(t) \quad (10.71)$$

and

$$\Sigma^\mu{}_\nu(t) \equiv 2S_{\lambda\nu}{}^\mu(q(t))\dot{q}^\lambda(t), \quad (10.72)$$

equation (10.70) can be written as a vector differential equation:

$$\frac{d}{dt}\delta^S b = -G\delta^S b + \Sigma(t) \delta q^\nu(t). \quad (10.73)$$

Although not necessary for the further development, we solve this equation by

$$\delta^S b(t) = \int_{t_a}^t dt' U(t, t') \Sigma(t') \delta q(t'), \quad (10.74)$$

with the matrix

$$U(t, t') = T \exp \left[- \int_{t'}^t dt'' G(t'') \right]. \quad (10.75)$$

In the absence of torsion, $\Sigma(t)$ vanishes identically and $\delta^S b(t) \equiv 0$, and the variations $\delta^S q^\mu(t)$ coincide with the auxiliary closed nonholonomic variations $\delta q^\mu(t)$ [see Fig. 10.3(b)]. In a space with torsion, the variations $\delta^S q^\mu(t)$ and $\delta q^\mu(t)$ are different from each other [see Fig. 10.3(c)].

Under an arbitrary nonholonomic variation $\delta^S q^\mu(t) = \delta q^\mu + \delta^S b^\mu$, the action (10.3) changes by

$$\delta^S \mathcal{A} = M \int_{t_a}^{t_b} dt \left(g_{\mu\nu} \dot{q}^\nu \delta^S \dot{q}^\mu + \frac{1}{2} \partial_\mu g_{\lambda\kappa} \delta^S q^\mu \dot{q}^\lambda \dot{q}^\kappa \right). \quad (10.76)$$

After a partial integration of the $\delta\dot{q}$ -term we use (10.65), (10.62), and the identity $\partial_\mu g_{\nu\lambda} \equiv \Gamma_{\mu\nu\lambda} + \Gamma_{\mu\lambda\nu}$, which follows directly from the definitions $g_{\mu\nu} \equiv e^i{}_\mu e^i{}_\nu$ and $\Gamma_{\mu\nu}{}^\lambda \equiv e_i{}^\lambda \partial_\mu e^i{}_\nu$, and obtain

$$\delta^S \mathcal{A} = M \int_{t_a}^{t_b} dt \left[-g_{\mu\nu} \left(\ddot{q}^\nu + \bar{\Gamma}_{\lambda\kappa}{}^\nu \dot{q}^\lambda \dot{q}^\kappa \right) \delta q^\mu + \left(g_{\mu\nu} \dot{q}^\nu \frac{d}{dt} \delta^S b^\mu + \Gamma_{\mu\lambda\kappa} \delta^S b^\mu \dot{q}^\lambda \dot{q}^\kappa \right) \right]. \quad (10.77)$$

To derive the equation of motion we first vary the action in a space without torsion. Then $\delta^S b^\mu(t) \equiv 0$, and (10.77) becomes

$$\delta^S \mathcal{A} = -M \int_{t_a}^{t_b} dt g_{\mu\nu} \left(\ddot{q}^\nu + \bar{\Gamma}_{\lambda\kappa}{}^\nu \dot{q}^\lambda \dot{q}^\kappa \right) \delta q^\nu. \quad (10.78)$$

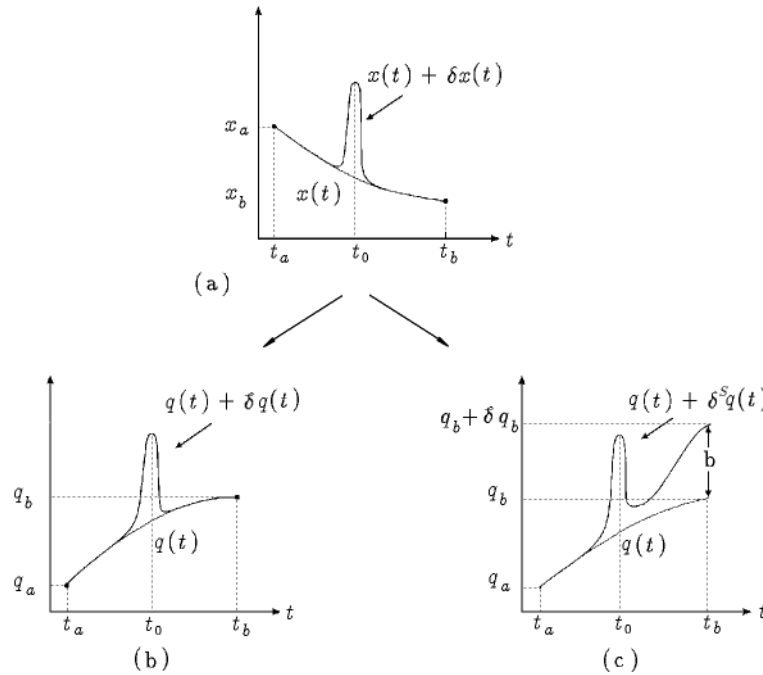

Figure 10.3 Images under holonomic and nonholonomic mapping of fundamental δ -function path variation. In the holonomic case, the paths $x(t)$ and $x(t) + \delta x(t)$ in (a) turn into the paths $q(t)$ and $q(t) + \delta q(t)$ in (b). In the nonholonomic case with $S_{\mu\nu}^\lambda \neq 0$, they go over into $q(t)$ and $q(t) + \delta^S q(t)$ shown in (c) with a closure failure b^μ at t_b analogous to the Burgers vector b^μ in a solid with dislocations.

Thus, the action principle $\delta^S \mathcal{A} = 0$ produces the equation for the geodesics (10.9), which are the correct particle trajectories in the absence of torsion.

In the presence of torsion, $\delta^S b^\mu$ is nonzero, and the equation of motion receives a contribution from the second parentheses in (10.77). After inserting (10.70), the nonlocal terms proportional to $\delta^S b^\mu$ cancel and the total nonholonomic variation of the action becomes

$$\begin{aligned} \delta^S \mathcal{A} &= -M \int_{t_a}^{t_b} dt g_{\mu\nu} \left[\ddot{q}^\nu + \left(\bar{\Gamma}_{\lambda\kappa}{}^\nu + 2S^\nu{}_{\lambda\kappa} \right) \dot{q}^\lambda \dot{q}^\kappa \right] \delta q^\mu \\ &= -M \int_{t_a}^{t_b} dt g_{\mu\nu} \left(\ddot{q}^\nu + \Gamma_{\lambda\kappa}{}^\nu \dot{q}^\lambda \dot{q}^\kappa \right) \delta q^\mu. \end{aligned} \quad (10.79)$$

The second line follows from the first after using the identity $\Gamma_{\lambda\kappa}{}^\nu = \bar{\Gamma}_{\{\lambda\kappa\}^\nu} + 2S^\nu{}_{\{\lambda\kappa\}}$. The curly brackets indicate the symmetrization of the enclosed indices. Setting $\delta^S \mathcal{A} = 0$ and inserting for $\delta q(t)$ the image under (10.64) of an arbitrary δ -function variation $\delta x^i(t) \propto \epsilon^i \delta(t - t_0)$ gives the autoparallel equations of motions (10.18), which is what we wanted to show.

The above variational treatment of the action is still somewhat complicated and calls for a simpler procedure [4]. The extra term arising from the second parenthesis in the variation (10.77) can be traced to a simple property of the auxiliary closed

nonholonomic variations (10.64). To find this we form the time derivative $d_t \equiv d/dt$ of the defining equation (10.64) and find

$$d_t \delta q^\mu(t) = \partial_\nu e_i^\mu(q(t)) \dot{q}^\nu(t) \delta x^i(t) + e_i^\mu(q(t)) d_t \delta x^i(t). \quad (10.80)$$

Let us now perform variation δ and t -derivative in the opposite order and calculate $d_t \delta q^\mu(t)$. From (10.59) and (10.13) we have the relation

$$d_t q^\lambda(t) = e_i^\lambda(q(t)) d_t x^i(t). \quad (10.81)$$

Varying this gives

$$\delta d_t q^\mu(t) = \partial_\nu e_i^\mu(q(t)) \delta q^\nu d_t x^i(t) + e_i^\mu(q(t)) \delta d_t x^i. \quad (10.82)$$

Since the variation in x^i -space commute with the t -derivatives [recall (10.63)], we obtain

$$\delta d_t q^\mu(t) - d_t \delta q^\mu(t) = \partial_\nu e_i^\mu(q(t)) \delta q^\nu d_t x^i(t) - \partial_\nu e_i^\mu(q(t)) \dot{q}^\nu(t) \delta x^i(t). \quad (10.83)$$

After re-expressing $\delta x^i(t)$ and $d_t x^i(t)$ back in terms of $\delta q^\mu(t)$ and $d_t q^\mu(t) = \dot{q}^\mu(t)$, and using (10.17), (10.24), this becomes

$$\delta d_t q^\mu(t) - d_t \delta q^\mu(t) = 2S_{\nu\lambda}{}^\mu \dot{q}^\nu(t) \delta q^\lambda(t). \quad (10.84)$$

Thus, due to the closure failure in spaces with torsion, the operations d_t and δ do not commute in front of the path $q^\mu(t)$. In other words, in contrast to the open variations δ^S (and of course the usual ones δ), the auxiliary closed nonholonomic variations δ of velocities $\dot{q}^\mu(t)$ no longer coincide with the velocities of variations. This property is responsible for shifting the trajectory from geodesics to autoparallels.

Indeed, let us vary an action

$$\mathcal{A} = \int_{t_1}^{t_2} dt L(q^\mu(t), \dot{q}^\mu(t)) \quad (10.85)$$

directly by $\delta q^\mu(t)$ and impose (10.84), we find

$$\delta \mathcal{A} = \int_{t_1}^{t_2} dt \left\{ \frac{\partial L}{\partial q^\mu} \delta q^\mu + \frac{\partial L}{\partial \dot{q}^\mu} \frac{d}{dt} \delta q^\mu + 2 S_{\nu\lambda}{}^\mu \dot{q}^\nu \delta q^\lambda \right\}. \quad (10.86)$$

After a partial integration of the second term using the vanishing $\delta q^\mu(t)$ at the endpoints, we obtain the Euler-Lagrange equation

$$\frac{\partial L}{\partial q^\mu} - \frac{d}{dt} \frac{\partial L}{\partial \dot{q}^\mu} = -2 S_{\mu\nu}{}^\lambda \dot{q}^\nu \frac{\partial L}{\partial \dot{q}^\lambda}. \quad (10.87)$$

This differs from the standard Euler-Lagrange equation by an additional contribution due to the torsion tensor. For the action (10.3), we thus obtain the equation of motion

$$M \left[\ddot{q}^\mu + g^{\mu\kappa} \left(\partial_\nu g_{\lambda\kappa} - \frac{1}{2} \partial_\kappa g_{\nu\lambda} \right) - 2 S_{\nu\lambda}{}^\mu \right] \dot{q}^\nu \dot{q}^\lambda = 0, \quad (10.88)$$

which is once more Eq. (10.18) for autoparallels.

10.3 Path Integral in Spaces with Curvature and Torsion

We now turn to the quantum mechanics of a point particle in a general metric-affine space. Proceeding in analogy with the earlier treatment in spherical coordinates, we first consider the path integral in a flat space with Cartesian coordinates

$$\langle \mathbf{x} t | \mathbf{x}' t' \rangle = \frac{1}{\sqrt{2\pi i \epsilon \hbar / M}^D} \prod_{n=1}^N \left[\int_{-\infty}^{\infty} dx_n \right] \prod_{n=1}^{N+1} K_0^\epsilon(\Delta \mathbf{x}_n), \quad (10.89)$$

where $K_0^\epsilon(\Delta \mathbf{x}_n)$ is an abbreviation for the short-time amplitude

$$K_0^\epsilon(\Delta \mathbf{x}_n) \equiv \langle \mathbf{x}_n | \exp \left(-\frac{i}{\hbar} \epsilon \hat{H} \right) | \mathbf{x}_{n-1} \rangle = \frac{1}{\sqrt{2\pi i \epsilon \hbar / M}^D} \exp \left[\frac{i}{\hbar} \frac{M}{2} \frac{(\Delta \mathbf{x}_n)^2}{\epsilon} \right], \quad (10.90)$$

with $\Delta \mathbf{x}_n \equiv \mathbf{x}_n - \mathbf{x}_{n-1}$, $\mathbf{x} \equiv \mathbf{x}_{N+1}$, $\mathbf{x}' \equiv \mathbf{x}_0$. A possible external potential has been omitted since this would contribute in an additive way, uninfluenced by the space geometry.

Our basic postulate is that the path integral in a general metric-affine space should be obtained by an appropriate nonholonomic transformation of the amplitude (10.89) to a space with curvature and torsion.

10.3.1 Nonholonomic Transformation of Action

The short-time action contains the square distance $(\Delta \mathbf{x}_n)^2$ which we have to transform to q -space. For an infinitesimal coordinate difference $\Delta \mathbf{x}_n \approx d\mathbf{x}_n$, the square distance is obviously given by $(d\mathbf{x})^2 = g_{\mu\nu} dq^\mu dq^\nu$. For a finite $\Delta \mathbf{x}_n$, however, we know from Chapter 8 that we must expand $(\Delta \mathbf{x}_n)^2$ up to the fourth order in $\Delta q_n^\mu = q_n^\mu - q_{n-1}^\mu$ to find all terms contributing to the relevant order ϵ .

It is important to realize that with the mapping from dx^i to dq^μ not being holonomic, the finite quantity Δq^μ is not uniquely determined by Δx^i . A unique relation can only be obtained by integrating the functional relation (10.60) along a specific path. The preferred path is the classical orbit, i.e., the autoparallel in the q -space. It is characterized by being the image of a straight line in x -space. There the velocity $\dot{x}^i(t)$ is constant, and the orbit has the linear time dependence

$$\Delta x^i(t) = \dot{x}^i(t_0) \Delta t, \quad (10.91)$$

where the time t_0 can lie anywhere on the t -axis. Let us choose for t_0 the final time in each interval (t_n, t_{n-1}) . At that time, $\dot{x}_n^i \equiv \dot{x}^i(t_n)$ is related to $\dot{q}_n^\mu \equiv \dot{q}^\mu(t_n)$ by

$$\dot{x}_n^i = e^i{}_\mu(q_n) \dot{q}_n^\mu. \quad (10.92)$$

It is easy to express \dot{q}_n^μ in terms of $\Delta q_n^\mu = q_n^\mu - q_{n-1}^\mu$ along the classical orbit. First we expand $q^\mu(t_{n-1})$ into a Taylor series around t_n . Dropping the time arguments, for brevity, we have

$$\Delta q \equiv q^\lambda - q'^\lambda = \epsilon \dot{q}^\lambda - \frac{\epsilon^2}{2!} \ddot{q}^\lambda + \frac{\epsilon^3}{3!} \overset{\cdot}{\ddot{q}}^\lambda + \dots, \quad (10.93)$$

where $\epsilon = t_n - t_{n-1}$ and $\dot{q}^\lambda, \ddot{q}^\lambda, \dots$ are the time derivatives at the final time t_n . An expansion of this type is referred to as a *postpoint expansion*. Due to the arbitrariness of the choice of the time t_0 in Eq. (10.92), the expansion can be performed around any other point just as well, such as t_{n-1} and $\bar{t}_n = (t_n + t_{n-1})/2$, giving rise to the so-called *prepoint* or *midpoint* expansions of Δq .

Now, the term \ddot{q}^λ in (10.93) is given by the equation of motion (10.18) for the autoparallel

$$\ddot{q}^\lambda = -\Gamma_{\mu\nu}{}^\lambda \dot{q}^\mu \dot{q}^\nu. \quad (10.94)$$

A further time derivative determines

$$\dot{\ddot{q}}^\lambda = -(\partial_\sigma \Gamma_{\mu\nu}{}^\lambda - 2\Gamma_{\mu\nu}{}^\tau \Gamma_{\{\sigma\tau\}}{}^\lambda) \dot{q}^\mu \dot{q}^\nu \dot{q}^\sigma. \quad (10.95)$$

Inserting these expressions into (10.93) and inverting the expansion, we obtain \dot{q}^λ at the final time t_n expanded in powers of Δq . Using (10.91) and (10.92) we arrive at the mapping of the finite coordinate differences:

$$\begin{aligned} \Delta x^i &= e^i{}_\lambda \dot{q}^\lambda \Delta t \\ &= e^i{}_\lambda \left[\Delta q^\lambda - \frac{1}{2!} \Gamma_{\mu\nu}{}^\lambda \Delta q^\mu \Delta q^\nu + \frac{1}{3!} \left(\partial_\sigma \Gamma_{\mu\nu}{}^\lambda + \Gamma_{\mu\nu}{}^\tau \Gamma_{\{\sigma\tau\}}{}^\lambda \right) \Delta q^\mu \Delta q^\nu \Delta q^\sigma + \dots \right], \end{aligned} \quad (10.96)$$

where $e^i{}_\lambda$ and $\Gamma_{\mu\nu}{}^\lambda$ are evaluated at the postpoint.

It is useful to introduce

$$\Delta \xi^\mu \equiv e_i{}^\mu \Delta x^i \quad (10.97)$$

as *autoparallel coordinates* or *normal coordinates* to parametrize the neighborhood of a point q . If the space has no torsion, they are also called *Riemann normal coordinates* or *geodesic coordinates*.

The normal coordinates (10.97) are expanded in (10.150) in powers of Δq^μ around the postpoint. There exists also a prepoint version of $\Delta \xi$ in which all signs of Δq are simply the opposite. The prepoint version, for instance, has the expansion:

$$\Delta \xi^\lambda = \Delta q^\lambda + \frac{1}{2!} \Gamma_{\mu\nu}{}^\lambda \Delta q^\mu \Delta q^\nu + \frac{1}{3!} \left(\partial_\sigma \Gamma_{\mu\nu}{}^\lambda + \Gamma_{\mu\nu}{}^\tau \Gamma_{\{\sigma\tau\}}{}^\lambda \right) \Delta q^\mu \Delta q^\nu \Delta q^\sigma + \dots \quad (10.98)$$

In contrast to the finite differences Δq^μ , the normal coordinates $\Delta \xi^\mu$ in the neighborhood of a point are vectors and thus allow for a *covariant Taylor expansion* of a function $f(q^\mu + \Delta q^\mu)$. Its form is found by performing an ordinary Taylor expansion of a function $F(x)$ in Cartesian coordinates

$$F(x + \Delta x) = F(x) + \partial_i F(x) \Delta x^i + \frac{1}{2!} \partial_i \partial_j F(x) \Delta x^i \Delta x^j + \dots, \quad (10.99)$$

and transforming this to coordinates q^μ . The function $F(x)$ becomes $f(q) = F(x(q))$, and the derivatives $\partial_{i_1} \partial_{i_2} \dots \partial_{i_n} f(x)$ go over into covariant derivatives:

$e_{i_1}{}^\mu e_{i_2}{}^\mu \cdots e_{i_n}{}^\mu D_{\mu_1} D_{\mu_2} \cdots D_{\mu_n} f(q)$. For instance, $\partial_i F(x) = e_i{}^\mu \partial_\mu f(q) = e_i{}^\mu D_\mu f(q)$, and

$$\begin{aligned} \partial_i \partial_j f(q) &= e_i{}^\mu \partial_\mu e_j{}^\nu \partial_\nu f(q) = [e_i{}^\mu e_j{}^\nu \partial_\mu \partial_\nu + e_i{}^\mu (\partial_\mu e_j{}^\nu) \partial_\nu] f(q) \\ &= e_i{}^\mu e_j{}^\nu [\partial_\mu \partial_\nu - \Gamma_{\mu\nu}{}^\lambda \partial_\lambda] f(q) = e_i{}^\mu e_j{}^\nu D_\mu \partial_\nu f(q) = e_i{}^\mu e_j{}^\nu D_\mu D_\nu f(q), \end{aligned} \quad (10.100)$$

where we have used (10.17) to express $\partial_\mu e_j{}^\nu = -\Gamma_{\mu\sigma}{}^\nu e_j{}^\sigma$, and changed dummy indices. The differences Δx^i in (10.99) are replaced by $e^i{}_\mu \Delta \xi^\mu$ with the prepoint expansion (10.98). In this way we arrive at the covariant Taylor expansion

$$f(q + \Delta q) = F(x) + D_\mu f(q) \Delta \xi^\mu + \frac{1}{2!} D_\mu D_\nu f(q) \Delta \xi^\mu \Delta \xi^\nu + \dots \quad (10.101)$$

Indeed, re-expanding the right-hand side in powers of Δq^μ via (10.98) we may verify that the affine connections cancel against those in the covariant derivatives of $f(q)$, so that (10.101) reduces to the ordinary Taylor expansion of $f(q + \Delta q)$ in powers of Δq .

Note that the expansion (10.96) differs only slightly from a naive Taylor expansion of the difference around the postpoint:

$$\Delta x^i = x^i(q) - x^i(q - \Delta q) = e^i{}_\lambda \Delta q^\lambda - \frac{1}{2} e^i{}_{\nu,\mu} \Delta q^\mu \Delta q^\nu + \frac{1}{3!} e^i{}_{\nu,\mu\sigma} \Delta q^\mu \Delta q^\nu \Delta q^\sigma + \dots, \quad (10.102)$$

where a subscript λ separated by a comma denotes the partial derivative $\partial_\lambda = \partial/\partial q^\lambda$, i.e., $f_{,\lambda} \equiv \partial_\lambda f$. The right-hand side can be rewritten with the help of the completeness relation (10.13) as

$$\Delta x^i = e^i{}_\lambda \left[\Delta q^\lambda - \frac{1}{2} e_j{}^\lambda e^j{}_{\nu,\mu} \Delta q^\mu \Delta q^\nu + \frac{1}{3!} e_j{}^\lambda e^j{}_{\nu,\mu\sigma} \Delta q^\mu \Delta q^\nu \Delta q^\sigma + \dots \right]. \quad (10.103)$$

The expansion coefficients can be expressed in terms of the affine connection (10.16), using the derived relation

$$e_i{}^\lambda e^i{}_{\nu,\mu\sigma} = \partial_\sigma (e_i{}^\lambda e^i{}_{\nu,\mu}) - e^{i\tau} e^i{}_{\nu,\mu} e^j{}_\tau e^{j\lambda}{}_{,\sigma} = \partial_\sigma \Gamma_{\mu\nu}{}^\lambda + \Gamma_{\mu\nu}{}^\tau \Gamma_{\sigma\tau}{}^\lambda. \quad (10.104)$$

Thus we obtain

$$\Delta x^i = e^i{}_\lambda \left[\Delta q^\lambda - \frac{1}{2!} \Gamma_{\mu\nu}{}^\lambda \Delta q^\mu \Delta q^\nu + \frac{1}{3!} (\partial_\sigma \Gamma_{\mu\nu}{}^\lambda + \Gamma_{\mu\nu}{}^\tau \Gamma_{\sigma\tau}{}^\lambda) \Delta q^\mu \Delta q^\nu \Delta q^\sigma + \dots \right]. \quad (10.105)$$

This differs from the true expansion (10.150) only by the absence of the symmetrization of the indices in the last affine connection.

Inserting (10.96) into the short-time amplitude (10.90), we obtain

$$K_0^\xi(\Delta \mathbf{x}) = \langle \mathbf{x} | \left(-\frac{i}{\hbar} \epsilon \hat{H} \right) | \mathbf{x} - \Delta \mathbf{x} \rangle = \frac{1}{\sqrt{2\pi i \epsilon \hbar / M}} e^{i\mathcal{A}_\xi(q, q - \Delta q) / \hbar}, \quad (10.106)$$

with the short-time postpoint action

$$\begin{aligned} \mathcal{A}_{>}^\epsilon(q, q - \Delta q) &= (\Delta x^i)^2 = \epsilon \frac{M}{2} g_{\mu\nu} \dot{q}^\mu \dot{q}^\nu \\ &= \frac{M}{2\epsilon} \left\{ g_{\mu\nu} \Delta q^\mu \Delta q^\nu - \Gamma_{\mu\nu\lambda} \Delta q^\mu \Delta q^\nu \Delta q^\lambda \right. \\ &\quad \left. + \left[\frac{1}{3} g_{\mu\tau} \left(\partial_\kappa \Gamma_{\lambda\nu}{}^\tau + \Gamma_{\lambda\nu}{}^\delta \Gamma_{\{\kappa\delta\}}{}^\tau \right) + \frac{1}{4} \Gamma_{\lambda\kappa}{}^\sigma \Gamma_{\mu\nu\sigma} \right] \Delta q^\mu \Delta q^\nu \Delta q^\lambda \Delta q^\kappa + \dots \right\}. \end{aligned} \quad (10.107)$$

Separating the affine connection into Christoffel symbol and torsion, this can also be written as

$$\begin{aligned} \mathcal{A}_{>}^\epsilon(q, q - \Delta q) &= \frac{M}{2\epsilon} \left\{ g_{\mu\nu} \Delta q^\mu \Delta q^\nu - \bar{\Gamma}_{\mu\nu\lambda} \Delta q^\mu \Delta q^\nu \Delta q^\lambda \right. \\ &\quad \left. + \left[\frac{1}{3} g_{\mu\tau} \left(\partial_\kappa \bar{\Gamma}_{\lambda\nu}{}^\tau + \bar{\Gamma}_{\lambda\nu}{}^\delta \bar{\Gamma}_{\delta\kappa}{}^\tau \right) + \frac{1}{4} \bar{\Gamma}_{\lambda\kappa}{}^\sigma \bar{\Gamma}_{\mu\nu\sigma} + \frac{1}{3} S^\sigma{}_{\lambda\kappa} S_{\sigma\mu\nu} \right] \Delta q^\mu \Delta q^\nu \Delta q^\lambda \Delta q^\kappa + \dots \right\}. \end{aligned} \quad (10.108)$$

Note that in contrast to the formulas for the short-time action derived in Chapter 8, the right-hand side contains only *intrinsic* quantities of q -space. For the systems treated there (which all lived in a Euclidean space parametrized with curvilinear coordinates), the present intrinsic result reduces to the previous one.

Take, for example, a two-dimensional Euclidean space parametrized by radial coordinates treated in Section 8.1. The postpoint expansion (10.96) reads for the components r, ϕ of \dot{q}^λ

$$\dot{r} = \frac{\Delta r}{\epsilon} + \frac{r(\Delta\phi)^2}{2\epsilon} - \frac{\Delta r(\Delta\phi)^2}{\epsilon} + \dots, \quad (10.109)$$

$$\dot{\phi} = \frac{\Delta\phi}{\epsilon} - \frac{\Delta r \Delta\phi}{\epsilon r} - \frac{(\Delta\phi)^3}{6\epsilon} + \dots. \quad (10.110)$$

Inserting these into the short-time action which is here simply

$$\mathcal{A}^\epsilon = \frac{M}{2} \epsilon (\dot{r}^2 + r^2 \dot{\phi}^2), \quad (10.111)$$

we find the time-sliced action

$$\mathcal{A}^\epsilon = \frac{M}{2\epsilon} \left[\Delta r^2 + r^2 (\Delta\phi)^2 - r \Delta r (\Delta\phi)^2 - \frac{1}{12} r^2 (\Delta\phi)^4 + \dots \right]. \quad (10.112)$$

A symmetrization of the postpoint expressions using the fact that r^2 stands for

$$r_n^2 = r_n (r_{n-1} + \Delta r_n), \quad (10.113)$$

leads to the short-time action displaying the subscripts n

$$\mathcal{A}^\epsilon = \frac{M}{2\epsilon} \left[\Delta r_n^2 + r_n r_{n-1} (\Delta\phi_n)^2 - \frac{1}{12} r_n r_{n-1} (\Delta\phi_n)^4 + \dots \right]. \quad (10.114)$$

This agrees with the previous expansion of the time-sliced action in Eq. (8.53). While the previous result was obtained from a transformation of the time-sliced

Euclidean action to radial coordinates, the short-time action here is found from a purely intrinsic formulation. The intrinsic method has the obvious advantage of not being restricted to a Euclidean initial space and therefore has the chance of being true in an arbitrary metric-affine space.

At this point we observe that the final short-time action (10.107) could also have been introduced without any reference to the flat reference coordinates x^i . Indeed, the same action is obtained by evaluating the continuous action (10.3) for the small time interval $\Delta t = \epsilon$ along the classical orbit between the points q_{n-1} and q_n . Due to the equations of motion (10.18), the Lagrangian

$$L(q, \dot{q}) = \frac{M}{2} g_{\mu\nu}(q(t)) \dot{q}^\mu(t) \dot{q}^\nu(t) \quad (10.115)$$

is independent of time (this is true for autoparallels as well as geodesics). The short-time action

$$\mathcal{A}^\epsilon(q, q') = \frac{M}{2} \int_{t-\epsilon}^t dt g_{\mu\nu}(q(t)) \dot{q}^\mu(t) \dot{q}^\nu(t) \quad (10.116)$$

can therefore be written in either of the three forms

$$\mathcal{A}^\epsilon = \frac{M}{2} \epsilon g_{\mu\nu}(q) \dot{q}^\mu \dot{q}^\nu = \frac{M}{2} \epsilon g_{\mu\nu}(q') \dot{q}'^\mu \dot{q}'^\nu = \frac{M}{2} \epsilon g_{\mu\nu}(\bar{q}) \dot{\bar{q}}^\mu \dot{\bar{q}}^\nu, \quad (10.117)$$

where $q^\mu, q'^\mu, \bar{q}^\mu$ are the coordinates at the final time t_n , the initial time t_{n-1} , and the average time $(t_n + t_{n-1})/2$, respectively. The first expression obviously coincides with (10.107). The others can be used as a starting point for deriving equivalent prepoint or midpoint actions. The prepoint action $\mathcal{A}_<^\epsilon$ arises from the postpoint one $\mathcal{A}_>^\epsilon$ by exchanging Δq by $-\Delta q$ and the postpoint coefficients by the prepoint ones. The midpoint action has the most simple-looking appearance:

$$\begin{aligned} \bar{\mathcal{A}}^\epsilon(\bar{q} + \frac{\Delta q}{2}, \bar{q} - \frac{\Delta q}{2}) = & \quad (10.118) \\ \frac{M}{2\epsilon} \left[g_{\mu\nu}(\bar{q}) \Delta q^\mu \Delta q^\nu + \frac{1}{12} g_{\kappa\tau} \left(\partial_\lambda \Gamma_{\mu\nu}{}^\tau + \Gamma_{\mu\nu}{}^\delta \Gamma_{\{\lambda\delta\}{}^\tau} \right) \Delta q^\mu \Delta q^\nu \Delta q^\lambda \Delta q^\kappa + \dots \right], \end{aligned}$$

where the affine connection can be evaluated at any point in the interval (t_{n-1}, t_n) . The precise position is irrelevant to the amplitude, producing changes only in higher than the relevant orders of ϵ .

We have found the postpoint action most useful since it gives ready access to the time evolution of amplitudes, as will be seen below. The prepoint action is completely equivalent to it and useful if one wants to describe the time evolution backwards. Some authors favor the midpoint action because of its symmetry and the absence of cubic terms in Δq^μ in the expression (10.118).

The different completely equivalent ‘‘anypoint’’ formulations of the same short-time action, which is *universally defined* by the nonholonomic mapping procedure, must be distinguished from various so-called time-slicing ‘‘prescriptions’’ found in

the literature when setting up a lattice approximation to the Lagrangian (10.115). There, a *midpoint prescription* is often favored, in which one approximates L by

$$L(q, \dot{q}) \rightarrow L^\epsilon(q, \Delta q/\epsilon) = \frac{M}{2\epsilon^2} g_{\mu\nu}(\bar{q}) \Delta q^\mu(t) \Delta q^\nu(t), \quad (10.119)$$

and uses the associated short-time action

$$\bar{\mathcal{A}}_{\text{mpp}}^\epsilon = \epsilon L^\epsilon(q, \Delta q/\epsilon) \quad (10.120)$$

in the exponent of the path integrand. The motivation for this prescription lies in the popularity of H. Weyl's ordering prescription for products of position and momenta in operator quantum mechanics. From the discussion in Section 1.13 we know, however, that the Weyl prescription for the operator order in the kinetic energy $g^{\mu\nu}(\hat{q})\hat{p}_\mu\hat{p}_\nu/2M$ does not lead to the correct Laplace-Beltrami operator in general coordinates. The discussion in this section, on the other hand, will show that the Weyl-ordered action (10.120) differs from the midpoint form (10.118) of the correct short-time action by an additional forth-order term in Δq^μ , implying that the short-time action $\bar{\mathcal{A}}_{\text{mpp}}^\epsilon$ does not lead to the correct physics. Worse shortcomings are found when slicing the short-time action following a pre- or postpoint prescription. There is, in fact, no freedom of choice of different slicing prescriptions, in contrast to ubiquitous statements in the literature. The short-time action is completely fixed as being the unique nonholonomic image of the Euclidean time-sliced action. This also solves uniquely the operator-ordering problem which has plagued theorists for many decades.

In the following, the action \mathcal{A}^ϵ without subscript will always denote the preferred postpoint expression (10.107):

$$\mathcal{A}^\epsilon \equiv \mathcal{A}_>^\epsilon(q, q - \Delta q). \quad (10.121)$$

10.3.2 Measure of Path Integration

We now turn to the integration measure in the Cartesian path integral (10.89)

$$\frac{1}{\sqrt{2\pi i\epsilon\hbar/M}^D} \prod_{n=1}^N d^D x_n.$$

This has to be transformed to the general metric-affine space. We imagine evaluating the path integral starting out from the latest time and performing successively the integrations over x_N, x_{N-1}, \dots , i.e., in each short-time amplitude we integrate over the earlier position coordinate, the prepoint coordinate. For the purpose of this discussion, we relabel the product $\prod_{n=1}^N d^D x_n^i$ by $\prod_{n=2}^{N+1} dx_{n-1}^i$, so that the integration in each time slice (t_n, t_{n-1}) with $n = N+1, N, \dots$ runs over dx_{n-1}^i .

In a flat space parametrized with curvilinear coordinates, the transformation of the integrals over $d^D x_{n-1}^i$ into those over $d^D q_{n-1}^\mu$ is obvious:

$$\prod_{n=2}^{N+1} \int d^D x_{n-1}^i = \prod_{n=2}^{N+1} \left\{ \int d^D q_{n-1}^\mu \det [e_\mu^i(q_{n-1})] \right\}. \quad (10.122)$$

The determinant of $e^i{}_\mu$ is the square root of the determinant of the metric $g_{\mu\nu}$:

$$\det(e^i{}_\mu) = \sqrt{\det g_{\mu\nu}(q)} \equiv \sqrt{g(q)}, \quad (10.123)$$

and the measure may be rewritten as

$$\prod_{n=2}^{N+1} \int d^D x_{n-1}^i = \prod_{n=2}^{N+1} \left[\int d^D q_{n-1}^\mu \sqrt{g(q_{n-1})} \right]. \quad (10.124)$$

This expression is not directly applicable. When trying to do the $d^D q_{n-1}^\mu$ -integrations successively, starting from the final integration over dq_N^μ , the integration variable q_{n-1} appears for each n in the argument of $\det[e^i{}_\mu(q_{n-1})]$ or $g_{\mu\nu}(q_{n-1})$. To make this q_{n-1} -dependence explicit, we expand in the measure (10.122) $e^i{}_\mu(q_{n-1}) = e^i{}_\mu(q_n - \Delta q_n)$ around the postpoint q_n into powers of Δq_n . This gives

$$dx^i = e^i{}_\mu(q - \Delta q) dq^\mu = e^i{}_\mu dq^\mu - e^i{}_{\mu,\nu} dq^\mu \Delta q^\nu + \frac{1}{2} e^i{}_{\mu,\nu\lambda} dq^\mu \Delta q^\nu \Delta q^\lambda + \dots \quad (10.125)$$

omitting, as before, the subscripts of q_n and Δq_n . Thus the Jacobian of the coordinate transformation from dx^i to dq^μ is

$$J_0 = \det(e^i{}_\kappa) \det \left[\delta^\kappa{}_\mu - e^i{}_{\mu,\nu} \Delta q^\nu + \frac{1}{2} e^i{}_{\mu,\nu\lambda} \Delta q^\nu \Delta q^\lambda \right], \quad (10.126)$$

giving the relation between the infinitesimal integration volumes $d^D x^i$ and $d^D q^\mu$:

$$\prod_{n=2}^{N+1} \int d^D x_{n-1}^i = \prod_{n=2}^{N+1} \left\{ \int d^D q_{n-1}^\mu J_{0n} \right\}. \quad (10.127)$$

The well-known expansion formula

$$\det(1 + B) = \exp \operatorname{tr} \log(1 + B) = \exp \operatorname{tr} (B - B^2/2 + B^3/3 - \dots) \quad (10.128)$$

allows us now to rewrite J_0 as

$$J_0 = \det(e^i{}_\kappa) \exp \left(\frac{i}{\hbar} \mathcal{A}_{J_0}^\epsilon \right), \quad (10.129)$$

with the determinant $\det(e^i{}_\mu) = \sqrt{g(q)}$ evaluated at the postpoint. This equation defines an effective action associated with the Jacobian, for which we obtain the expansion

$$\frac{i}{\hbar} \mathcal{A}_{J_0}^\epsilon = -e^i{}_\kappa e^i{}_{\kappa,\mu} \Delta q^\mu + \frac{1}{2} \left[e^i{}_\mu e^i{}_{\mu,\nu\lambda} - e^i{}_\mu e^i{}_{\kappa,\nu} e^j{}_\kappa e^j{}_{\mu,\lambda} \right] \Delta q^\nu \Delta q^\lambda + \dots \quad (10.130)$$

The expansion coefficients are expressed in terms of the affine connection (10.16) using the relations:

$$e_{i\nu,\mu} e^i{}_{\kappa,\lambda} = e_i{}^\sigma e^i{}_{\nu,\mu} e_{j\sigma} e^j{}_{\kappa,\lambda} = \Gamma_{\mu\nu}{}^\sigma \Gamma_{\lambda\kappa\sigma} \quad (10.131)$$

$$\begin{aligned} e_{i\mu} e^i{}_{\nu,\lambda\kappa} &= g_{\mu\tau} [\partial_\kappa (e_i{}^\tau e^i{}_{\nu,\lambda}) - e^{i\sigma} e^i{}_{\nu,\lambda} e^j{}_\sigma e^j{}_{\tau,\kappa}] \\ &= g_{\mu\tau} (\partial_\kappa \Gamma_{\lambda\nu}{}^\tau + \Gamma_{\lambda\nu}{}^\sigma \Gamma_{\kappa\sigma}{}^\tau). \end{aligned} \quad (10.132)$$

The Jacobian action becomes therefore:

$$\frac{i}{\hbar} \mathcal{A}_{J_0}^\epsilon = -\Gamma_{\mu\nu}{}^\nu \Delta q^\mu + \frac{1}{2} \partial_\mu \Gamma_{\nu\kappa}{}^\kappa \Delta q^\nu \Delta q^\mu + \dots \quad (10.133)$$

The same result would, incidentally, be obtained by writing the Jacobian in accordance with (10.124) as

$$J_0 = \sqrt{g(q - \Delta q)}, \quad (10.134)$$

which leads to the alternative formula for the Jacobian action

$$\exp\left(\frac{i}{\hbar} \mathcal{A}_{J_0}^\epsilon\right) = \frac{\sqrt{g(q - \Delta q)}}{\sqrt{g(q)}}. \quad (10.135)$$

An expansion in powers of Δq gives

$$\exp\left(\frac{i}{\hbar} \mathcal{A}_{J_0}^\epsilon\right) = 1 - \frac{1}{\sqrt{g(q)}} \sqrt{g(q)}_{,\mu} \Delta q^\mu + \frac{1}{2\sqrt{g(q)}} \sqrt{g(q)}_{,\mu\nu} \Delta q^\mu \Delta q^\nu + \dots \quad (10.136)$$

Using the formula

$$\frac{1}{\sqrt{g}} \partial_\mu \sqrt{g} = \frac{1}{2} g^{\sigma\tau} \partial_\mu g_{\sigma\tau} = \bar{\Gamma}_{\mu\nu}{}^\nu, \quad (10.137)$$

this becomes

$$\exp\left(\frac{i}{\hbar} \mathcal{A}_{J_0}^\epsilon\right) = 1 - \bar{\Gamma}_{\mu\nu}{}^\nu \Delta q^\mu + \frac{1}{2} (\partial_\mu \bar{\Gamma}_{\nu\lambda}{}^\lambda + \bar{\Gamma}_{\mu\sigma}{}^\sigma \bar{\Gamma}_{\nu\lambda}{}^\lambda) \Delta q^\mu \Delta q^\nu + \dots, \quad (10.138)$$

so that

$$\frac{i}{\hbar} \mathcal{A}_{J_0}^\epsilon = -\bar{\Gamma}_{\mu\nu}{}^\nu \Delta q^\mu + \frac{1}{2} \partial_\mu \bar{\Gamma}_{\nu\lambda}{}^\lambda \Delta q^\mu \Delta q^\nu + \dots \quad (10.139)$$

In a space without torsion where $\bar{\Gamma}_{\mu\nu}{}^\lambda \equiv \Gamma_{\mu\nu}{}^\lambda$, the Jacobian actions (10.133) and (10.139) are trivially equal to each other. But the equality holds also in the presence of torsion. Indeed, when inserting the decomposition (10.27), $\Gamma_{\mu\nu}{}^\lambda = \bar{\Gamma}_{\mu\nu}{}^\lambda + K_{\mu\nu}{}^\lambda$, into (10.133), the contortion tensor drops out since it is antisymmetric in the last two indices and these are contracted in both expressions.

In terms of $\mathcal{A}_{J_{0n}}^\epsilon$, we can rewrite the transformed measure (10.122) in the more useful form

$$\prod_{n=2}^{N+1} \int d^D x_{n-1}^i = \prod_{n=2}^{N+1} \left\{ \int d^D q_{n-1}^\mu \det [e_\mu^i(q_n)] \exp\left(\frac{i}{\hbar} \mathcal{A}_{J_{0n}}^\epsilon\right) \right\}. \quad (10.140)$$

In a flat space parametrized in terms of curvilinear coordinates, the right-hand sides of (10.122) and (10.140) are related by an ordinary coordinate transformation, and both give the correct measure for a time-sliced path integral. In a general

metric-affine space, however, this is no longer true. Since the mapping $dx^i \rightarrow dq^\mu$ is nonholonomic, there are in principle infinitely many ways of transforming the path integral measure from Cartesian coordinates to a non-Euclidean space. Among these, there exists a preferred mapping which leads to the correct quantum-mechanical amplitude in all known physical systems. This will serve to solve the path integral of the Coulomb system in Chapter 13.

The clue for finding the correct mapping is offered by an unaesthetic feature of Eq. (10.125): The expansion contains both differentials dq^μ and differences Δq^μ . This is somehow inconsistent. When time-slicing the path integral, the differentials dq^μ in the action are increased to finite differences Δq^μ . Consequently, the differentials in the measure should also become differences. A relation such as (10.125) containing simultaneously differences and differentials should not occur.

It is easy to achieve this goal by changing the starting point of the nonholonomic mapping and rewriting the initial flat space path integral (10.89) as

$$(\mathbf{x} \ t | \mathbf{x}' t') = \frac{1}{\sqrt{2\pi i \epsilon \hbar / M}^D} \prod_{n=1}^N \left[\int_{-\infty}^{\infty} d\Delta x_n \right] \prod_{n=1}^{N+1} K_0^\epsilon(\Delta \mathbf{x}_n). \quad (10.141)$$

Since x_n are Cartesian coordinates, the measures of integration in the time-sliced expressions (10.89) and (10.141) are certainly identical:

$$\prod_{n=1}^N \int d^D x_n \equiv \prod_{n=2}^{N+1} \int d^D \Delta x_n. \quad (10.142)$$

Their images under a nonholonomic mapping, however, are different so that the initial form of the time-sliced path integral is a matter of choice. The initial form (10.141) has the obvious advantage that the integration variables are precisely the quantities Δx_n^i which occur in the short-time amplitude $K_0^\epsilon(\Delta x_n)$.

Under a nonholonomic transformation, the right-hand side of Eq. (10.142) leads to the integral measure in a general metric-affine space

$$\prod_{n=2}^{N+1} \int d^D \Delta x_n \rightarrow \prod_{n=2}^{N+1} \left[\int d^D \Delta q_n J_n \right], \quad (10.143)$$

with the Jacobian following from (10.96) (omitting n)

$$J = \frac{\partial(\Delta x)}{\partial(\Delta q)} = \det(e^i{}_\kappa) \det \left[\delta_\mu{}^\lambda - \Gamma_{\{\mu\nu\}}{}^\lambda \Delta q^\nu + \frac{1}{2} \left(\partial_{\{\sigma} \Gamma_{\mu\nu\}}{}^\lambda + \Gamma_{\{\mu\nu}{}^\tau \Gamma_{\{\tau\sigma\}}{}^\lambda \right) \Delta q^\nu \Delta q^\sigma + \dots \right]. \quad (10.144)$$

In a space with curvature and torsion, the measure on the right-hand side of (10.143) replaces the flat-space measure on the right-hand side of (10.124). The curly double brackets around the indices ν, κ, σ, μ indicate a symmetrization in τ and σ followed

by a symmetrization in μ, ν , and σ . With the help of formula (10.128) we now calculate the Jacobian action

$$\frac{i}{\hbar} \mathcal{A}_J^\epsilon = -\Gamma_{\{\mu\nu\}}^\mu \Delta q^\nu + \frac{1}{2} \left[\partial_{\{\mu\}} \Gamma_{\nu\kappa}^\kappa + \Gamma_{\{\nu\kappa\}}^\sigma \Gamma_{\{\sigma|\mu\}}^\kappa - \Gamma_{\{\nu\kappa\}}^\sigma \Gamma_{\{\sigma\mu\}}^\kappa \right] \Delta q^\nu \Delta q^\mu + \dots \quad (10.145)$$

This expression differs from the earlier Jacobian action (10.133) by the symmetrization symbols. Dropping them, the two expressions coincide. This is allowed if q^μ are curvilinear coordinates in a flat space. Since then the transformation functions $x^i(q)$ and their first derivatives $\partial_\mu x^i(q)$ are integrable and possess commuting derivatives, the two Jacobian actions (10.133) and (10.145) are identical.

There is a further good reason for choosing (10.142) as a starting point for the nonholonomic transformation of the measure. According to Huygens' principle of wave optics, each point of a wave front is a center of a new spherical wave propagating from that point. Therefore, in a time-sliced path integral, the differences Δx_n^i play a more fundamental role than the coordinates themselves. Intimately related to this is the observation that in the canonical form, a short-time piece of the action reads

$$\int \frac{dp_n}{2\pi\hbar} \exp \left[\frac{i}{\hbar} p_n (x_n - x_{n-1}) - \frac{ip_n^2}{2M\hbar} t \right].$$

Each momentum is associated with a coordinate difference $\Delta x_n \equiv x_n - x_{n-1}$. Thus, we should expect the spatial integrations conjugate to p_n to run over the coordinate differences $\Delta x_n = x_n - x_{n-1}$ rather than the coordinates x_n themselves, which makes the important difference in the subsequent nonholonomic coordinate transformation.

We are thus led to postulate the following time-sliced path integral in q -space:

$$\langle q | e^{-i(t-t')\hat{H}/\hbar} | q' \rangle = \frac{1}{\sqrt{2\pi i \hbar \epsilon / M}^D} \prod_{n=2}^{N+1} \left[\int d^D \Delta q_n \frac{\sqrt{g(q_n)}}{\sqrt{2\pi i \epsilon \hbar / M}^D} \right] e^{i \sum_{n=1}^{N+1} (\mathcal{A}^\epsilon + \mathcal{A}_J^\epsilon) / \hbar}, \quad (10.146)$$

where the integrals over Δq_n may be performed successively from $n = N$ down to $n = 1$.

Let us emphasize that this expression has not been *derived* from the flat space path integral. It is the result of a specific new *quantum equivalence principle* which rules how a flat space path integral behaves under nonholonomic coordinate transformations.

It is useful to re-express our result in a different form which clarifies best the relation with the naively expected measure of path integration (10.124), the product of integrals

$$\prod_{n=1}^N \int d^D x_n = \prod_{n=1}^N \left[\int d^D q_n \sqrt{g(q_n)} \right]. \quad (10.147)$$

The measure in (10.146) can be expressed in terms of (10.147) as

$$\prod_{n=2}^{N+1} \left[\int d^D \Delta q_n \sqrt{g(q_n)} \right] = \prod_{n=1}^N \left[\int d^D q_n \sqrt{g(q_n)} e^{-i\mathcal{A}_{J_0}^\epsilon/\hbar} \right]. \quad (10.148)$$

The corresponding expression for the entire time-sliced path integral (10.146) in the metric-affine space reads

$$\langle q | e^{-i(t-t')\hat{H}/\hbar} | q' \rangle = \frac{1}{\sqrt{2\pi i\hbar\epsilon/M}^D} \prod_{n=1}^N \left[\int d^D q_n \frac{\sqrt{g(q_n)}}{\sqrt{2\pi i\hbar\epsilon/M}^D} \right] e^{i\sum_{n=1}^{N+1} (\mathcal{A}^\epsilon + \Delta\mathcal{A}_J^\epsilon)/\hbar}, \quad (10.149)$$

where $\Delta\mathcal{A}_J^\epsilon$ is the difference between the correct and the wrong Jacobian actions in Eqs. (10.133) and (10.145):

$$\Delta\mathcal{A}_J^\epsilon \equiv \mathcal{A}_J^\epsilon - \mathcal{A}_{J_0}^\epsilon. \quad (10.150)$$

In the absence of torsion where $\Gamma_{\{\mu\nu\}}^\lambda = \bar{\Gamma}_{\mu\nu}^\lambda$, this simplifies to

$$\frac{i}{\hbar} \Delta\mathcal{A}_J^\epsilon = \frac{1}{6} \bar{R}_{\mu\nu} \Delta q^\mu \Delta q^\nu, \quad (10.151)$$

where $\bar{R}_{\mu\nu}$ is the Ricci tensor associated with the Riemann curvature tensor, i.e., the contraction (10.41) of the Riemann curvature tensor associated with the Christoffel symbol $\bar{\Gamma}_{\mu\nu}^\lambda$.

Being quadratic in Δq , the effect of the additional action can easily be evaluated perturbatively using the methods explained in Chapter 8, according to which $\Delta q^\mu \Delta q^\nu$ may be replaced by its lowest order expectation

$$\langle \Delta q^\mu \Delta q^\nu \rangle_0 = i\epsilon\hbar g^{\mu\nu}(q)/M.$$

Then $\Delta\mathcal{A}_J^\epsilon$ yields the additional effective potential

$$V_{\text{eff}}(q) = -\frac{\hbar^2}{6M} \bar{R}(q), \quad (10.152)$$

where \bar{R} is the Riemann curvature scalar. By including this potential in the action, the path integral in a curved space can be written down in the naive form (10.147) as follows:

$$\langle q | e^{-i(t-t')\hat{H}/\hbar} | q' \rangle = \frac{1}{\sqrt{2\pi i\hbar\epsilon/M}^D} \prod_{n=1}^N \left[\int d^D q_n \frac{\sqrt{g(q_n)}}{\sqrt{2\pi i\hbar\epsilon/M}^D} e^{i\hbar R(q_n)/6M} \right] e^{i\sum_{n=1}^{N+1} \mathcal{A}^\epsilon[q_n]/\hbar}. \quad (10.153)$$

This time-sliced expression will from now on be the definition of a path integral in curved space written in the continuum notation as

$$\langle q | e^{-i(t-t')\hat{H}/\hbar} | q' \rangle = \int \mathcal{D}^D q \sqrt{g(q)} e^{i\int_{t_a}^{t_b} dt \mathcal{A}[q]/\hbar}. \quad (10.154)$$

The integrals over q_n in (10.153) are conveniently performed successively downwards over $\Delta q_{n+1} = q_{n+1} - q_n$ at fixed q_{n+1} . The weights $\sqrt{g(q_n)} = \sqrt{g(q_{n+1} - \Delta q_{n+1})}$ require a postpoint expansion leading to the naive Jacobian J_0 of (10.126) and the Jacobian action $\mathcal{A}_{J_0}^\epsilon$ of Eq. (10.133).

It is important to observe that the above time-sliced definition is automatically invariant under coordinate transformations. This is an immediate consequence of the definition via the nonholonomic mapping from a flat-space path integral.

It goes without saying that the path integral (10.153) also has a phase space version. It is obtained by omitting all $(M/2\epsilon)(\Delta q_n)^2$ terms in the short-time actions \mathcal{A}^ϵ and extending the multiple integral by the product of momentum integrals

$$\prod_{n=1}^{N+1} \left[\frac{dp_n}{2\pi\hbar\sqrt{g(q_n)}} \right] e^{(i/\hbar) \sum_{n=1}^{N+1} [p_{n\mu} \Delta q^\mu - \epsilon \frac{1}{2M} g^{\mu\nu}(q_n) p_{n\mu} p_{n\nu}]}. \quad (10.155)$$

When using this expression, all problems which were encountered in the literature with canonical transformations of path integrals disappear.

An important property of the definition of the path integral in spaces with curvature and torsion as a nonholonomic image of a Euclidean path integral is that this image is automatically invariant under ordinary holonomic coordinate transformations.

10.4 Completing the Solution of Path Integral on Surface of Sphere in D Dimensions

The measure of path integration in Eq. (10.146) allows us to finally complete the calculation, initiated in Sections 8.7–8.9, of the path integrals of a point particle on the surface of a sphere on group spaces in any number of dimensions. Indeed, using the result (10.152) we are now able to solve the problems discussed in Section 8.7 in conjunction with the energy formula (8.225). Thus we are finally in a position to find the correct energies and amplitudes of these systems.

A sphere of radius r embedded in D dimensions has an intrinsic dimension $D' \equiv D - 1$ and a curvature scalar

$$\bar{R} = \frac{(D' - 1)D'}{r^2}. \quad (10.156)$$

This is most easily derived as follows. Consider a line element in D dimensions

$$(d\mathbf{x})^2 = (dx^1)^2 + (dx^2)^2 + \dots + (dx^D)^2 \quad (10.157)$$

and restrict the motion to a spherical surface

$$(x^1)^2 + (x^2)^2 + \dots + (x^D)^2 = r^2, \quad (10.158)$$

by eliminating x^D . This brings (10.157) to the form

$$(d\mathbf{x})^2 = (dx^1)^2 + (dx^2)^2 + \dots + (dx^{D'})^2 + \frac{(x^1 dx^1 + dx^2 + \dots + x^{D'} dx^{D'})^2}{r^2 - r'^2}, \quad (10.159)$$

where $r'^2 \equiv (x^1)^2 + (x^2)^2 + \dots + (x^{D'})^2$. The metric on the D' -dimensional surface is therefore

$$g_{\mu\nu}(x) = \delta_{\mu\nu} + \frac{x^\mu x^\nu}{r'^2 - r^2}. \quad (10.160)$$

Since \bar{R} will be constant on the spherical surface, we may evaluate it for small x^μ ($\mu = 1, \dots, D'$) where $g_{\mu\nu}(x) \approx \delta_{\mu\nu} + x^\mu x^\nu / r^2$ and the Christoffel symbols (10.7) are $\Gamma_{\mu\nu}^\lambda \approx \Gamma_{\mu\nu\lambda} \approx \delta_{\mu\nu} x_\lambda / r^2$. Inserting this into (10.35) we obtain the curvature tensor for small x^μ :

$$\bar{R}_{\mu\nu\lambda\kappa} \approx \frac{1}{r^2} (\delta_{\mu\kappa} \delta_{\nu\lambda} - \delta_{\mu\lambda} \delta_{\nu\kappa}). \quad (10.161)$$

This can be extended covariantly to the full surface of the sphere by replacing $\delta_{\mu\lambda}$ by the metric $g_{\mu\lambda}(x)$:

$$\bar{R}_{\mu\nu\lambda\kappa}(x) = \frac{1}{r^2} [g_{\mu\kappa}(x)g_{\nu\lambda}(x) - g_{\mu\lambda}(x)g_{\nu\kappa}(x)], \quad (10.162)$$

so that Ricci tensor is [recall (10.41)]

$$\bar{R}_{\nu\kappa}(x) = \bar{R}_{\mu\nu\kappa}{}^\mu(x) = \frac{D' - 1}{r^2} g_{\nu\kappa}(x). \quad (10.163)$$

Contracting this with $g^{\nu\kappa}$ [recall (10.42)] yields indeed the curvature scalar (10.156). The effective potential (10.152) is therefore

$$V_{\text{eff}} = -\frac{\hbar^2}{6Mr^2}(D - 2)(D - 1). \quad (10.164)$$

It supplies precisely the missing energy which changes the energy (8.225) *near* the sphere, corrected by the expectation of the quartic term ϑ_n^4 in the action, to the proper value

$$E_l = \frac{\hbar^2}{2Mr^2} l(l + D - 2). \quad (10.165)$$

Astonishingly, this elementary result of Schrödinger quantum mechanics was found only a decade ago by path integration [5]. Other time-slicing procedures yield extra terms proportional to the scalar curvature \bar{R} , which are absent in our theory. Here the scalar curvature is a trivial constant, so it would remain undetectable in atomic experiments which measure only energy differences. The same result will be derived in general in Eqs. (11.25) and in Section 11.3.

An important property of this spectrum is that the ground state energy vanished for all dimensions D . This property would not have been found in the naive measure of path integration on the right-hand side of Eq. (10.147) which is used in most works on this subject. The correction term (10.151) coming from the nonholonomic mapping of the flat-space measure is essential for the correct result.

More evidence for the correctness of the measure in (10.146) will be supplied in Chapter 13 where we solve the path integrals of the most important atomic system, the hydrogen atom.

We remark that for $t \rightarrow t'$, the amplitude (10.153) shows the states $|q\rangle$ to obey the covariant orthonormality relation

$$\langle q|q'\rangle = \sqrt{g(q)}^{-1} \delta^{(D)}(q - q'). \quad (10.166)$$

The completeness relation reads

$$\int d^D q \sqrt{g(q)} |q\rangle \langle q| = 1. \quad (10.167)$$

10.5 External Potentials and Vector Potentials

An important generalization of the above path integral formulas (10.146), (10.149), (10.153) of a point particle in a space with curvature and torsion includes the presence of an external potential and a vector potential. These allow us to describe, for instance, a particle in external electric and magnetic fields. The classical action is then

$$\mathcal{A}_{\text{em}} = \int_{t_a}^{t_b} dt \left[\frac{e}{c} A_\mu(q(t)) \dot{q}^\mu - V(q(t)) \right]. \quad (10.168)$$

To find the time-sliced action we proceed as follows. First we set up the correct time-sliced expression in Euclidean space and Cartesian coordinates. For a single slice it reads, in the postpoint form,

$$\mathcal{A}^\epsilon = \frac{M}{2\epsilon} (\Delta x^i)^2 + \frac{e}{c} A_i(\mathbf{x}) \Delta x^i - \frac{e}{2c} A_{i,j}(\mathbf{x}) \Delta x^i \Delta x^j - \epsilon V(\mathbf{x}) + \dots \quad (10.169)$$

As usual, we have neglected terms which do not contribute in the continuum limit. The derivation of this time-sliced expression proceeds by calculating, as in (10.116), the action

$$\mathcal{A}^\epsilon = \int_{t-\epsilon}^t dt L(t) \quad (10.170)$$

along the classical trajectory in Euclidean space, where

$$L(t) = \frac{M}{2} \dot{\mathbf{x}}^2(t) + \frac{e}{c} \mathbf{A}(\mathbf{x}(t)) \dot{\mathbf{x}}(t) - V(\mathbf{x}(t)) \quad (10.171)$$

is the classical Lagrangian. In contrast to (10.116), however, the Lagrangian has now a nonzero time derivative (omitting the time arguments):

$$\frac{d}{dt} L = M \dot{\mathbf{x}} \ddot{\mathbf{x}} + \frac{e}{c} \mathbf{A}(\mathbf{x}) \ddot{\mathbf{x}} + \frac{e}{c} A_{i,j}(\mathbf{x}) \dot{x}^i \dot{x}^j - V_i(\mathbf{x}) \dot{x}^i. \quad (10.172)$$

For this reason we cannot simply write down an expression such as (10.117) but we have to expand the Lagrangian around the postpoint leading to the series

$$\mathcal{A}^\epsilon = \int_{t-\epsilon}^t dt L(t) = \epsilon L(t) - \frac{1}{2}\epsilon^2 \frac{d}{dt} L(t) + \dots \quad (10.173)$$

The evaluation makes use of the equation of motion

$$M\ddot{x}^i = -\frac{e}{c}(A_{i,j}(\mathbf{x}) - A_{j,i}(\mathbf{x}))\dot{x}^j - V_i(\mathbf{x}), \quad (10.174)$$

from which we derive the analog of Eq. (10.96): First we have the postpoint expansion

$$\begin{aligned} \Delta x^i &= -\epsilon \dot{x}^i + \frac{1}{2}\epsilon^2 \ddot{x}^i + \dots \\ &= -\epsilon \dot{x}^i - \frac{e}{2Mc}\epsilon^2 [(A_{i,j} - A_{j,i})\dot{x}^j + V_i(\mathbf{x})] + \dots \end{aligned} \quad (10.175)$$

Inverting this gives

$$\dot{x}^i = -\frac{\Delta x^i}{\epsilon} - \frac{e}{2Mc}(A_{i,j} - A_{j,i})\Delta x^j + \dots \quad (10.176)$$

When inserted into (10.173), this yields indeed the time-sliced short-time action (10.169).

The quadratic term $\Delta x^i \Delta x^j$ in the action (10.169) can be replaced by the perturbative expectation value

$$\Delta x^i \Delta x^j \rightarrow \langle \Delta x^i \Delta x^j \rangle = \delta_{ij} i \frac{\hbar \epsilon}{M}, \quad (10.177)$$

so that \mathcal{A}^ϵ becomes

$$\mathcal{A}^\epsilon = \frac{M}{2\epsilon}(\Delta x^i)^2 + \frac{e}{c}A_i(\mathbf{x})\Delta x^i - i\epsilon \frac{\hbar e}{2Mc}A_{i,i}(\mathbf{x}) - \epsilon V(\mathbf{x}) + \dots \quad (10.178)$$

Incidentally, the action (10.169) could also have been written as

$$\mathcal{A}^\epsilon = \frac{M}{2\epsilon}(\Delta x^i)^2 + \frac{e}{c}A_i(\bar{\mathbf{x}})\Delta x^i - \epsilon V(\mathbf{x}) + \dots, \quad (10.179)$$

where $\bar{\mathbf{x}}$ is the midpoint value of the slice coordinates

$$\bar{\mathbf{x}} = \mathbf{x} - \frac{1}{2}\Delta \mathbf{x}, \quad (10.180)$$

i.e., more explicitly,

$$\bar{\mathbf{x}}(t_n) \equiv \frac{1}{2}[\mathbf{x}(t_n) + \mathbf{x}(t_{n-1})]. \quad (10.181)$$

Thus, with an external vector potential in Cartesian coordinates, a midpoint “pre-scription” for \mathcal{A}^ϵ happens to yield the correct expression (10.179).

Having found the time-sliced action in Cartesian coordinates, it is easy to go over to spaces with curvature and torsion. We simply insert the nonholonomic transformation (10.96) for the differentials Δx^i . This gives again the short-time action (10.107), extended by the interaction due to the potentials

$$\mathcal{A}_{\text{em}}^\epsilon = \frac{e}{c} A_\mu \Delta q^\mu - \frac{e}{2c} \partial_\nu A_\mu \Delta q^\mu \Delta q^\nu - \epsilon V(q) + \dots \quad (10.182)$$

The second term can be evaluated perturbatively leading to

$$\mathcal{A}_{\text{em}}^\epsilon = \frac{e}{c} A_\mu \Delta q^\mu - i\epsilon \frac{\hbar e}{2Mc} \partial_\mu A^\mu - \epsilon V(q) + \dots \quad (10.183)$$

The sum over all slices,

$$\mathcal{A}_{\text{em}}^N = \sum_{n=1}^{N+1} \mathcal{A}_{\text{em}}^\epsilon, \quad (10.184)$$

has to be added to the action in each time-sliced expression (10.146), (10.149), and (10.153).

10.6 Perturbative Calculation of Path Integrals in Curved Space

In Sections 2.15 and 3.21 we have given a perturbative definition of path integrals which does not require the rather cumbersome time slicing but deals directly with a continuous time. We shall now extend this definition to curved space in such a way that it leads to the same result as the time-sliced definition given in Section 10.3. In particular, we want to ensure that this definition preserves the fundamental property of coordinate independence achieved in the time-sliced definition via the non-holonomic mapping principle, as observed at the end of Subsection 10.3.2. In a perturbative calculation, this property will turn out to be highly nontrivial. In addition, we want to be sure that the ground state energy of a particle on a sphere is zero in any number of dimensions, just as in the time-sliced calculation leading to Eq. (10.165). This implies that also in the perturbative definition of path integral, the operator-ordering problem will be completely solved.

10.6.1 Free and Interacting Parts of Action

The partition function of a point particle in a curved space with an intrinsic dimension D is given by the path integral over all periodic paths on the imaginary-time axis τ :

$$Z = \int \mathcal{D}^D q \sqrt{g} e^{-\mathcal{A}[q]}, \quad (10.185)$$

where $\mathcal{A}[q]$ is the Euclidean action

$$\mathcal{A}[q] = \int_0^\beta d\tau \left[\frac{1}{2} g_{\mu\nu}(q(\tau)) \dot{q}^\mu(\tau) \dot{q}^\nu(\tau) + V(q(\tau)) \right]. \quad (10.186)$$

We have set \hbar and the particle mass M equal to unity. For a space with constant curvature, this is a generalization of the action for a particle on a sphere (8.147), also called a *nonlinear σ -model* (see p. 746). The perturbative definition of Sections 2.15 and 3.21 amounts to the following calculation rules. Expand the metric $g_{\mu\nu}(q)$ and the potential $V(q)$ around some point q_a^μ in powers of $\delta q^\mu \equiv q^\mu - q_a^\mu$. After this, separate the action $\mathcal{A}[q]$ into a harmonically fluctuating part

$$\mathcal{A}^{(0)}[q_a; \delta q] \equiv \frac{1}{2} \int_0^\beta d\tau g_{\mu\nu}(q_a) \left[\delta \dot{q}^\mu(\tau) \delta \dot{q}^\nu(\tau) + \omega^2 \delta q^\mu(\tau) \delta q^\nu(\tau) \right], \quad (10.187)$$

and an interacting part

$$\mathcal{A}^{\text{int}}[q_a; \delta q] \equiv \mathcal{A}[q] - \mathcal{A}^{(0)}[q_a; \delta q]. \quad (10.188)$$

The second term in (10.187) is called *frequency term* or *mass term*. It is not invariant under coordinate transformations. The implications of this will be seen later. When studying the partition function in the limit of large β , the frequency ω cannot be set equal to zero since this would lead to infinities in the perturbation expansion, as we shall see below.

A delicate problem is posed by the square root of the determinant of the metric in the functional integration measure in (10.185). In a purely formal continuous definition of the measure, we would write it as

$$\int \mathcal{D}^D q \sqrt{g} \equiv \prod_\tau \int d^D q(\tau) \sqrt{g(\tau)} = \left[\prod_\tau \int d^D q(\tau) \sqrt{g(q_a)} \right] \exp \left[\frac{1}{2} \sum_\tau \log \frac{g(q(\tau))}{g(q_a)} \right]. \quad (10.189)$$

The formal sum over all continuous times τ in the exponent corresponds to an integral $\int d\tau$ divided by the spacing of the points, which on a sliced time axis would be the slicing parameter ϵ . Here it is $d\tau$. The ratio $1/d\tau$ may formally be identified with $\delta(0)$, in accordance with the defining integral $\int d\tau \delta(\tau) = 1$. The infinity of $\delta(0)$ may be regularized in some way, for instance by a cutoff in the Fourier representation $\delta(0) \equiv \int d\omega / (2\pi)$ at large frequencies ω , a so-called *UV-cutoff*. Leaving the regularization unspecified, we rewrite the measure (10.189) formally as

$$\int \mathcal{D}^D q \sqrt{g} \equiv \left[\prod_\tau \int d^D q(\tau) \sqrt{g(q_a)} \right] \exp \left[\frac{1}{2} \delta(0) \int_0^\beta d\tau \log \frac{g(q(\tau))}{g(q_a)} \right], \quad (10.190)$$

and further as

$$\int \mathcal{D}^D q \sqrt{g(q_a)} e^{-\mathcal{A}^g[q]}, \quad (10.191)$$

where we have introduced an effective action associated with the measure:

$$\mathcal{A}_g[q] = -\frac{1}{2}\delta(0) \int_0^\beta d\tau \log \frac{g(q(\tau))}{g(q_a)}. \quad (10.192)$$

For a perturbative treatment, this action is expanded in powers of $\delta q(\tau)$ and is a functional of this variable:

$$\mathcal{A}_g[q_a, \delta q] = -\frac{1}{2}\delta(0) \int_0^\beta d\tau [\log g(q_a + \delta q(\tau)) - \log g(q_a)]. \quad (10.193)$$

This is added to (10.188) to yield the total interaction

$$\mathcal{A}_{\text{tot}}^{\text{int}}[q_a, \delta q] = \mathcal{A}^{\text{int}}[q_a, \delta q] + \mathcal{A}_g[q_a, \delta q]. \quad (10.194)$$

The path integral for the partition function is now written as

$$Z = \int \mathcal{D}^D q \sqrt{g(q_a)} e^{-\mathcal{A}^{(0)}[q]} e^{-\mathcal{A}_{\text{tot}}^{\text{int}}[q]}. \quad (10.195)$$

According to the rules of perturbation theory, we expand the factor $e^{-\mathcal{A}_{\text{tot}}^{\text{int}}}$ in powers of the total interaction, and obtain the perturbation series

$$\begin{aligned} Z &= \int \mathcal{D}^D q \sqrt{g(q_a)} \left(1 - \mathcal{A}_{\text{tot}}^{\text{int}} + \frac{1}{2} \mathcal{A}_{\text{tot}}^{\text{int}2} - \dots\right) e^{-\mathcal{A}^{(0)}[q]} \\ &= Z_\omega \left[1 - \langle \mathcal{A}_{\text{tot}}^{\text{int}} \rangle + \frac{1}{2!} \langle \mathcal{A}_{\text{tot}}^{\text{int}2} \rangle - \dots\right], \end{aligned} \quad (10.196)$$

where

$$Z_\omega \equiv e^{-\beta F_\omega} = \int \mathcal{D}^D q \sqrt{g(q_a)} e^{-\mathcal{A}^{(0)}[q]} \quad (10.197)$$

is the path integral over the free part, and the symbol $\langle \dots \rangle$ denotes the expectation values in this path integral

$$\langle \dots \rangle = Z_\omega^{-1} \int \mathcal{D}^D q \sqrt{g(q_a)} (\dots) e^{-\mathcal{A}^{(0)}[q]}. \quad (10.198)$$

With the usual definition of the cumulants $\langle \mathcal{A}_{\text{tot}}^{\text{int}} \rangle_c = \langle \mathcal{A}_{\text{tot}}^{\text{int}} \rangle$, $\langle \mathcal{A}_{\text{tot}}^{\text{int}2} \rangle_c = \langle \mathcal{A}_{\text{tot}}^{\text{int}2} \rangle - \langle \mathcal{A}_{\text{tot}}^{\text{int}} \rangle^2$, \dots [recall (3.485), (3.486)], this can be written as

$$Z \equiv e^{-\beta F} = \exp \left[-\beta F_\omega - \langle \mathcal{A}_{\text{tot}}^{\text{int}} \rangle_c + \frac{1}{2!} \langle \mathcal{A}_{\text{tot}}^{\text{int}2} \rangle_c - \dots \right], \quad (10.199)$$

where $F_\omega \equiv -\beta^{-1} \log Z$ the free energy associated with Z_ω .

The cumulants are now calculated according to Wick's rule order by order in \hbar , treating the δ -function at the origin $\delta(0)$ as if it were finite. The perturbation series will contain factors of $\delta(0)$ and its higher powers. Fortunately, these unpleasant terms will turn out to cancel each other at each order in a suitably defined expansion

parameter. On account of these cancellations, we may ultimately discard all terms containing $\delta(0)$, or set $\delta(0)$ equal to zero, in accordance with Veltman's rule (2.508).

The harmonic path integral (10.197) is performed using formulas (2.489) and (2.505). Assuming for a moment what we shall prove below that we may choose coordinates in which $g_{\mu\nu}(q_a) = \delta_{\mu\nu}$, we obtain directly in D dimensions

$$Z_\omega = \int \mathcal{D}q e^{-\mathcal{A}_\omega[q]} = \exp \left[-\frac{D}{2} \text{Tr} \log(-\partial^2 + \omega^2) \right] \equiv e^{-\beta F_\omega}. \quad (10.200)$$

The expression in brackets specifies the free energy F_ω of the harmonic oscillator at the inverse temperature β .

10.6.2 Zero Temperature

For simplicity, we first consider the limit of zero temperature or $\beta \rightarrow \infty$. Then F_ω becomes equal to the sum of D ground state energies $\omega/2$ of the oscillator, one for each dimension:

$$F_\omega = \frac{1}{\beta} \frac{D}{2} \text{Tr} \log(-\partial^2 + \omega^2) \xrightarrow{\beta \rightarrow \infty} \frac{D}{2} \int_{-\infty}^{\infty} \frac{dk}{2\pi} \log(k^2 + \omega^2) = \frac{D}{2} \omega. \quad (10.201)$$

The Wick contractions in the cumulants $\langle \mathcal{A}_{\text{tot}}^{\text{int}^2} \rangle_c$ of the expansion (10.198) contain only connected diagrams. They contain temporal integrals which, after suitable partial integrations, become products of the following basic correlation functions

$$G_{\mu\nu}^{(2)}(\tau, \tau') \equiv \langle q_\mu(\tau) q_\nu(\tau') \rangle = \text{---} , \quad (10.202)$$

$$\partial_\tau G_{\mu\nu}^{(2)}(\tau, \tau') \equiv \langle \dot{q}_\mu(\tau) q_\nu(\tau') \rangle = \text{---} \cdots \text{---} , \quad (10.203)$$

$$\partial_{\tau'} G_{\mu\nu}^{(2)}(\tau, \tau') \equiv \langle q_\mu(\tau) \dot{q}_\nu(\tau') \rangle = \cdots \text{---} , \quad (10.204)$$

$$\partial_\tau \partial_{\tau'} G_{\mu\nu}^{(2)}(\tau, \tau') \equiv \langle \dot{q}_\mu(\tau) \dot{q}_\nu(\tau') \rangle = \cdots \cdots \cdots . \quad (10.205)$$

The right-hand sides define line symbols to be used for drawing Feynman diagrams for the interaction terms.

Under the assumption $g_{\mu\nu}(q_a) = \delta_{\mu\nu}$, the correlation function $G_{\mu\nu}^{(2)}(\tau, \tau')$ factorizes as

$$G_{\mu\nu}^{(2)}(\tau, \tau') = \delta_{\mu\nu} \Delta(\tau - \tau'), \quad (10.206)$$

with $\Delta(\tau - \tau')$ abbreviating the correlation the zero-temperature Green function $G_{\omega^2, e}^{\text{p}}(\tau)$ of Eq. (3.249) (remember the present units with $M = \hbar = 1$):

$$\Delta(\tau - \tau') = \int_{-\infty}^{\infty} \frac{dk}{2\pi} \frac{e^{ik(\tau - \tau')}}{k^2 + \omega^2} = \frac{1}{2\omega} e^{-\omega|\tau - \tau'|}. \quad (10.207)$$

As a consequence, the second correlation function (10.203) has a discontinuity

$$\partial_\tau G_{\mu\nu}^{(2)}(\tau, \tau') = \delta_{\mu\nu} i \int_{-\infty}^{\infty} \frac{dk}{2\pi} \frac{e^{ik(\tau - \tau')} k}{k^2 + \omega^2} = \delta_{\mu\nu} \dot{\Delta}(\tau - \tau') \equiv -\frac{1}{2} \delta_{\mu\nu} \epsilon(\tau - \tau') e^{-\omega|\tau - \tau'|}, \quad (10.208)$$

where $\epsilon(\tau - \tau')$ is the distribution defined in Eq. (1.315) which has a jump at $\tau = \tau'$ from -1 to 1 . It can be written as an integral over a δ -function:

$$\epsilon(\tau - \tau') \equiv -1 + 2 \int_{-\infty}^{\tau} d\tau'' \delta(\tau'' - \tau'). \quad (10.209)$$

The third correlation function (10.204) is simply the negative of (10.203):

$$\partial_{\tau'} G_{\mu\nu}^{(2)}(\tau, \tau') = -\partial_{\tau} G_{\mu\nu}^{(2)}(\tau, \tau') = -\delta_{\mu\nu} \dot{\Delta}(\tau - \tau'). \quad (10.210)$$

At the point $\tau = \tau'$, the momentum integral (10.208) vanishes by antisymmetry:

$$\partial_{\tau} G_{\mu\nu}^{(2)}(\tau, \tau')|_{\tau=\tau'} = -\partial_{\tau'} G_{\mu\nu}^{(2)}(\tau, \tau')|_{\tau=\tau'} = \delta_{\mu\nu} i \int_{-\infty}^{\infty} \frac{dk}{2\pi} \frac{k}{k^2 + \omega^2} = \delta_{\mu\nu} \dot{\Delta}(0) = 0. \quad (10.211)$$

The fourth correlation function (10.205) contains a δ -function:

$$\begin{aligned} \partial_{\tau} \partial_{\tau'} G_{\mu\nu}^{(2)}(\tau, \tau') &= -\partial_{\tau}^2 G_{\mu\nu}^{(2)}(\tau, \tau') = \delta_{\mu\nu} \int_{-\infty}^{\infty} \frac{dk}{2\pi} \frac{e^{ik(\tau-\tau')} k^2}{k^2 + \omega^2} = -\delta_{\mu\nu} \ddot{\Delta}(\tau - \tau') \quad (10.212) \\ &= \delta_{\mu\nu} \int_{-\infty}^{\infty} \frac{dk}{2\pi} e^{ik(\tau-\tau')} \left(1 - \frac{\omega^2}{k^2 + \omega^2} \right) = \delta_{\mu\nu} \delta(\tau - \tau') - \omega^2 G_{\mu\nu}^{(2)}(\tau, \tau'). \end{aligned}$$

The Green functions for $\mu = \nu$ are plotted in Fig. 10.4.

Figure 10.4 Green functions for perturbation expansions in curvilinear coordinates in natural units with $\omega = 1$. The third contains a δ -function at the origin.

The last equation is actually the defining equation for the Green function, which is always the solution of the inhomogeneous equation of motion associated with the harmonic action (10.187), which under the assumption $g_{\mu\nu}(q_a) = \delta_{\mu\nu}$ reads for each component:

$$-\ddot{q}(\tau) + \omega^2 q(\tau) = \delta(\tau - \tau'). \quad (10.213)$$

The Green function $\Delta(\tau - \tau')$ solves this equation, satisfying

$$\ddot{\Delta}(\tau) = \omega^2 \Delta(\tau) - \delta(\tau). \quad (10.214)$$

When trying to evaluate the different terms produced by the Wick contractions, we run into a serious problem. The different terms containing products of time derivatives of Green functions contain effectively products of δ -functions and

Heaviside functions. In the mathematical theory of distributions, such integrals are undefined. We shall offer two ways to resolve this problem. One is based on extending the integrals over the time axis to integrals over a d -dimensional *time space*, and continuing the results at the end back to $d = 1$. The extension makes the path integral a *functional integral* of the type used in quantum field theories. It will turn out that this procedure leads to well-defined finite results, also for the initially divergent terms coming from the effective action of the measure (10.193). In addition, and very importantly, it guarantees that the perturbatively defined path integral is invariant under coordinate transformations.

For the time-sliced definition in Section 10.3, coordinate independence was an automatic consequence of the nonholonomic mapping from a flat-space path integral. In the perturbative definition, the coordinate independence has been an outstanding problem for many years, and was only solved recently in Refs. [23]–[25].

In d -dimensional quantum field theory, path integrals between two and four spacetime dimensions have been defined by perturbation expansions for a long time. Initial difficulties in guaranteeing coordinate independence were solved by 't Hooft and Veltman [29] using dimensional regularization with minimal subtractions. For a detailed description of this method see the textbook [30]. Coordinate independence emerges after calculating all Feynman integrals in an arbitrary number of dimensions d , and continuing the results to the desired physical integer value. Infinities occurring in the limit are absorbed into parameters of the action. In contrast, and surprisingly, numerous attempts [31]–[36] to define the simpler *quantum-mechanical* path integrals in curved space by perturbation expansions encountered problems. Although all final results are finite and unique, the Feynman integrals in the expansions are highly singular and mathematically undefined. When evaluated in momentum space, they yield different results depending on the order of integration. Various definitions chosen by the earlier authors were not coordinate-independent, and this could only be cured by adding coordinate-dependent “correction terms” to the classical action — a highly unsatisfactory procedure violating the basic Feynman postulate that physical amplitudes should consist of a sum over all paths with phase factors $e^{i\mathcal{A}/\hbar}$ containing only the classical actions along the paths.

The calculations in d spacetime dimensions and the continuation to $d = 1$ will turn out to be somewhat tedious. We shall therefore find in Subsection 10.11.4 a method of doing the calculations directly for $d = 1$.

10.7 Model Study of Coordinate Invariance

Let us consider first a simple model which exhibits typical singular Feynman integrals encountered in curvilinear coordinates and see how these can be turned into a finite perturbation expansion which is invariant under coordinate transformations. For simplicity, we consider an ordinary harmonic oscillator in one dimension, with the action

$$\mathcal{A}_\omega = \frac{1}{2} \int_0^\beta d\tau \left[\dot{x}^2(\tau) + \omega^2 x^2(\tau) \right]. \quad (10.215)$$

The partition function of this system is exactly given by (10.201):

$$Z_\omega = \int \mathcal{D}x e^{-\mathcal{A}_\omega[x]} = \exp \left[-\frac{D}{2} \text{Tr} \log(-\partial^2 + \omega^2) \right] \equiv e^{-\beta F_\omega}. \quad (10.216)$$

A nonlinear transformation of $x(\tau)$ to some other coordinate $q(\tau)$ turns (10.216) into a path integral of the type (10.185) which has a singular perturbation expansion. For simplicity we assume a specific simple coordinate transformation preserving the reflection symmetry $x \longleftrightarrow -x$ of the initial oscillator, whose power series expansion starts out like

$$x(\tau) = f_\eta(\eta q(\tau)) \equiv \frac{1}{\eta} f(\eta q(\tau)) = q - \frac{\eta}{3} q^3 + a \frac{\eta^2}{5} q^5 - \dots, \quad (10.217)$$

where η is an expansion parameter which will play the role of a coupling constant counting the orders of the perturbation expansion. An extra parameter a is introduced for the sake of generality. We shall see that it does not influence the conclusions.

The transformation changes the partition function (10.216) into

$$Z = \int \mathcal{D}q(\tau) e^{-\mathcal{A}_J[q]} e^{-\mathcal{A}[q]}, \quad (10.218)$$

where $\mathcal{A}[q]$ is the transformed action, whereas

$$\mathcal{A}_J[q] = -\delta(0) \int d\tau \log \frac{\partial f(q(\tau))}{\partial q(\tau)} \quad (10.219)$$

is an effective action coming from the Jacobian of the coordinate transformation

$$J = \prod_\tau \sqrt{\frac{\partial f(q(\tau))}{\partial q(\tau)}}. \quad (10.220)$$

The Jacobian plays the role of the square root of the determinant of the metric in (10.185), and $\mathcal{A}_J[q]$ corresponds to the effective action $\mathcal{A}_g[\delta q]$ in Eq. (10.193).

The transformed action is decomposed into a free part

$$\mathcal{A}_\omega[q] = \frac{1}{2} \int_0^\beta d\tau [\dot{q}^2(\tau) + \omega^2 q^2(\tau)], \quad (10.221)$$

and an interacting part corresponding to (10.188), which reads to second order in η :

$$\begin{aligned} \mathcal{A}^{\text{int}}[q] = \int_0^\beta d\tau \left\{ -\eta \left[q^2(\tau) \dot{q}^2(\tau) + \frac{\omega^2}{3} q^4(\tau) \right] \right. \\ \left. + \eta^2 \left[\left(\frac{1}{2} + a \right) q^4(\tau) \dot{q}^2(\tau) + \omega^2 \left(\frac{1}{18} + \frac{2a}{5} \right) q^6(\tau) \right] \right\}. \end{aligned} \quad (10.222)$$

This is found from (10.188) by inserting the one-dimensional metric

$$g_{00}(q) = g(q) = [f'(\eta q)]^2 = 1 - 2\eta q^2 + (1 + 2a)\eta^2 q^4 + \dots \quad (10.223)$$

To the same order in η , the Jacobian action (10.219) is

$$\mathcal{A}_J[q] = -\delta(0) \int_0^\beta d\tau \left[-\eta q^2(\tau) + \eta^2 \left(a - \frac{1}{2} \right) q^4(\tau) \right], \quad (10.224)$$

and the perturbation expansion (10.199) is to be performed with the total interaction

$$\mathcal{A}_{\text{tot}}^{\text{int}}[q] = \mathcal{A}^{\text{int}}[q] + \mathcal{A}_J[q]. \quad (10.225)$$

For $\eta = 0$, the transformed partition function (10.218) coincides trivially with (10.216). When expanding Z of Eq. (10.218) in powers of η , we obtain sums of Feynman diagrams contributing to each order η^n . This sum must vanish to ensure coordinate independence of the path integral. From the connected diagrams in the cumulants in (10.199) we obtain the free energy

$$\beta F = \beta F_\omega + \beta \sum_{n=1} \eta^n F_n = \beta F_\omega + \langle \mathcal{A}_{\text{tot}}^{\text{int}} \rangle_c - \frac{1}{2!} \langle \mathcal{A}_{\text{tot}}^{\text{int}^2} \rangle_c + \dots \quad (10.226)$$

The perturbative treatment is coordinate-independent if F does not depend on the parameters η and a of the coordinate transformation (10.217). Hence all expansion terms F_n must vanish. This will indeed happen, albeit in a quite nontrivial way.

10.7.1 Diagrammatic Expansion

The graphical expansion for the ground state energy will be carried here only up to three loops. At any order η^n , there exist different types of Feynman diagrams with $L = n + 1, n$, and $n - 1$ number of loops coming from the interaction terms (10.222) and (10.224), respectively. The diagrams are composed of the three types of lines in (10.202)–(10.205), and new interaction vertices for each power of η . The diagrams coming from the Jacobian action (10.224) are easily recognized by an accompanying power of $\delta(0)$.

First we calculate the contribution to the free energy of the first cumulant $\langle \mathcal{A}_{\text{tot}}^{\text{int}} \rangle_c$ in the expansion (10.226). The associated diagrams contain only lines whose end points have equal times. Such diagrams will be called *local*.

To lowest order in η , the cumulant contains the terms

$$\beta F_1 = \eta \int_0^\beta d\tau \left\langle - \left[q^2(\tau) \dot{q}^2(\tau) + \frac{\omega^2}{3} q^4(\tau) \right] + \delta(0) q^2(\tau) \right\rangle_c.$$

There are two diagrams originating from the interaction, one from the Jacobian action:

$$\beta F_1 = -\eta \text{---}\text{---}\text{---} - \eta \omega^2 \text{---}\text{---} + \eta \delta(0) \text{---}\text{---}. \quad (10.227)$$

The first cumulant contains also terms of order η^2 :

$$\eta^2 \int_0^\beta d\tau \left\langle \left[\left(\frac{1}{2} + a \right) q^4(\tau) \dot{q}^2(\tau) + \omega^2 \left(\frac{1}{18} + \frac{2a}{5} \right) q^6(\tau) \right] - \delta(0) \left(a - \frac{1}{2} \right) q^4(\tau) \right\rangle_c.$$

The interaction gives rise to two three-loop diagrams, the Jacobian action to a single two-loop diagram:

$$\beta F_2^{(1)} = \eta^2 \left[3 \left(\frac{1}{2} + a \right) \text{diagram}_1 + 15 \omega^2 \left(\frac{1}{18} + \frac{a}{5} \right) \text{diagram}_2 - 3 \left(a - \frac{1}{2} \right) \delta(0) \text{diagram}_3 \right]. \quad (10.228)$$

We now come to the contribution of the second cumulant $\langle \mathcal{A}_{\text{tot}}^{\text{int}2} \rangle_c$ in the expansion (10.226). Keeping only terms contributing to order η^2 we have to calculate the expectation value

$$-\frac{1}{2!} \eta^2 \int_0^\beta d\tau \int_0^\beta d\tau' \left\langle \left[-q^2(\tau) \dot{q}^2(\tau) - \frac{\omega^2}{3} q^4(\tau) + \delta(0) q^2(\tau) \right] \times \left[-q^2(\tau') \dot{q}^2(\tau') - \frac{\omega^2}{3} q^4(\tau') + \delta(0) q^2(\tau') \right] \right\rangle_c. \quad (10.229)$$

Only the connected diagrams contribute to the cumulant, and these are necessarily nonlocal. The simplest diagrams are those containing factors of $\delta(0)$:

$$\beta F_2^{(2)} = -\frac{\eta^2}{2!} \left\{ 2\delta^2(0) \text{diagram}_1 - 4\delta(0) \left[\text{diagram}_2 + \text{diagram}_3 + 2\omega^2 \text{diagram}_4 \right] \right\}. \quad (10.230)$$

The remaining diagrams have either the form of three bubble in a chain, or of a watermelon, each with all possible combinations of the three line types (10.202)–(10.205). The sum of the three-bubbles diagrams is

$$\beta F_2^{(3)} = -\frac{\eta^2}{2!} \left[4 \text{diagram}_1 + 2 \text{diagram}_2 + 2 \text{diagram}_3 + 8\omega^2 \text{diagram}_4 + 8\omega^2 \text{diagram}_5 + 8\omega^4 \text{diagram}_6 \right], \quad (10.231)$$

while the watermelon-like diagrams contribute

$$\beta F_2^{(4)} = -\frac{\eta^2}{2!} 4 \left[\frac{2}{3} \omega^4 \text{diagram}_1 + \text{diagram}_2 + 4 \text{diagram}_3 + \text{diagram}_4 + 4\omega^2 \text{diagram}_5 \right]. \quad (10.232)$$

Since the equal-time expectation value $\langle \dot{q}(\tau) q(\tau) \rangle$ vanishes according to Eq. (10.211), diagrams with a local contraction of a mixed line (10.203) vanish trivially, and have been omitted.

We now show that if we calculate all Feynman integrals in $d = 1 - \varepsilon$ time dimensions and take the limit $\varepsilon \rightarrow 0$ at the end, we obtain unique finite results. These have the desired property that the sum of all Feynman diagrams contributing to each order η^n vanishes, thus ensuring invariance of the perturbative expressions (10.196) and (10.199) under coordinate transformations.

10.7.2 Diagrammatic Expansion in d Time Dimensions

As a first step, we extend the dimension of the τ -axis to d , assuming τ to be a vector $\tau \equiv (\tau^0, \dots, \tau^d)$, in which the zeroth component is the physical imaginary time, the others are auxiliary coordinates to be eliminated at the end. Then we replace the harmonic action (10.215) by

$$\mathcal{A}_\omega = \frac{1}{2} \int d^d\tau \left[\partial_\alpha x(\tau) \partial_\alpha x(\tau) + \omega^2 x^2(\tau) \right], \tag{10.233}$$

and the terms \dot{q}^2 in the transformed action (10.222) accordingly by $\partial_a q(\tau) \partial_a q(\tau)$.

The correlation functions (10.206), (10.208), and (10.212) are replaced by two-point functions

$$G^{(2)}(\tau, \tau') = \langle q(\tau) q(\tau') \rangle = \Delta(\tau - \tau') = \int \frac{d^d k}{(2\pi)^d} \frac{e^{ik(\tau - \tau')}}{k^2 + \omega^2}, \tag{10.234}$$

and its derivatives

$$G_\alpha^{(2)}(\tau, \tau') = \langle \partial_\alpha q(\tau) q(\tau') \rangle = \Delta_\alpha(\tau - \tau') = \int \frac{d^d k}{(2\pi)^d} \frac{ik_\alpha}{k^2 + \omega^2} e^{ik(\tau - \tau')}, \tag{10.235}$$

$$G_{\alpha\beta}^{(2)}(\tau, \tau') = \langle \partial_\alpha q(\tau) \partial_\beta q(\tau') \rangle = \Delta_{\alpha\beta}(\tau - \tau') = \int \frac{d^d k}{(2\pi)^d} \frac{k_\alpha k_\beta}{k^2 + \omega^2} e^{ik(\tau - \tau')}. \tag{10.236}$$

The configuration space is still one-dimensional so that the indices μ, ν and the corresponding tensors in Eqs. (10.206), (10.208), and (10.212) are absent.

The analytic continuation to $d = 1 - \varepsilon$ time dimensions is most easily performed if the Feynman diagrams are calculated in momentum space. The three types of lines represent the analytic expressions

$$\text{---} = \frac{1}{p^2 + \omega^2}, \quad \text{---} \cdots = i \frac{p_\alpha}{p^2 + \omega^2}, \quad \cdots \cdots = \frac{p_\alpha p_\beta}{p^2 + \omega^2}. \tag{10.237}$$

Most diagrams in the last section converge in one-dimensional momentum space, thus requiring no regularization to make them finite, as we would expect for a quantum-mechanical system. Trouble arises, however, in some multiple momentum integrals, which yield different results depending on the order of their evaluation.

As a typical example, take the Feynman integral

$$\text{---} \ominus = - \int d^d \tau_1 \Delta(\tau_1 - \tau_2) \Delta_\alpha(\tau_1 - \tau_2) \Delta_\beta(\tau_1 - \tau_2) \Delta_{\alpha\beta}(\tau_1 - \tau_2). \tag{10.238}$$

For the ordinary one-dimensional Euclidean time, a Fourier transformation yields the triple momentum space integral

$$X = \int \frac{dk}{2\pi} \frac{dp_1}{2\pi} \frac{dp_2}{2\pi} \frac{k^2 (p_1 p_2)}{(k^2 + \omega^2)(p_1^2 + \omega^2)(p_2^2 + \omega^2)[(k + p_1 + p_2)^2 + \omega^2]}. \tag{10.239}$$

Integrating this first over k , then over p_1 and p_2 yields $1/32\omega$. In the order first p_1 , then p_2 and k , we find $-3/32\omega$, whereas the order first p_1 , then k and p_2 , gives again $1/32\omega$. As we shall see below in Eq. (10.284), the correct result is $1/32\omega$.

The unique correct evaluation will be possible by extending the momentum space to d dimensions and taking the limit $d \rightarrow 1$ at the end. The way in which the ambiguity will be resolved may be illustrated by a typical Feynman integral

$$Y_d = \int \frac{d^d k}{(2\pi)^d} \frac{d^d p_1}{(2\pi)^d} \frac{d^d p_2}{(2\pi)^d} \frac{k^2 (p_1 p_2) - (k p_1)(k p_2)}{(k^2 + \omega^2)(p_1^2 + \omega^2)(p_2^2 + \omega^2)[(k + p_1 + p_2)^2 + \omega^2]}, \quad (10.240)$$

whose numerator vanished trivially in $d = 1$ dimensions. Due to the different contractions in d dimensions, however, Y_0 will be seen to have the nonzero value $Y_0 = 1/32\omega - (-1/32\omega)$ in the limit $d \rightarrow 1$, the result being split according to the two terms in the numerator [to appear in the Feynman integrals (10.282) and (10.284); see also Eq. (10.355)].

The diagrams which need a careful treatment are easily recognized in configuration space, where the one-dimensional correlation function (10.234) is the continuous function (10.207). Its first derivative (10.208) which has a jump at equal arguments is a rather unproblematic distribution, as long as the remaining integrand does not contain δ -functions or their derivatives. These appear with second derivatives of $\Delta(\tau, \tau')$, where the d -dimensional evaluation must be invoked to obtain a unique result.

10.8 Calculating Loop Diagrams

The loop integrals encountered in d dimensions are based on the basic one-loop integral

$$I \equiv \int \frac{\bar{d}^d k}{k^2 + \omega^2} = \frac{\omega^{d-2}}{(4\pi)^{d/2}} \Gamma(1 - d/2) \underset{d=1}{=} \frac{1}{2\omega}, \quad (10.241)$$

where we have abbreviated $\bar{d}^d k \equiv d^d k / (2\pi)^d$ by analogy with $\hbar \equiv h/2\pi$. The integral exists only for $\omega \neq 0$ since it is otherwise divergent at small k . Such a divergence is called infrared divergence (IR-divergence) and ω plays the role of an infrared (IR) cutoff.

By differentiation with respect to ω^2 we can easily generalize (10.241) to

$$I_\alpha^\beta \equiv \int \frac{\bar{d}^d k (k^2)^\beta}{(k^2 + \omega^2)^\alpha} = \frac{\omega^{d+2\beta-2\alpha}}{(4\pi)^{d/2}} \frac{\Gamma(d/2 + \beta) \Gamma(\alpha - \beta - d/2)}{\Gamma(d/2) \Gamma(\alpha)}. \quad (10.242)$$

Note that for consistency of dimensional regularization, all integrals over a pure power of the momentum must vanish:

$$I_0^\beta = \int \bar{d}^d k (k^2)^\beta = 0. \quad (10.243)$$

We recognize *Veltman's rule* of Eq. (2.508).

With the help of Eqs. (10.241) and (10.242) we calculate immediately the local expectation values (10.234) and (10.236) and thus the local diagrams in (10.227) and (10.228):

$$\text{⊙} = \langle q^2 \rangle = \int \frac{\bar{d}^d k}{k^2 + \omega^2} \stackrel{\equiv}{=} \frac{1}{2\omega}, \quad (10.244)$$

$$\text{⊗} = \langle q^2 \rangle^2 = \left(\int \frac{\bar{d}^d k}{k^2 + \omega^2} \right)^2 \stackrel{\equiv}{=} \frac{1}{4\omega^2}, \quad (10.245)$$

$$\text{⊕} = \langle q^2 \rangle^3 = \left(\int \frac{\bar{d}^d k}{k^2 + \omega^2} \right)^3 \stackrel{\equiv}{=} \frac{1}{8\omega^3}, \quad (10.246)$$

$$\text{⊗} \text{⊙} = \langle q^2 \rangle \langle \partial q \partial q \rangle = \int \frac{\bar{d}^d k}{k^2 + \omega^2} \int \frac{\bar{d}^d p p^2}{p^2 + \omega^2} \stackrel{\equiv}{=} -\frac{1}{4}, \quad (10.247)$$

$$\text{⊕} \text{⊙} = \langle qq \rangle^2 \langle \partial q \partial q \rangle = \left(\int \frac{\bar{d}^d k}{k^2 + \omega^2} \right)^2 \int \frac{\bar{d}^d p p^2}{p^2 + \omega^2} \stackrel{\equiv}{=} -\frac{1}{8\omega}. \quad (10.248)$$

The two-bubble diagrams in Eq. (10.230) can also be easily computed

$$\text{⊙} \text{⊙} = \int d^d \tau_1 \Delta^2(\tau_1 - \tau_2) \int \frac{\bar{d}^d p}{(p^2 + \omega^2)^2} \stackrel{\equiv}{=} \frac{1}{4\omega^3}, \quad (10.249)$$

$$\text{⊗} \text{⊗} = \int d^d \tau_1 \Delta(\tau_1 - \tau_1) \Delta_\alpha^2(\tau_1 - \tau_2) \int \frac{\bar{d}^d k}{k^2 + \omega^2} \int \frac{\bar{d}^d p p^2}{(p^2 + \omega^2)^2} \stackrel{\equiv}{=} \frac{1}{8\omega^2}, \quad (10.250)$$

$$\text{⊗} \text{⊙} = \int d^d \tau_1 \Delta_{\alpha\alpha}(\tau_1 - \tau_1) \Delta^2(\tau_1 - \tau_2) \int \frac{\bar{d}^d k k^2}{k^2 + \omega^2} \int \frac{\bar{d}^d p}{(p^2 + \omega^2)^2} \stackrel{\equiv}{=} -\frac{1}{8\omega^2}, \quad (10.251)$$

$$\text{⊗} \text{⊗} = \int d^d \tau_1 \Delta(\tau_1 - \tau_1) \Delta^2(\tau_1 - \tau_2) \int \frac{\bar{d}^d k}{k^2 + \omega^2} \int \frac{\bar{d}^d p}{(p^2 + \omega^2)^2} \stackrel{\equiv}{=} \frac{1}{8\omega^4}. \quad (10.252)$$

For the three-bubble diagrams in Eq. (10.231) we find

$$\begin{aligned} \text{⊗} \text{⊗} \text{⊗} &= \int d^d \tau_1 \Delta(\tau_1 - \tau_1) \Delta_\alpha^2(\tau_1 - \tau_2) \Delta(\tau_2 - \tau_2) \\ &= \left(\int \frac{\bar{d}^d q}{q^2 + \omega^2} \right)^2 \int \frac{\bar{d}^d p (p^2)^2}{(p^2 + \omega^2)^2} \stackrel{\equiv}{=} -\frac{3}{16\omega}, \end{aligned} \quad (10.253)$$

$$\begin{aligned} \text{⊗} \text{⊗} \text{⊙} &= \int d^d \tau_1 \Delta_{\alpha\alpha}(\tau_1 - \tau_1) \Delta^2(\tau_1 - \tau_2) \Delta_{\beta\beta}(\tau_2 - \tau_2) \\ &= \left[\int \frac{\bar{d}^d q (q^2)^2}{q^2 + \omega^2} \right]^2 \int \frac{\bar{d}^d k}{(k^2 + \omega^2)^2} \stackrel{\equiv}{=} \frac{1}{16\omega}, \end{aligned} \quad (10.254)$$

$$\begin{aligned} \text{⊗} \text{⊗} \text{⊗} &= \int d^d \tau_1 \Delta(\tau_1 - \tau_1) \Delta_\alpha^2(\tau_1 - \tau_2) \Delta_{\beta\beta}(\tau_2 - \tau_2) \\ &= \int \frac{\bar{d}^d k}{k^2 + \omega^2} \int \frac{\bar{d}^d p p^2}{(p^2 + \omega^2)^2} \int \frac{\bar{d}^d q q^2}{q^2 + \omega^2} \stackrel{\equiv}{=} -\frac{1}{16\omega}, \end{aligned} \quad (10.255)$$

$$\text{⊗} \text{⊗} \text{⊗} = \int d^d \tau_1 \Delta_{\alpha\alpha}(\tau_1 - \tau_1) \Delta^2(\tau_1 - \tau_2) \Delta(\tau_2 - \tau_2)$$

$$= \int \frac{\bar{d}^d k k^2}{k^2 + \omega^2} \int \frac{\bar{d}^d p}{(p^2 + \omega^2)^2} \int \frac{\bar{d}^d q}{q^2 + \omega^2} \stackrel{d=1}{=} -\frac{1}{16\omega^3}, \tag{10.256}$$

$$= \int d^d \tau_1 \Delta(\tau_1 - \tau_1) \Delta_\alpha^2(\tau_1 - \tau_2) \Delta(\tau_2 - \tau_2)$$

$$= \int \frac{\bar{d}^d k}{k^2 + \omega^2} \int \frac{\bar{d}^d p p^2}{(p^2 + \omega^2)^2} \int \frac{\bar{d}^d q}{q^2 + \omega^2} \stackrel{d=1}{=} \frac{1}{16\omega^3}, \tag{10.257}$$

$$= \int d^d \tau_1 \Delta(\tau_1 - \tau_1) \Delta^2(\tau_1 - \tau_2) \Delta(\tau_2 - \tau_2)$$

$$= \int \frac{\bar{d}^d k}{k^2 + \omega^2} \int \frac{\bar{d}^d p}{(p^2 + \omega^2)^2} \int \frac{\bar{d}^d q}{q^2 + \omega^2} \stackrel{d=1}{=} \frac{1}{16\omega^5}. \tag{10.258}$$

In these diagrams, it does not make any difference if we replace $\Delta_{\alpha\alpha}^2$ by $\Delta_{\alpha\beta}^2$.

We now turn to the watermelon-like diagrams in Eq. (10.232) which are more tedious to calculate. They require a further basic integral [26]:

$$J(p^2) = \int \frac{\bar{d}^d k}{(k^2 + \omega^2)[(k + p)^2 + \omega^2]} = \int_0^1 dx \int \frac{\bar{d}^d k}{[k^2 + p^2 x(1 - x) + \omega^2]^2}$$

$$= \frac{\Gamma(2 - d/2)}{(4\pi)^{d/2}} \left(\frac{p^2 + 4\omega^2}{4}\right)^{d/2-2} F\left(2 - \frac{d}{2}, \frac{1}{2}; \frac{3}{2}; \frac{p^2}{p^2 + 4\omega^2}\right), \tag{10.259}$$

where $F(a, b; c; z)$ is the hypergeometric function (1.453). For $d = 1$, the result is simply

$$J(p^2) = \frac{1}{\omega(p^2 + 4\omega^2)}. \tag{10.260}$$

We also define the more general integrals

$$J_{\alpha_1 \dots \alpha_n}(p) = \int \frac{\bar{d}^d k k_{\alpha_1} \dots k_{\alpha_n}}{(k^2 + \omega^2)[(k + p)^2 + \omega^2]}, \tag{10.261}$$

and further

$$J_{\alpha_1 \dots \alpha_n, \beta_1 \dots \beta_m}(p) = \int \frac{\bar{d}^d k k_{\alpha_1} \dots k_{\alpha_n} (k + p)_{\beta_1} \dots (k + p)_{\beta_m}}{(k^2 + \omega^2)[(k + p)^2 + \omega^2]}. \tag{10.262}$$

The latter are linear combinations of momenta and the former, for instance

$$J_{\alpha, \beta}(p) = J_\alpha(p) p_\beta + J_{\alpha\beta}(p). \tag{10.263}$$

Using Veltman's rule (10.243), all integrals (10.262) can be reduced to combinations of $p, I, J(p^2)$. Relevant examples for our discussion are

$$J_\alpha(p) = \int \frac{\bar{d}^d k k_\alpha}{(k^2 + \omega^2)[(k + p)^2 + \omega^2]} = -\frac{1}{2} p_\alpha J(p^2), \tag{10.264}$$

and

$$J_{\alpha\beta}(p) = \int \frac{\bar{d}^d k \, k_\alpha k_\beta}{(k^2 + \omega^2)[(k+p)^2 + \omega^2]} = \left[\delta_{\alpha\beta} + (d-2) \frac{p_\alpha p_\beta}{p^2} \right] \frac{I}{2(d-1)} + \left[-\delta_{\alpha\beta}(p^2 + 4\omega^2) + \frac{p_\alpha p_\beta}{p^2} (dp^2 + 4\omega^2) \right] \frac{J(p^2)}{4(d-1)}, \quad (10.265)$$

whose trace is

$$J_{\alpha\alpha}(p) = \int \frac{\bar{d}^d k \, k^2}{(k^2 + \omega^2)[(k+p)^2 + \omega^2]} = I - \omega^2 J(p^2). \quad (10.266)$$

Similarly we expand

$$J_{\alpha\alpha\beta}(p) = \int \frac{\bar{d}^d k \, k^2 k_\beta}{(k^2 + \omega^2)[(k+p)^2 + \omega^2]} = \frac{1}{2} p_\beta [-I + \omega^2 J(p^2)]. \quad (10.267)$$

The integrals appear in the following subdiagrams

$$\begin{array}{lll} \begin{array}{c} k \\ \circlearrowleft \\ k+p \end{array} = J(p^2), & \begin{array}{c} k \\ \circlearrowleft \\ k+p, \alpha \end{array} = J_{,\alpha}(p), & \begin{array}{c} k \\ \circlearrowleft \\ k+p, \alpha\beta \end{array} = J_{,\alpha\beta}(p), \\ \begin{array}{c} k, \alpha \\ \circlearrowleft \\ k+p \end{array} = J_\alpha(p), & \begin{array}{c} k, \alpha \\ \circlearrowleft \\ k+p, \beta \end{array} = J_{\alpha,\beta}(p), & \begin{array}{c} k, \alpha \\ \circlearrowleft \\ k+p, \beta\gamma \end{array} = J_{\alpha,\beta\gamma}(p), \\ \begin{array}{c} k, \alpha \\ \circlearrowleft \\ k+p \end{array} = J_{\alpha\beta}(p), & \begin{array}{c} k, \alpha\beta \\ \circlearrowleft \\ k+p, \gamma \end{array} = J_{\alpha\beta,\gamma}(p), & \begin{array}{c} k, \alpha\beta \\ \circlearrowleft \\ k+p, \gamma\delta \end{array} = J_{\alpha\beta,\gamma\delta}(p). \end{array} \quad (10.268)$$

All two- and three-loop integrals needed for the calculation can be brought to the generic form

$$K(a, b) = \int \bar{d}^d p \, (p^2)^a J^b(p^2), \quad a \geq 0, \quad b \geq 1, \quad a \leq b, \quad (10.269)$$

and evaluated recursively as follows [27]. From the Feynman parametrization of the first line of Eq. (10.259) we observe that the two basic integrals (10.241) and (10.259) satisfy the differential equation

$$J(p^2) = -\frac{\partial I}{\partial \omega^2} + \frac{1}{2} p^2 \frac{\partial J(p^2)}{\partial \omega^2} - 2p^2 \frac{\partial J(p^2)}{\partial p^2}. \quad (10.270)$$

Differentiating $K(a+1, b)$ from Eq. (10.269) with respect to ω^2 , and using Eq. (10.270), we find the recursion relation

$$K(a, b) = \frac{2b(d/2 - 1) I K(a-1, b-1) - 2\omega^2(2a - 2 - b + d) K(a-1, b)}{(b+1)d/2 - 2b + a}, \quad (10.271)$$

which may be solved for increasing a starting with

$$\begin{aligned} K(0, 0) &= 0, & K(0, 1) &= \int \bar{d}^d p \, J(p^2) = I^2, \\ K(0, 2) &= \int \bar{d}^d p \, J^2(p^2) = A, \quad \dots, \end{aligned} \quad (10.272)$$

where A is the integral

$$A \equiv \int \frac{\bar{d}^d p_1 \bar{d}^d p_2 \bar{d}^d k}{(p_1^2 + \omega^2)(p_2^2 + \omega^2)(k^2 + \omega^2)[(p_1 + p_2 + k)^2 + \omega^2]}. \quad (10.273)$$

This integral will be needed only in $d = 1$ dimensions where it can be calculated directly from the configuration space version of this integral. For this we observe that the first watermelon-like diagram in (10.232) corresponds to an integral over the product of two diagrams $J(p^2)$ in (10.268):

$$\textcircled{\ominus} = \int d^d \tau_1 \Delta(\tau_1 - \tau_2) \Delta(\tau_1 - \tau_2) \Delta(\tau_1 - \tau_2) \Delta(\tau_1 - \tau_2) = \int \bar{d}^d k J^2(k) = A. \quad (10.274)$$

Thus we find A in $d = 1$ dimensions from the simple τ -integral

$$A = \int_{-\infty}^{\infty} d\tau \Delta^4(\tau, 0) = \int_{-\infty}^{\infty} dx \left(\frac{1}{2\omega} e^{-\omega|x|} \right)^4 = \frac{1}{32\omega^5}. \quad (10.275)$$

Since this configuration space integral contains no δ -functions, the calculation in $d = 1$ dimension is without subtlety.

With the help of Eqs. (10.271), (10.272), and Veltman's rule (10.243), according to which

$$K(a, 0) \equiv 0, \quad (10.276)$$

we find further the integrals

$$\int \bar{d}^d p p^2 J(p^2) = K(1, 1) = -2\omega^2 I^2, \quad (10.277)$$

$$\int \bar{d}^d p p^2 J^2(p^2) = K(1, 2) = \frac{4}{3}(I^3 - \omega^2 A), \quad (10.278)$$

$$\int \bar{d}^d p (p^2)^2 J^2(p^2) = K(2, 2) = -8\omega^2 \frac{(6 - 5d)I^3 + 2d\omega^2 A}{3(4 - 3d)}. \quad (10.279)$$

We are thus prepared to calculate all remaining three-loop contributions from the watermelon-like diagrams in Eq. (10.232). The second is an integral over the product of subdiagrams $J_{\alpha\beta}$ in (10.268) and yields

$$\begin{aligned} \textcircled{\ominus} &= \int d^d \tau_1 \Delta^2(\tau_1 - \tau_2) \Delta_{\alpha\beta}^2(\tau_1 - \tau_2) \\ &= \int \bar{d}^d p \bar{d}^d k \bar{d}^d q \frac{(pk)^2}{(p^2 + \omega^2)(k^2 + \omega^2)(q^2 + \omega^2)[(p + k + q)^2 + \omega^2]} \\ &\stackrel{q \rightarrow q-p}{=} \int \bar{d}^d q J_{\alpha\beta}(q) J_{\alpha\beta}(q) = \int \bar{d}^d k \frac{1}{16} (k^2)^2 J^2(k) \\ &\quad + \int \bar{d}^d k \frac{1}{4(d-1)} \left\{ dI^2 + [(d-2)k^2 - 4\omega^2] I J(k) + \frac{1}{4} (k^2 + 4\omega^2)^2 J^2(k) \right\} \\ &= -\frac{\omega^2}{2} \frac{(6 - 5d)I^3 + 2d\omega^2 A}{3(4 - 3d)} - \frac{\omega^2}{6(4 - 3d)} [(6 - 5d)I^3 + 2d\omega^2 A] \\ &= -\frac{\omega^2}{3(4 - 3d)} [(8 - 7d)I^3 + (d + 4)\omega^2 A] \stackrel{d=1}{=} -\frac{\omega^2}{3} (I^3 + 5\omega^2 A) = -\frac{3}{32\omega}. \end{aligned} \quad (10.280)$$

The third diagram contains two mixed lines. It is an integral over a product of the diagrams $J_\alpha(p)$ and $J_{\beta,\alpha\beta}$ in (10.268) and gives

$$\begin{aligned}
\textcircled{\ominus} &= -\int d^d\tau_1\Delta(\tau_1-\tau_2)\Delta_\alpha(\tau_1-\tau_2)\Delta_\beta(\tau_1-\tau_2)\Delta_{\alpha\beta}(\tau_1-\tau_2) \\
&= \int \bar{d}^d k \bar{d}^d p_1 \bar{d}^d p_2 \frac{(kp_1)(kp_2)}{(k^2+\omega^2)(p_1^2+\omega^2)(p_2^2+\omega^2)[(k+p_1+p_2)^2+\omega^2]} \\
&\stackrel{p_2 \rightarrow p_2-k}{=} \int \bar{d}^d p [p_\beta J_\alpha(p) J_{\alpha\beta}(p) + J_\alpha(p) J_{\beta\alpha\beta}(p)] \\
&= -\frac{1}{8} \int \bar{d}^d p p^2 J(p^2) [(p^2+2\omega^2)J(p^2) - 2I] \quad (10.281) \\
&= -\frac{\omega^2}{6(4-3d)} [(8-5d)I^3 - 2(4-d)\omega^2 A] \stackrel{d=1}{=} -\frac{\omega^2}{2}(I^3 - 2\omega^2 A) = -\frac{1}{32\omega}.
\end{aligned}$$

The fourth diagram contains four mixed lines and is evaluated as follows:

$$\textcircled{\ominus} = -\int d^d\tau_1\Delta_\alpha(\tau_1-\tau_2)\Delta_\alpha(\tau_1-\tau_2)\Delta_\beta(\tau_1-\tau_2)\Delta_\beta(\tau_1-\tau_2). \quad (10.282)$$

Since the integrand is regular and vanishes at infinity, we can perform a partial integration and rewrite the configuration space integral as

$$\begin{aligned}
\textcircled{\ominus} &= \int d^d\tau_1\Delta(\tau_1-\tau_2)\Delta_{\alpha\alpha}(\tau_1-\tau_2)\Delta_\beta(\tau_1-\tau_2)\Delta_\beta(\tau_1-\tau_2) \\
&\quad + 2 \int d^d\tau_1\Delta(\tau_1-\tau_2)\Delta_\alpha(\tau_1-\tau_2)\Delta_\beta(\tau_1-\tau_2)\Delta_{\alpha\beta}(\tau_1-\tau_2). \quad (10.283)
\end{aligned}$$

The second integral has just been evaluated in (10.282). The first is precisely the integral Eq. (10.239) discussed above. It is calculated as follows:

$$\begin{aligned}
&\int d^d\tau_1\Delta(\tau_1-\tau_2)\Delta_{\alpha\alpha}(\tau_1-\tau_2)\Delta_\beta(\tau_1-\tau_2)\Delta_\beta(\tau_1-\tau_2) \\
&= \int \bar{d}^d k \bar{d}^d p_1 \bar{d}^d p_2 \frac{k^2(p_1 p_2)}{(k^2+\omega^2)(p_1^2+\omega^2)(p_2^2+\omega^2)[(k+p_1+p_2)^2+\omega^2]} \\
&= \int \bar{d}^d p [p_\alpha J_\alpha(p) J_{\beta\beta} + J_\alpha(p) J_{\beta\alpha\beta}(p)] = \frac{\omega^2}{4} \int \bar{d}^d p p^2 J^2(p^2) \\
&= -\frac{\omega^2}{3}(I^3 - \omega^2 A) \stackrel{d=1}{=} \frac{1}{32\omega}. \quad (10.284)
\end{aligned}$$

Hence we obtain

$$\textcircled{\ominus} = \frac{1}{32\omega}. \quad (10.285)$$

The fifth diagram in (10.232) is an integral of the product of two subdiagrams $J_\alpha(p)$ in (10.268) and yields

$$\textcircled{\ominus} = \int d^d\tau_1\Delta(\tau_1-\tau_2)\Delta_\alpha^2(\tau_1-\tau_2)\Delta(\tau_1-\tau_2)$$

$$\begin{aligned}
&= - \int \bar{d}^d k \bar{d}^d p_1 \bar{d}^d p_2 \frac{p_1 p_2}{(k^2 + \omega^2)(p_1^2 + \omega^2)(p_2^2 + \omega^2)[(k + p_1 + p_2)^2 + \omega^2]} \\
&\stackrel{k \rightarrow k - p_2}{=} - \int \bar{d}^d k \bar{d}^d p_1 \bar{d}^d p_2 \frac{p_1 p_2}{[(k - p_2)^2 + \omega^2](p_1^2 + \omega^2)(p_2^2 + \omega^2)[(k + p_1)^2 + \omega^2]} \\
&\stackrel{p_2 \rightarrow -p_2}{=} \int \bar{d}^d k \bar{d}^d p_1 \frac{p_{1\alpha}}{(p_1^2 + \omega^2)[(p_1 + k)^2 + \omega^2]} \int \bar{d}^d p_2 \frac{p_{2\alpha}}{(p_2^2 + \omega^2)[(p_2 + k)^2 + \omega^2]} \\
&= \int \bar{d}^d k J_\alpha^2(k) = \frac{1}{4} \int \bar{d}^d k k^2 J^2(k^2) \\
&= \frac{1}{4} \frac{4}{3} (I^3 - \omega^2 A) \stackrel{d=1}{=} \frac{1}{32\omega^3}. \tag{10.286}
\end{aligned}$$

We can now sum up all contributions to the free energy in Eqs. (10.227)–(10.232). An immediate simplification arises from the Veltman’s rule (10.243). This implies that all δ -functions at the origin are zero in dimensional regularization:

$$\delta^{(d)}(0) = \int \frac{d^d k}{(2\pi)^d} = 0. \tag{10.287}$$

The first-order contribution (10.227) to the free energy is obviously zero by Eqs. (10.245) and (10.247).

The first second-order contribution $\beta F_2^{(1)}$ becomes, from (10.246) and (10.248):

$$F_2^{(1)} = \eta^2 \left[3 \left(\frac{1}{2} + a \right) \left(-\frac{1}{8\omega} \right) + 15\omega^2 \left(\frac{1}{18} + \frac{a}{5} \right) \right] = -\frac{\eta^2}{12\omega}. \tag{10.288}$$

The parameter a has disappeared from this equation.

The second second-order contribution $\beta F_2^{(2)}$ vanishes trivially, by Veltman’s rule (10.287).

The third second-order contribution $\beta F_2^{(3)}$ in (10.231) vanishes nontrivially using (10.253)–(10.258):

$$\begin{aligned}
F_2^{(3)} &= -\frac{\eta^2}{2!} \left[4 \left(-\frac{1}{16\omega} \right) + 2 \left(-\frac{3}{16\omega} \right) + 2 \left(\frac{1}{16\omega} \right) \right. \\
&\quad \left. + 8\omega^2 \left(-\frac{1}{16\omega^3} \right) + 8\omega^2 \left(\frac{1}{16\omega^3} \right) + 8\omega^4 \left(\frac{1}{16\omega^5} \right) \right] = 0. \tag{10.289}
\end{aligned}$$

The fourth second-order contribution, finally, associated with the watermelon-like diagrams in (10.232) yield via (10.281), (10.282), (10.285), (10.286), and (10.274):

$$\beta F_2^{(4)} = -\frac{\eta^2}{2!} \left[-\frac{3}{32\omega} + 4 \left(-\frac{1}{32\omega} \right) + \frac{1}{32\omega} + 4\omega^2 \left(\frac{1}{32\omega^3} \right) + \frac{2}{3}\omega^4 \left(\frac{1}{32\omega^5} \right) \right] = \frac{\eta^2}{12\omega}, \tag{10.290}$$

canceling (10.288), and thus the entire free energy. This proves the invariance of the perturbatively defined path integral under coordinate transformations.

10.8.1 Reformulation in Configuration Space

The Feynman integrals in momentum space in the last section corresponds in τ -space to integrals over products of distributions. For many applications it is desirable to do the calculations directly in τ -space. This will lead to an extension of distribution theory which allows us to do precisely that.

In dimensional regularization, an important simplification came from Veltman's rule (10.287), according to which the delta function at the origin vanishes. In the more general calculations to come, we shall encounter generalized δ -functions, which are multiple derivatives of the ordinary δ -function:

$$\delta_{\alpha_1 \dots \alpha_n}^{(d)}(\tau) \equiv \partial_{\alpha_1 \dots \alpha_n} \delta^{(d)}(\tau) = \int \bar{d}^d k (ik)_{\alpha_1} \dots (ik)_{\alpha_n} e^{ikx}, \quad (10.291)$$

with $\partial_{\alpha_1 \dots \alpha_n} \equiv \partial_{\alpha_1} \dots \partial_{\alpha_n}$ and $\bar{d}^d k \equiv d^d k / (2\pi)^d$. By Veltman's rule (10.243), all these vanish at the origin:

$$\delta_{\alpha_1 \dots \alpha_n}^{(d)}(0) = \int \bar{d}^d k (ik)_{\alpha_1} \dots (ik)_{\alpha_n} = 0. \quad (10.292)$$

In the extended coordinate space, the correlation function $\Delta(\tau, \tau')$ in (10.234), which we shall also write as $\Delta(\tau - \tau')$, is at equal times given by the integral [compare (10.241)]

$$\Delta(0) = \int \frac{\bar{d}^d k}{k^2 + \omega^2} = \frac{\omega^{d-2}}{(4\pi)^{d/2}} \Gamma\left(1 - \frac{d}{2}\right) = I \underset{d=1}{=} \frac{1}{2\omega}. \quad (10.293)$$

The extension (10.235) of the time derivative (10.208),

$$\Delta_\alpha(\tau) = \int \bar{d}^d k \frac{ik_\alpha}{k^2 + \omega^2} e^{ik\tau} \quad (10.294)$$

vanishes at equal times, just like (10.211):

$$\Delta_\alpha(0) = 0. \quad (10.295)$$

This follows directly from a Taylor series expansion of $1/(k^2 + \omega^2)$ in powers of k^2 , after imposing (10.292).

The second derivative of $\Delta(\tau)$ has the Fourier representation (10.236). Contracting the indices yields

$$\Delta_{\alpha\alpha}(\tau) = - \int \bar{d}^d k \frac{k^2}{k^2 + \omega^2} e^{ikx} = -\delta^{(d)}(\tau) + \omega^2 \Delta(\tau). \quad (10.296)$$

This equation is a direct consequence of the definition of the correlation function as a solution to the inhomogeneous field equation

$$(-\partial_\alpha^2 + \omega^2)q(\tau) = \delta^{(d)}(\tau). \quad (10.297)$$

Inserting Veltman's rule (10.287) into (10.296), we obtain

$$\Delta_{\alpha\alpha}(0) = \omega^2 \Delta(0) \underset{d=1}{=} \frac{\omega}{2}. \quad (10.298)$$

This ensures the vanishing of the first-order contribution (10.227) to the free energy

$$F_1 = -g\eta [-\Delta_{\alpha\alpha}(0) + \omega^2 \Delta(0)] \Delta(0) = 0. \quad (10.299)$$

The same equation (10.296) allows us to calculate immediately the second-order contribution (10.228) from the local diagrams

$$\begin{aligned} F_2^{(1)} &= -\eta^2 3g^2 \left[\left(\frac{1}{2} + a \right) \Delta_{\alpha\alpha}(0) - 5 \left(\frac{1}{18} + \frac{a}{5} \right) \omega^2 \Delta(0) \right] \Delta^2(0) \\ &= -\eta^2 \frac{2}{3} \omega^2 \Delta^3(0) \stackrel{d=1}{=} -\frac{\eta^2}{12\omega}. \end{aligned} \quad (10.300)$$

The other contributions to the free energy in the expansion (10.226) require rules for calculating products of two and four distributions, which we are now going to develop.

10.8.2 Integrals over Products of Two Distributions

The simplest integrals are

$$\begin{aligned} \int d^d\tau \Delta^2(\tau) &= \int \bar{d}^d p \bar{d}^d k \frac{\delta^{(d)}(k+p)}{(p^2 + \omega^2)(k^2 + \omega^2)} \\ &= \int \frac{\bar{d}^d k}{(k^2 + \omega^2)^2} = \frac{\omega^{d-4}}{(4\pi)^{d/2}} \Gamma\left(2 - \frac{d}{2}\right) = \frac{(2-d)}{2\omega^2} \Delta(0), \end{aligned} \quad (10.301)$$

and

$$\begin{aligned} \int d^d\tau \Delta_\alpha^2(\tau) &= -\int d^d\tau \Delta(\tau) [-\delta^{(d)}(\tau) + \omega^2 \Delta(\tau)] = \Delta(0) - \omega^2 \int d^d\tau \Delta^2(\tau) \\ &= \frac{d}{2} \Delta(0). \end{aligned} \quad (10.302)$$

To obtain the second result we have performed a partial integration and used (10.296).

In contrast to (10.301) and (10.302), the integral

$$\begin{aligned} \int d^d\tau \Delta_{\alpha\beta}^2(\tau) &= \int \bar{d}^d p \bar{d}^d k \frac{(kp)^2 \delta^{(d)}(k+p)}{(k^2 + \omega^2)(p^2 + \omega^2)} \\ &= \int \bar{d}^d k \frac{(k^2)^2}{(k^2 + \omega^2)^2} = \int d^d\tau \Delta_{\alpha\alpha}^2(\tau) \end{aligned} \quad (10.303)$$

diverges formally in $d = 1$ dimension. In dimensional regularization, however, we may decompose $(k^2)^2 = (k^2 + \omega^2)^2 - 2\omega^2(k^2 + \omega^2) + \omega^4$, and use (10.292) to evaluate

$$\begin{aligned} \int d^d\tau \Delta_{\alpha\alpha}^2(\tau) &= \int \bar{d}^d k \frac{(k^2)^2}{(k^2 + \omega^2)^2} = -2\omega^2 \int \frac{\bar{d}^d k}{(k^2 + \omega^2)} + \omega^4 \int \frac{\bar{d}^d k}{(k^2 + \omega^2)^2} \\ &= -2\omega^2 \Delta(0) + \omega^4 \int d^d\tau \Delta^2(\tau). \end{aligned} \quad (10.304)$$

Together with (10.301), we obtain the relation between integrals of products of two distributions

$$\begin{aligned} \int d^d\tau \Delta_{\alpha\beta}^2(\tau) &= \int d^d\tau \Delta_{\alpha\alpha}^2(\tau) = -2\omega^2 \Delta(0) + \omega^4 \int d^d\tau \Delta^2(\tau) \\ &= -(1 + d/2) \omega^2 \Delta(0). \end{aligned} \quad (10.305)$$

An alternative way of deriving the equality (10.303) is to use partial integrations and the identity

$$\partial_\alpha \Delta_{\alpha\beta}(\tau) = \partial_\beta \Delta_{\alpha\alpha}(\tau), \quad (10.306)$$

which follows directly from the Fourier representation (10.294).

Finally, from Eqs. (10.301), (10.302), and (10.305), we observe the useful identity

$$\int d^d\tau \left[\Delta_{\alpha\beta}^2(\tau) + 2\omega^2 \Delta_\alpha^2(\tau) + \omega^4 \Delta^2(\tau) \right] = 0, \quad (10.307)$$

which together with the inhomogeneous field equation (10.296) reduces the calculation of the second-order contribution of all three-bubble diagrams (10.231) to zero:

$$F_2^{(3)} = -g^2 \Delta^2(0) \int d^d\tau \left[\Delta_{\alpha\beta}^2(\tau) + 2\omega^2 \Delta_\alpha^2(\tau) + \omega^4 \Delta^2(\tau) \right] = 0. \quad (10.308)$$

10.8.3 Integrals over Products of Four Distributions

Consider now the more delicate integrals arising from watermelon-like diagrams in (10.232) which contain products of four distributions, a nontrivial tensorial structure, and overlapping divergences. We start from the second to fourth diagrams:

$$\text{Diagram 1} = \int d^d\tau \Delta^2(\tau) \Delta_{\alpha\beta}^2(\tau), \quad (10.309)$$

$$4 \text{ Diagram 2} = 4 \int d^d\tau \Delta(\tau) \Delta_\alpha(\tau) \Delta_\beta(\tau) \Delta_{\alpha\beta}(\tau), \quad (10.310)$$

$$\text{Diagram 3} = \int d^d\tau \Delta_\alpha(\tau) \Delta_\alpha(\tau) \Delta_\beta(\tau) \Delta_\beta(\tau). \quad (10.311)$$

To isolate the subtleties with the tensorial structure exhibited in Eq. (10.240), we introduce the integral

$$Y_d = \int d^d\tau \Delta^2(\tau) \left[\Delta_{\alpha\beta}^2(\tau) - \Delta_{\alpha\alpha}^2(\tau) \right]. \quad (10.312)$$

In $d = 1$ dimension, the bracket vanishes formally, but the limit $d \rightarrow 1$ of the integral is nevertheless finite. We now decompose the Feynman diagram (10.309), into the sum

$$\int d^d\tau \Delta^2(\tau) \Delta_{\alpha\beta}^2(\tau) = \int d^d\tau \Delta^2(\tau) \Delta_{\alpha\alpha}^2(\tau) + Y_d. \quad (10.313)$$

To obtain an analogous decomposition for the other two diagrams (10.310) and (10.311), we derive a few useful relations using the inhomogeneous field equation (10.296), partial integrations, and Veltman's rules (10.287) or (10.292). From the inhomogeneous field equation, there is the relation

$$- \int d^d\tau \Delta_{\alpha\alpha}(\tau) \Delta^3(\tau) = \Delta^3(0) - \omega^2 \int d^d\tau \Delta^4(\tau). \quad (10.314)$$

By a partial integration, the left-hand side becomes

$$\int d^d\tau \Delta_{\alpha\alpha}(\tau)\Delta^3(\tau) = -3 \int d^d\tau \Delta_{\alpha}^2(\tau)\Delta^2(\tau), \quad (10.315)$$

leading to

$$\int d^d\tau \Delta_{\alpha}^2(\tau)\Delta^2(\tau) = \frac{1}{3}\Delta^3(0) - \frac{1}{3}\omega^2 \int d^d\tau \Delta^4(\tau). \quad (10.316)$$

Invoking once more the inhomogeneous field equation (10.296) and Veltman's rule (10.287), we obtain the integrals

$$\int d^d\tau \Delta_{\alpha\alpha}^2(\tau)\Delta^2(\tau) - \omega^4 \int d^d\tau \Delta^4(\tau) + 2\omega^2\Delta^3(0) = 0, \quad (10.317)$$

and

$$\int d^d\tau \Delta_{\alpha\alpha}(\tau)\Delta_{\beta}^2(\tau)\Delta(\tau) = \omega^2 \int d^d\tau \Delta_{\beta}^2(\tau)\Delta^2(\tau). \quad (10.318)$$

Using (10.316), the integral (10.318) takes the form

$$\int d^d\tau \Delta_{\alpha\alpha}(\tau)\Delta_{\beta}^2(\tau)\Delta(\tau) = \frac{1}{3}\omega^2\Delta^3(0) - \frac{1}{3}\omega^4 \int d^d\tau \Delta^4(\tau). \quad (10.319)$$

Partial integration, together with Eqs. (10.317) and (10.319), leads to

$$\begin{aligned} \int d^d\tau \partial_{\beta}\Delta_{\alpha\alpha}(\tau)\Delta_{\beta}(\tau)\Delta^2(\tau) &= - \int d^d\tau \Delta_{\alpha\alpha}^2(\tau)\Delta^2(\tau) - 2 \int d^d\tau \Delta_{\alpha\alpha}(\tau)\Delta_{\beta}^2(\tau)\Delta(\tau) \\ &= \frac{4}{3}\omega^2\Delta^3(0) - \frac{1}{3}\omega^4 \int d^d\tau \Delta^4(\tau). \end{aligned} \quad (10.320)$$

A further partial integration, and use of Eqs. (10.306), (10.318), and (10.320) produces the decompositions of the second and third Feynman diagrams (10.310) and (10.311):

$$4 \int d^d\tau \Delta(\tau)\Delta_{\alpha}(\tau)\Delta_{\beta}(\tau)\Delta_{\alpha\beta}(\tau) = 4\omega^2 \int d^d\tau \Delta^2(\tau)\Delta_{\alpha}^2(\tau) - 2Y_d, \quad (10.321)$$

and

$$\int d^d\tau \Delta_{\alpha}^2(\tau)\Delta_{\beta}^2(\tau) = -3\omega^2 \int d^d\tau \Delta^2(\tau)\Delta_{\alpha}^2(\tau) + Y_d. \quad (10.322)$$

We now make the important observation that the subtle integral Y_d of Eq. (10.312) appears in Eqs. (10.313), (10.321), and (10.322) in such a way that it drops out from the sum of the watermelon-like diagrams in (10.232):

$$\textcircled{\text{---}} + 4 \textcircled{\text{---}} + \textcircled{\text{---}} = \int d^d\tau \Delta^2(\tau)\Delta_{\alpha\alpha}^2(\tau) + \omega^2 \int d^d\tau \Delta^2(\tau)\Delta_{\alpha}^2(\tau). \quad (10.323)$$

Using now the relations (10.316) and (10.317), the right-hand side becomes a sum of completely regular integrals involving only products of propagators $\Delta(\tau)$.

We now add to this sum the first and last watermelon-like diagrams in Eq. (10.232)

$$\frac{2}{3}\omega^4 \textcircled{\ominus} = \frac{2}{3}\omega^4 \int d^d\tau \Delta^4(\tau), \quad (10.324)$$

and

$$4\omega^2 \textcircled{\ominus} = 4\omega^2 \int d^d\tau \Delta^2(\tau)\Delta_\alpha^2(\tau), \quad (10.325)$$

and obtain for the total contribution of all watermelon-like diagrams in (10.232) the simple expression for $\eta = 1$:

$$\begin{aligned} F_2^{(4)} &= -2\eta^2 g^2 \int d^d\tau \Delta^2(\tau) \left[\frac{2}{3}\omega^4 \Delta^2(\tau) + \Delta_{\alpha\alpha}^2(\tau) + 5\omega^2 \Delta_\alpha^2(\tau) \right] \\ &= \eta^2 \frac{2}{3} \omega^2 \Delta^3(0) \stackrel{d=1}{=} \frac{\eta^2}{12\omega}. \end{aligned} \quad (10.326)$$

This cancels the finite contribution (10.300), thus making also the second-order free energy in (10.222) vanish, and confirming the invariance of the perturbatively defined path integral under coordinate transformations up to this order.

Thus we have been able to relate all diagrams involving singular time derivatives of correlation functions to integrals over products of the regular correlation function (10.234), where they can be replaced directly by their $d = 1$ -version (10.207). The disappearance of the ambiguous integral Y_d in the combination of watermelon-like diagrams (10.323) has the pleasant consequence that ultimately all calculations can be done in $d = 1$ dimensions after all. This leads us to expect that the dimensional regularization may be made superfluous by a more comfortable calculation procedure. This is indeed so and the rules will be developed in Section 10.11. Before we come to this it is useful, however, to point out a pure x -space way of finding the previous results.

10.9 Distributions as Limits of Bessel Function

In dimensional regularization it is, of course, possible to perform the above configuration space integrals over products of distributions without any reference to momentum space integrals. For this we express all distributions explicitly in terms of modified Bessel functions $K_\alpha(y)$.

10.9.1 Correlation Function and Derivatives

The basic correlation function in d -dimension is obtained from the integral in Eq. (10.234), as

$$\Delta(\tau) = c_d y^{1-d/2} K_{1-d/2}(y), \quad (10.327)$$

where $y \equiv m|\tau|$ is reduced length of τ_α , with the usual Euclidean norm $|x| = \sqrt{\tau_1^2 + \dots + \tau_d^2}$, and $K_{1-d/2}(y)$ is the modified Bessel function. The constant factor in front is

$$c_d = \frac{\omega^{d-2}}{(2\pi)^{d/2}}. \quad (10.328)$$

In one dimension, the correlation function (10.327) reduces to (10.202). The short-distance properties of the correlation functions is governed by the small- y behavior of Bessel function at origin⁴

$$K_\beta(y) \underset{y \approx 0}{\approx} \frac{1}{2} \Gamma(\beta) (y/2)^{\mp\beta}, \quad \text{Re } \beta \gtrsim 0. \quad (10.329)$$

In the application to path integrals, we set the dimension equal to $d = 1 - \varepsilon$ with a small positive ε , whose limit $\varepsilon \rightarrow 0$ will yield the desired results in $d = 1$ dimension. In this regime, Eq. (10.329) shows that the correlation function (10.327) is regular at the origin, yielding once more (10.293). For $d = 1$, the result is $\Delta(0) = 1/2\omega$, as stated in Eq. (10.298).

The first derivative of the correlation function (10.327), which is the d -dimensional extension of time derivative (10.203), reads

$$\Delta_\alpha(\tau) = -c_d y^{1-d/2} K_{d/2}(y) \partial_\alpha y, \quad (10.330)$$

where $\partial_\alpha y = m \tau_\alpha / |x|$. By Eq. (10.329), this is regular at the origin for $\varepsilon > 0$, such that the antisymmetry $\Delta_\alpha(-x) = -\Delta_\alpha(x)$ makes $\Delta_\alpha(0) = 0$, as observed after Eq. (10.294).

Explicitly, the small- τ behavior of the correlation function and its derivative is

$$\Delta(\tau) \propto \text{const.}, \quad \Delta_\alpha(\tau) \propto |\tau|^\varepsilon \partial_\alpha |\tau|. \quad (10.331)$$

In contrast to these two correlation functions, the second derivative

$$\Delta_{\alpha\beta}(\tau) = \Delta(\tau) (\partial_\alpha y)(\partial_\beta y) + \frac{c_d}{(d-2)} y^{d/2} K_{d/2}(y) \partial_{\alpha\beta} y^{2-d}, \quad (10.332)$$

is singular at short distance. The singularity comes from the second term in (10.332):

$$\partial_{\alpha\beta} y^{2-d} = (2-d) \frac{\omega^{2-d}}{|y|^d} \left(\delta_{\alpha\beta} - d \frac{y_\alpha y_\beta}{y^2} \right), \quad (10.333)$$

which is a distribution that is ambiguous at origin, and defined up to the addition of a $\delta^{(d)}(\tau)$ -function. It is regularized in the same way as the divergence in the Fourier representation (10.292). Contracting the indices α and β in Eq. (10.333), we obtain

$$\partial^2 y^{2-d} = (2-d) \omega^{2-d} S_d \delta^{(d)}(\tau), \quad (10.334)$$

where $S_d = 2\pi^{d/2}/\Gamma(d/2)$ is the surface of a unit sphere in d dimensions [recall Eq. (1.558)]. As a check, we take the trace of $\Delta_{\alpha\beta}(\tau)$ in Eq. (10.332), and reproduce the inhomogeneous field equation (10.296):

$$\begin{aligned} \Delta_{\alpha\alpha}(\tau) &= \omega^2 \Delta(\tau) - c_d m^{2-d} S_d \frac{1}{2} \Gamma(d/2) 2^{d/2} \delta^{(d)}(\tau) \\ &= \omega^2 \Delta(\tau) - \delta^{(d)}(\tau). \end{aligned} \quad (10.335)$$

Since $\delta^{(d)}(\tau)$ vanishes at the origin by (10.292), we find once more Eq. (10.298).

A further relation between distributions is found from the derivative

$$\partial_\alpha \Delta_{\alpha\beta}(\tau) = \partial_\beta \left[-\delta^{(d)}(\tau) + \omega^2 \Delta(\tau) \right] + \omega S_d \left[\Delta(\tau) |y|^{d-1} (\partial_\beta y) \right] \delta^{(d)}(\tau) = \partial_\beta \Delta_{\lambda\lambda}(\tau). \quad (10.336)$$

⁴M. Abramowitz and I. Stegun, *op. cit.*, Formula 9.6.9.

10.9.2 Integrals over Products of Two Distributions

Consider now the integrals over products of such distributions. If an integrand $f(|x|)$ depends only on $|x|$, we may perform the integrals over the directions of the vectors

$$\int d^d \tau f(\tau) = S_d \int_0^\infty dr r^{d-1} f(r), \quad r \equiv |x|. \tag{10.337}$$

Using the integral formula⁵

$$\int_0^\infty dy y K_\beta^2(y) = \frac{1}{2} \frac{\pi \beta}{\sin \pi \beta} = \frac{1}{2} \Gamma(1 + \beta) \Gamma(1 - \beta), \tag{10.338}$$

we can calculate directly:

$$\begin{aligned} \int d^d \tau \Delta^2(\tau) &= \omega^{-d} c_d^2 S_d \int_0^\infty dy y K_{1-d/2}^2(y) \\ &= \omega^{-d} c_d^2 S_d \frac{1}{2} (1-d/2) \Gamma(1-d/2) \Gamma(d/2) = \frac{2-d}{2\omega^2} \Delta(0), \end{aligned} \tag{10.339}$$

and

$$\begin{aligned} \int d^d \tau \Delta_\alpha^2(\tau) &= \omega^{2-d} c_d^2 S_d \int_0^\infty dy y K_{d/2}^2(y) \\ &= \omega^{2-d} c_d^2 S_d \frac{1}{2} \Gamma(1+d/2) \Gamma(1-d/2) = \frac{d}{2} \Delta(0), \end{aligned} \tag{10.340}$$

in agreement with Eqs. (10.301) and (10.302). Inserting $\Delta(0) = 1/2\omega$ from (10.293), these integrals give us once more the values of the Feynman diagrams (10.249), (10.252), (10.253), (10.256), and (10.258).

Note that due to the relation⁶

$$K_{d/2}(y) = -y^{d/2-1} \frac{d}{dy} \left[y^{1-d/2} K_{1-d/2}(y) \right], \tag{10.341}$$

the integral over y in Eq. (10.340) can also be performed by parts, yielding

$$\begin{aligned} \int d^d \tau \Delta_\alpha^2(\tau) &= -\omega^{2-d} c_d^2 S_d \left(y^{d/2} K_{d/2} \right) \left(y^{1-d/2} K_{1-d/2} \right) \Big|_0^\infty - \omega^2 \int d^d \tau \Delta^2(\tau) \\ &= \Delta(0) - \omega^2 \int d^d \tau \Delta^2(\tau). \end{aligned} \tag{10.342}$$

The upper limit on the right-hand side gives zero because of the exponentially fast decrease of the Bessel function at infinity. This was obtained before in Eq. (10.302) from a partial integration and the inhomogeneous field equation (10.296).

Using the explicit representations (10.327) and (10.332), we calculate similarly the integral

$$\begin{aligned} \int d^d \tau \Delta_{\alpha\alpha}^2(\tau) &= \int d^d \tau \Delta_{\alpha\beta}^2(\tau) = \omega^4 \int d^d \tau \Delta^2(\tau) - \omega^{4-d} c_d^2 \Gamma(d/2) \Gamma(1-d/2) S_d \\ &= \omega^4 \int d^d \tau \Delta^2(\tau) - 2\omega^2 \Delta(0) = -(1+d/2) \omega^2 \Delta(0). \end{aligned} \tag{10.343}$$

⁵I.S. Gradshteyn and I.M. Ryzhik, *op. cit.*, Formula 6.521.3

⁶*ibid.*, Formulas 8.485 and 8.486.12

The first equality follows from partial integrations. In the last equality we have used (10.339). We have omitted the integral containing the modified Bessel functions

$$(d - 1) \left[\int_0^\infty dz K_{d/2}(z) K_{1-d/2}(z) + \frac{d}{2} \int_0^\infty dz z^{-1} K_{d/2}^2(z) \right], \tag{10.344}$$

since this vanishes in one dimension as follows:

$$-\frac{\pi}{4} \Gamma(1 - \varepsilon/2) [\Gamma(\varepsilon/2) + \Gamma(-\varepsilon/2)] \varepsilon^2 \Gamma(\varepsilon) \underset{\varepsilon \rightarrow 0}{=} 0.$$

Inserting into (10.343) $\Delta(0) = 1/2\omega$ from (10.293), we find once more the value of the right-hand Feynman integral (10.250) and the middle one in (10.253).

By combining the result (10.303) with (10.339) and (10.340), we can derive by proper integrations the fundamental rule in this generalized distribution calculus that the integral over the square of the δ -function vanishes. Indeed, solving the inhomogeneous field equation (10.296) for $\delta^{(d)}(\tau)$, and squaring it, we obtain

$$\int d^d\tau \left[\delta^{(d)}(\tau) \right]^2 = \omega^4 \int d^d\tau \Delta^2(\tau) + 2\omega^2 \int d^d\tau \Delta_\alpha^2(\tau) + \int d^d\tau \Delta_{\beta\beta}^2(\tau) = 0. \tag{10.345}$$

Thus we may formally calculate

$$\int d^d\tau \delta^{(d)}(\tau) \delta^{(d)}(\tau) = \delta^{(d)}(0) = 0, \tag{10.346}$$

pretending that one of the two δ -functions is an admissible smooth test function $f(\tau)$ of ordinary distribution theory, where

$$\int d^d\tau \delta^{(d)}(\tau) f(\tau) = f(0). \tag{10.347}$$

10.9.3 Integrals over Products of Four Distributions

The calculation of the configuration space integrals over products of four distributions in $d = 1$ dimension is straightforward as long as they are unique. Only if they are ambiguous, they require a calculation in $d = 1 - \varepsilon$ dimension, with the limit $\varepsilon \rightarrow 0$ taken at the end.

A unique case is

$$\begin{aligned} \int d^d\tau \Delta^4(\tau) &= c_d^4 \omega^{-d} S_d \int_0^\infty dy y^{3-d} K_{1-d/2}^4(y) \\ &\underset{d=1}{=} c_1^4 \omega^{-1} S_1 \frac{\pi^2}{2^4} \Gamma^4\left(\frac{3}{2} - \frac{d}{2}\right) \Gamma(d) = \frac{1}{32\omega^5}, \end{aligned} \tag{10.348}$$

where we have set

$$y \equiv \omega\tau. \tag{10.349}$$

Similarly, we derive by partial integration

$$\begin{aligned} \int d^d\tau \Delta^2(\tau) \Delta_\alpha^2(\tau) &= \omega^{2-d} c_d^4 S_d \int_0^\infty dy y^{3-d} K_{d/2}^2(y) K_{1-d/2}^2(y) \\ &= \frac{1}{3} \omega^{2-d} c_d^4 S_d \left[2^{-d-1} \Gamma(d/2) \Gamma^3(1-d/2) \right. \\ &\quad \left. + \int_0^\infty dy \left(y^{1-d/2} K_{1-d/2} \right)^3 \frac{d}{dy} \left(y^{d/2} K_{d/2} \right) \right] \\ &= \frac{1}{3} \left[\Delta^3(0) - \omega^2 \int d^d\tau \Delta^4(\tau) \right] \underset{d=1}{=} \frac{1}{32\omega}. \end{aligned} \tag{10.350}$$

Using (10.327), (10.330), and (10.332), we find for the integral in $d = 1 - \varepsilon$ dimensions

$$\int d^d \tau \Delta(\tau) \Delta_\alpha(\tau) \Delta_\beta(\tau) \Delta_{\alpha\beta}(\tau) = \omega^2 \int d^d \tau \Delta^2(\tau) \Delta_\alpha^2(\tau) - \frac{1}{2} Y_d, \tag{10.351}$$

where Y_d is the integral

$$Y_d = -2(d-1)\omega^{4-d} c_d^4 S_d \int_0^\infty dy y^{2-d} K_{1-d/2}(y) K_{d/2}^3(y). \tag{10.352}$$

In spite of the prefactor $d - 1$, this has a nontrivial limit for $d \rightarrow 1$, the zero being compensated by a pole from the small- y part of the integral at $y = 0$. In order to see this we use the integral representation of the Bessel function [28]:

$$K_\beta(y) = \pi^{-1/2} (y/2)^{-\beta} \Gamma\left(\frac{1}{2} + \beta\right) \int_0^\infty dt (\cosh t)^{-2\beta} \cos(y \sinh t). \tag{10.353}$$

In one dimension where $\beta = 1/2$, this becomes simply $K_{1/2}(y) = \sqrt{\pi/2y} e^{-y}$. For $\beta = d/2$ and $\beta = 1 - d/2$ written as $\beta = (1 \mp \varepsilon)/2$, it is approximately equal to

$$K_{(1 \mp \varepsilon)/2}(y) = \pi^{-1/2} (y/2)^{-(1 \mp \varepsilon)/2} \Gamma\left(1 \mp \frac{\varepsilon}{2}\right) \times \left[\frac{\pi}{2} e^{-y} \pm \varepsilon \int_0^\infty dt (\cosh t)^{-1} \ln(\cosh t) \cos(y \sinh t) \right], \tag{10.354}$$

where the t -integral is regular at $y = 0$.⁷ After substituting (10.354) into (10.352), we obtain the finite value

$$\begin{aligned} Y_d &\underset{\varepsilon \approx 0}{\approx} 2(\omega^{4-d} c_d^4 S_d) \varepsilon \frac{\pi^2}{4} \Gamma(1 + \varepsilon/2) \Gamma^3(1 - \varepsilon/2) \times 2^{-5\varepsilon} \Gamma(2\varepsilon) \\ &\underset{\varepsilon \rightarrow 0}{=} \left(\frac{1}{2\omega\pi^2}\right) \frac{\pi^2}{4} = \frac{1}{8\omega}. \end{aligned} \tag{10.355}$$

The prefactor $d - 1 = -\varepsilon$ in (10.352) has been canceled by the pole in $\Gamma(2\varepsilon)$.

This integral coincides with the integral (10.312) whose subtle nature was discussed in the momentum space formulation (10.240). Indeed, inserting the Bessel expressions (10.327) and (10.332) into (10.312), we find

$$\begin{aligned} &\int d^d \tau \Delta^2(\tau) [\Delta_{\alpha\beta}^2(\tau) - \Delta_{\alpha\alpha}^2(\tau)] \\ &= -(d-1)\omega^{4-d} c_d^4 S_d \int_0^\infty dy \left[y^{1-d/2} K_{1-d/2}(y) \right]^2 \frac{d}{dy} K_{d/2}^2(y), \end{aligned} \tag{10.356}$$

and a partial integration

$$\int_0^\infty dy \left[y^{1-d/2}(y) K_{1-d/2}(y) \right]^2 \frac{d}{dy} K_{d/2}^2(y) = 2 \int_0^\infty dy y^{2-d} K_{1-d/2}(y) K_{d/2}^3(y) \tag{10.357}$$

establishes contact with the integral (10.352) for Y_d . Thus Eq. (10.351) is the same as (10.321).

Knowing Y_d , we also determine, after integrations by parts, the integral

$$\int d^d \tau \Delta_\alpha^2(\tau) \Delta_\beta^2(\tau) = -3\omega^2 \int d^d \tau \Delta^2(\tau) \Delta_\alpha^2(\tau) + Y_d, \tag{10.358}$$

⁷I.S. Gradshteyn and I.M. Ryzhik, *op. cit.*, Formulas 3.511.1 and 3.521.2.

which is the same as (10.322). It remains to calculate one more unproblematic integral over four distributions:

$$\int d^d\tau \Delta^2(\tau)\Delta_{\lambda\lambda}^2(\tau) = \left[-2\omega^2 \Delta^3(0) + \omega^4 \int d^d\tau \Delta^4(\tau) \right]_{d=1} = -\frac{7}{32\omega}. \quad (10.359)$$

Combining this with (10.355) and (10.358) we find the Feynman diagram (10.281). The combination of (10.351) and (10.358) with (10.355) and (10.350), finally, yields the diagrams (10.325) and (10.324), respectively.

Thus we see that there is no problem in calculating integrals over products of distributions in configuration space which produce the same results as dimensional regularization in momentum space.

10.10 Simple Rules for Calculating Singular Integrals

The above methods of calculating the Feynman integrals in d time dimensions with a subsequent limit $d \rightarrow 1$ are obviously quite cumbersome. It is preferable to develop a simple procedure of finding the same results directly working with a one-dimensional time. This is possible if we only keep track of some basic aspects of the d -dimensional formulation [37].

Consider once more the ambiguous integrals coming from the first two watermelon diagrams in Eq. (10.232), which in the one-dimensional formulation represent the integrals

$$I_1 = \int_{-\infty}^{\infty} d\tau \ddot{\Delta}^2(\tau)\Delta^2(\tau), \quad (10.360)$$

$$I_2 = \int_{-\infty}^{\infty} d\tau \ddot{\Delta}(\tau)\dot{\Delta}^2(\tau)\Delta(\tau), \quad (10.361)$$

evaluated before in the d -dimensional equations (10.284) and (10.282). Consider first the integral (10.360) which contains a square of a δ -function. We separate this out by writing

$$I_1 = \int_{-\infty}^{\infty} d\tau \ddot{\Delta}^2(\tau)\Delta^2(\tau) = I_1^{\text{div}} + I_1^R, \quad (10.362)$$

with a divergent and a regular part

$$I_1^{\text{div}} = \Delta^2(0) \int_{-\infty}^{\infty} d\tau \delta^2(\tau), \quad I_1^R = \int_{-\infty}^{\infty} d\tau \Delta^2(\tau) [\ddot{\Delta}^2(\tau) - \delta^2(\tau)]. \quad (10.363)$$

All other watermelon diagrams (10.232) lead to the well-defined integrals

$$\int_{-\infty}^{\infty} d\tau \Delta^4(\tau) = \frac{1}{4\omega^2} \Delta^3(0), \quad (10.364)$$

$$\int_{-\infty}^{\infty} d\tau \dot{\Delta}^2(\tau)\Delta^2(\tau) = \frac{1}{4} \Delta^3(0), \quad (10.365)$$

$$\int_{-\infty}^{\infty} d\tau \dot{\Delta}^4(\tau) = \frac{1}{4} \omega^2 \Delta^3(0), \quad (10.366)$$

whose D -dimensional versions are (10.274), (10.286), and (10.282). Substituting these and (10.361), (10.362) into (10.232) yields the sum of all watermelon diagrams

$$\begin{aligned} & -\frac{4}{2!} \int_{-\infty}^{\infty} d\tau \left[\Delta^2(\tau) \ddot{\Delta}^2(\tau) + 4\Delta(\tau) \dot{\Delta}^2(\tau) \ddot{\Delta}(\tau) + \dot{\Delta}^4(\tau) + 4\omega^2 \Delta^2(\tau) \dot{\Delta}^2(\tau) + \frac{2}{3} \omega^4 \Delta^4(\tau) \right] \\ & = -2\Delta^2(0) \int_{-\infty}^{\infty} d\tau \delta^2(\tau) - 2(I_1^R + 4I_2) - \frac{17}{6} \omega^2 \Delta^3(0). \end{aligned} \quad (10.367)$$

Adding these to (10.230), (10.231), we obtain the sum of all second-order connected diagrams

$$\Sigma(\text{all}) = 3 \left[\delta(0) - \int_{-\infty}^{\infty} d\tau \delta^2(\tau) \right] \Delta^2(0) - 2(I_1^R + 4I_2) - \frac{7}{2} \omega^2 \Delta^3(0), \quad (10.368)$$

where the integrals I_1^R and I_2 are undefined. The sum has to vanish to guarantee coordinate independence. We therefore equate to zero both the singular and finite contributions in Eq. (10.368). The first yields the rule for the product of two δ -functions: $\delta^2(\tau) = \delta(0) \delta(\tau)$. This equality should of course be understood in the distributional sense: it holds after multiplying it with an arbitrary test function and integrating over τ .

$$\int d\tau \delta^2(\tau) f(\tau) \equiv \delta(0) f(0). \quad (10.369)$$

The equation leads to a perfect cancellation of all powers of $\delta(0)$ arising from the expansion of the Jacobian action, which is the fundamental reason why the heuristic *Veltman rule* of setting $\delta(0) = 0$ is applicable everywhere without problems.

The vanishing of the regular parts of (10.368) requires the integrals (10.361) and (10.362) to satisfy

$$I_1^R + 4I_2 = -\frac{7}{4} \omega^2 \Delta^3(0) = -\frac{7}{32\omega}. \quad (10.370)$$

At this point we run into two difficulties. First, this single equation (10.370) for the two undefined integrals I_1^R and I_2 is insufficient to specify both integrals, so that the requirement of reparametrization invariance alone is not enough to fix all ambiguous temporal integrals over products of distributions. Second, and more seriously, Eq. (10.370) leads to conflicts with standard integration rules based on the use of partial integration and equation of motion, and the independence of the order in which these operations are performed. Indeed, let us apply these rules to the calculation of the integrals I_1^R and I_2 in different orders. Inserting the equation of motion (10.214) into the finite part of the integral (10.362) and making use of the regular integral (10.364), we find immediately

$$\begin{aligned} I_1^R &= \int_{-\infty}^{\infty} d\tau \Delta^2(\tau) \left[\ddot{\Delta}^2(\tau) - \delta^2(\tau) \right] \\ &= -2\omega^2 \Delta^3(0) + \omega^4 \int_{-\infty}^{\infty} d\tau \Delta^4(\tau) = -\frac{7}{4} \omega^2 \Delta^3(0) = -\frac{7}{32\omega}. \end{aligned} \quad (10.371)$$

The same substitution of the equation of motion (10.214) into the other ambiguous integral I_2 of (10.361) leads, after performing the regular integral (10.365), to

$$\begin{aligned} I_2 &= - \int_{-\infty}^{\infty} d\tau \dot{\Delta}^2(\tau) \Delta(\tau) \delta(\tau) + \omega^2 \int_{-\infty}^{\infty} d\tau \dot{\Delta}^2(\tau) \Delta^2(\tau) \\ &= - \frac{1}{8\omega} \int_{-\infty}^{\infty} d\tau \epsilon^2(\tau) \delta(\tau) + \frac{1}{4} \omega^2 \Delta^3(0) = \frac{1}{8\omega} \left(-I_{\epsilon^2\delta} + \frac{1}{4} \right), \end{aligned} \quad (10.372)$$

where $I_{\epsilon^2\delta}$ denotes the undefined integral over a product of distributions

$$I_{\epsilon^2\delta} = \int_{-\infty}^{\infty} d\tau \epsilon^2(\tau) \delta(\tau). \quad (10.373)$$

The integral I_2 can apparently be fixed by applying partial integration to the integral (10.361) which reduces it to the completely regular form (10.366):

$$I_2 = \frac{1}{3} \int_{-\infty}^{\infty} d\tau \Delta(\tau) \frac{d}{d\tau} [\dot{\Delta}^3(\tau)] = -\frac{1}{3} \int_{-\infty}^{\infty} d\tau \dot{\Delta}^4(\tau) = -\frac{1}{12} \omega^2 \Delta^3(0) = -\frac{1}{96\omega}. \quad (10.374)$$

There are no boundary terms due to the exponential vanishing at infinity of all functions involved. From (10.372) and (10.374) we conclude that $I_{\epsilon^2\delta} = 1/3$. This, however, cannot be correct since the results (10.374) and (10.371) do not obey Eq. (10.370) which is needed for coordinate independence of the path integral. This was the reason why previous authors [32, 35] added a noncovariant correction term $\Delta V = -g^2(q^2/6)$ to the classical action (10.186), which is proportional to \hbar and thus violates Feynman's basic postulate that the phase factors $e^{iA/\hbar}$ in a path integral should contain only the classical action along the paths.

We shall see below that the correct value of the singular integral I in (10.373) is

$$I_{\epsilon^2\delta} = \int_{-\infty}^{\infty} d\tau \epsilon^2(\tau) \delta(\tau) = 0. \quad (10.375)$$

From the perspective of the previous sections where all integrals were defined in $d = 1 - \epsilon$ dimensions and continued to $\epsilon \rightarrow 0$ at the end, the inconsistency of $I_{\epsilon^2\delta} = 1/3$ is obvious: Arbitrary application of partial integration and equation of motion to one-dimensional integrals is forbidden, and this is the case in the calculation (10.374). Problems arise whenever several dots can correspond to different contractions of partial derivatives $\partial_\alpha, \partial_\beta, \dots$, from which they arise in the limit $d \rightarrow 1$. The different contractions may lead to different integrals.

In the pure one-dimensional calculation of the integrals I_1^R and I_2 , all ambiguities can be accounted for by using partial integration and equation of motion (10.214) only according to the following integration rules:

RULE 1. We perform a partial integration which allows us to apply subsequently the equation of motion (10.214).

RULE 2. If the equation of motion (10.214) leads to integrals of the type (10.373), they must be performed using naively the Dirac rule for the δ -function and the

property $\epsilon(0) = 0$. Examples are (10.375) and the trivially vanishing integrals for all odd powers of $\epsilon(\tau)$:

$$\int d\tau \epsilon^{2n+1}(\tau) \delta(\tau) = 0, \quad n = \text{integer}, \quad (10.376)$$

which follow directly from the antisymmetry of $\epsilon^{2n+1}(\tau)$ and the symmetry of $\delta(\tau)$ contained in the regularized expressions (10.330) and (10.332).

RULE 3. The above procedure leaves in general singular integrals, which must be treated once more with the same rules.

Let us show that calculating the integrals I_1^R and I_2 with these rules is consistent with the coordinate independence condition (10.370). In the integral I_2 of (10.361) we first apply partial integration to find

$$\begin{aligned} I_2 &= \frac{1}{2} \int_{-\infty}^{\infty} d\tau \Delta(\tau) \dot{\Delta}(\tau) \frac{d}{d\tau} [\dot{\Delta}^2(\tau)] \\ &= -\frac{1}{2} \int_{-\infty}^{\infty} d\tau \dot{\Delta}^4(\tau) - \frac{1}{2} \int_{-\infty}^{\infty} d\tau \Delta(\tau) \dot{\Delta}^2(\tau) \ddot{\Delta}(\tau), \end{aligned} \quad (10.377)$$

with no contributions from the boundary terms. Note that the partial integration (10.374) is forbidden since it does not allow for a subsequent application of the equation of motion (10.214). On the right-hand side of (10.377) it can be applied. This leads to a combination of two regular integrals (10.365) and (10.366) and the singular integral I , which we evaluate with the naive Dirac rule to $I = 0$, resulting in

$$\begin{aligned} I_2 &= -\frac{1}{2} \int_{-\infty}^{\infty} d\tau \dot{\Delta}^4(\tau) + \frac{1}{2} \int_{-\infty}^{\infty} d\tau \dot{\Delta}^2(\tau) \Delta(\tau) \delta(\tau) - \frac{1}{2} \omega^2 \int_{-\infty}^{\infty} d\tau \dot{\Delta}^2(\tau) \Delta^2(\tau) \\ &= \frac{1}{16\omega} I - \frac{1}{4} \omega^2 \Delta^3(0) = -\frac{1}{32\omega}. \end{aligned} \quad (10.378)$$

If we calculate the finite part I_1^R of the integral (10.362) with the new rules we obtain a result different from (10.371). Integrating the first term in brackets by parts and using the equation of motion (10.214), we obtain

$$\begin{aligned} I_1^R &= \int_{-\infty}^{\infty} d\tau \Delta^2(\tau) [\ddot{\Delta}^2(\tau) - \delta^2(\tau)] \\ &= \int_{-\infty}^{\infty} d\tau [-\ddot{\Delta}(\tau) \dot{\Delta}(\tau) \Delta^2(\tau) - 2\ddot{\Delta}(\tau) \dot{\Delta}^2(\tau) \Delta(\tau) - \Delta^2(\tau) \delta^2(\tau)] \\ &= \int_{-\infty}^{\infty} d\tau [\dot{\Delta}(\tau) \Delta^2(\tau) \dot{\delta}(\tau) - \Delta^2(\tau) \delta^2(\tau)] - 2I_2 - \omega^2 \int_{-\infty}^{\infty} d\tau \dot{\Delta}^2(\tau) \Delta^2(\tau). \end{aligned} \quad (10.379)$$

The last two terms are already known, while the remaining singular integral in brackets must be subjected once more to the same treatment. It is integrated by parts so that the equation of motion (10.214) can be applied to obtain

$$\begin{aligned} \int_{-\infty}^{\infty} d\tau [\dot{\Delta}(\tau) \Delta^2(\tau) \dot{\delta}(\tau) - \Delta^2(\tau) \delta^2(\tau)] &= - \int_{-\infty}^{\infty} d\tau [\ddot{\Delta}(\tau) \Delta^2(\tau) + 2\dot{\Delta}^2(\tau) \Delta(\tau)] \delta(\tau) \\ &\quad - \int_{-\infty}^{\infty} d\tau \Delta^2(\tau) \delta^2(\tau) = -\omega^2 \Delta^3(0) - \frac{1}{4\omega} I. \end{aligned} \quad (10.380)$$

Inserting this into Eq. (10.379) yields

$$I_1^R = \int_{-\infty}^{\infty} d\tau \Delta^2(\tau) [\ddot{\Delta}^2(\tau) - \delta^2(\tau)] = -2I_2 - \frac{5}{4}\omega^2 \Delta^3(0) - \frac{1}{4\omega} I = -\frac{3}{32\omega}, \quad (10.381)$$

the right-hand side following from $I = 0$, which is a consequence of Rule 3.

We see now that the integrals (10.378) and (10.381) calculated with the new rules obey Eq. (10.370) which guarantees coordinate independence of the path integral.

The applicability of Rules 1–3 follows immediately from the previously established dimensional continuation [23, 24]. It avoids completely the cumbersome calculations in $1 - \varepsilon$ -dimension with the subsequent limit $\varepsilon \rightarrow 0$. Only some intermediate steps of the derivation require keeping track of the d -dimensional origin of the rules. For this, we continue the imaginary time coordinate τ to a d -dimensional spacetime vector $\tau \rightarrow \tau^\mu = (\tau^0, \tau^1, \dots, \tau^{d-1})$, and note that the equation of motion (10.214) becomes a scalar field equation of the Klein-Gordon type

$$(-\partial_\alpha^2 + \omega^2) \Delta(\tau) = \delta^{(d)}(\tau). \quad (10.382)$$

In d dimensions, the relevant second-order diagrams are obtained by decomposing the harmonic expectation value

$$\int d^d\tau \langle q_\alpha^2(\tau) q^2(\tau) q_\beta^2(0) q^2(0) \rangle \quad (10.383)$$

into a sum of products of four two-point correlation functions according to the Wick rule. The fields $q_\alpha(\tau)$ are the d -dimensional extensions $q_\alpha(\tau) \equiv \partial_\alpha q(\tau)$ of $\dot{q}(\tau)$. Now the d -dimensional integrals, corresponding to the integrals (10.360) and (10.361), are defined uniquely by the contractions

$$\begin{aligned} I_1^d &= \int d^d\tau \left\langle \overbrace{q_\alpha(\tau) q_\alpha(\tau) q(\tau) q(\tau) q_\beta(0) q_\beta(0) q(0) q(0)} \right\rangle \\ &= \int d^d\tau \Delta^2(\tau) \Delta_{\alpha\beta}^2(\tau), \end{aligned} \quad (10.384)$$

$$\begin{aligned} I_2^d &= \int d^d\tau \left\langle \overbrace{q_\alpha(\tau) q_\alpha(\tau) q(\tau) q(\tau) q_\beta(0) q_\beta(0) q(0) q(0)} \right\rangle \\ &= \int d^d\tau \Delta(\tau) \Delta_\alpha(\tau) \Delta_\beta(\tau) \Delta_{\alpha\beta}(\tau). \end{aligned} \quad (10.385)$$

The different derivatives $\partial_\alpha \partial_\beta$ acting on $\Delta(\tau)$ prevent us from applying the field equation (10.382). This obstacle was hidden in the one-dimensional formulation. It can be overcome by a partial integration. Starting with I_2^d , we obtain

$$I_2^d = -\frac{1}{2} \int d^d\tau \Delta_\beta^2(\tau) [\Delta_\alpha^2(\tau) + \Delta(\tau) \Delta_{\alpha\alpha}(\tau)]. \quad (10.386)$$

Treating I_1^d likewise we find

$$I_1^d = -2I_2^d + \int d^d\tau \Delta^2(\tau) \Delta_{\alpha\alpha}^2(\tau) + 2 \int d^d\tau \Delta(\tau) \Delta_\beta^2(\tau) \Delta_{\alpha\alpha}(\tau). \quad (10.387)$$

In the second equation we have used the fact that $\partial_\alpha \Delta_{\alpha\beta} = \partial_\beta \Delta_{\lambda\lambda}$. The right-hand sides of (10.386) and (10.387) contain now the contracted derivatives ∂_α^2 such that we can apply the field equation (10.382). This mechanism works to all orders in the perturbation expansion which is the reason for the applicability of Rules 1 and 2 which led to the results (10.378) and (10.381) ensuring coordinate independence.

The value $I_{\epsilon^2\delta} = 0$ according to the Rule 2 can be deduced from the regularized equation (10.386) in $d = 1 - \epsilon$ dimensions by using the field equation (10.335) to rewrite I_2^d as

$$\begin{aligned} I_2^d &= -\frac{1}{2} \int d^d\tau \Delta_\beta^2(\tau) [\Delta_\alpha^2(\tau) + \omega^2 \Delta^2(\tau) - \Delta(\tau) \delta^{(d)}(\tau)] \\ &\stackrel{d \approx 1}{\approx} -\frac{1}{32\omega} + \frac{1}{2} \int d^d\tau \Delta_\beta^2(\tau) \Delta_\alpha^2(\tau) \Delta(\tau) \delta^{(d)}(\tau). \end{aligned}$$

Comparison with (10.372) yields the regularized expression for $I_{\epsilon^2\delta}$

$$I_{\epsilon^2\delta}^R = \left[\int_{-\infty}^{\infty} d\tau \epsilon^2(\tau) \delta(\tau) \right]^R = 8\omega \int d^d\tau \Delta_\beta^2(\tau) \Delta(\tau) \delta^{(d)}(\tau) = 0, \quad (10.388)$$

the vanishing for all $\epsilon > 0$ being a consequence of the small- τ behavior $\Delta(\tau) \Delta_\alpha^2(\tau) \propto |\tau|^{2\epsilon}$, which follows directly from (10.331).

Let us briefly discuss an alternative possibility of giving up partial integration completely in ambiguous integrals containing ϵ - and δ -function, or their time derivatives, which makes unnecessary to satisfy Eq. (10.374). This yields a freedom in the definition of integral over product of distribution (10.373) which can be used to fix $I_{\epsilon^2\delta} = 1/4$ from the requirement of coordinate independence [25]. Indeed, this value of I would make the integral (10.372) equal to $I_2 = 0$, such that (10.370) would be satisfied and coordinate independence ensured. In contrast, giving up partial integration, the authors of Refs. [31, 33] have assumed the vanishing $\epsilon^2(\tau)$ at $\tau = 0$ so that the integral $I_{\epsilon^2\delta}$ should vanish as well: $I_{\epsilon^2\delta} = 0$. Then Eq. (10.372) yields $I_2 = 1/32\omega$ which together with (10.371) does not obey the coordinate independence condition (10.370), making yet another noncovariant quantum correction $\Delta V = g^2(q^2/2)$ necessary in the action, which we reject since it contradicts Feynman's original rules of path integration. We do not consider giving up partial integration as an attractive option since it is an important tool for calculating higher-loop diagrams.

10.11 Perturbative Calculation on Finite Time Intervals

The above calculation rules can be extended with little effort to path integrals of time evolution amplitudes on finite time intervals. We shall use an imaginary time interval with $\tau_a = 0$ and $\tau_b = \beta$ to have the closest connection to statistical mechanics. The ends of the paths will be fixed at τ_a and τ_b to be able to extract quantum-mechanical time evolution amplitudes by a mere replacement $\tau \rightarrow -it$. The extension to a finite time interval is nontrivial since the Feynman integrals in frequency space become sums over discrete frequencies whose d -dimensional generalizations can usually not be evaluated with standard formulas. The above ambiguities of the integrals, however, will appear in the sums in precisely the same way as before. The reason is that they stem from

ordering ambiguities between q and \dot{q} in the perturbation expansions. These are properties of small time intervals and thus of high frequencies, where the sums can be approximated by integrals. In fact, we have seen in the last section, that all ambiguities can be resolved by a careful treatment of the singularities of the correlation functions at small temporal spacings. For integrals on a time axis it is thus completely irrelevant whether the total time interval is finite or infinite, and the ambiguities can be resolved in the same way as before [38].

This can also be seen technically by calculating the frequency sums in the Feynman integrals of finite-time path integrals with the help of the Euler-Maclaurin formula (2.594) or the equivalent ζ -function methods described in Subsection 2.15.6. The lowest approximation involves the pure frequency integrals whose ambiguities have been resolved in the preceding sections. The remaining correction terms in powers of the temperature $T = 1/\beta$ are all unique and finite [see Eq. (2.598) or (2.558)].

The calculations of the Feynman integrals will most efficiently proceed in configuration space as described in Subsection 10.8.1. Keeping track of certain minimal features of the unique definition of all singular integrals in d dimensions, we shall develop reduction rules based on the equation of motion and partial integration. These will allow us to bring all singular Feynman integrals to a regular form in which the integrations can be done directly in one dimension. The integration rules will be in complete agreement with much more cumbersome calculations in d dimensions with the limit $d \rightarrow 1$ taken at the end.

10.11.1 Diagrammatic Elements

The perturbation expansion for an evolution amplitude over a finite imaginary time proceeds as described in Section 10.6, except that the free energy in Eq. (10.201) becomes [recall (2.526)]

$$\begin{aligned} \beta F_\omega &= \frac{D}{2\beta} \text{Tr} \log(-\partial^2 + \omega^2) = \frac{D}{2\beta} \sum_n \log(\omega_n^2 + \omega^2) \\ &= \frac{D}{\beta} \log [2 \sinh(\hbar\beta\omega/2)]. \end{aligned} \quad (10.389)$$

As before, the diagrams contain four types of lines representing the correlation functions (10.202)–(10.191). Their explicit forms are, however, different. It will be convenient to let the frequency ω in the free part of the action (10.187) go to zero. Then the free energy (10.389) diverges logarithmically in ω . This divergence is, however, trivial. As explained in Section 2.9, the divergence is removed by replacing ω by the length of the q -axis according to the rule (2.361). For finite time intervals, the correlation functions are no longer given by (10.207) which would not have a finite limit for $\omega \rightarrow 0$. Instead, they satisfy Dirichlet boundary conditions, where we can go to $\omega = 0$ without problem. The finiteness of the time interval removes a possible infrared divergence for $\omega \rightarrow 0$. The Dirichlet boundary conditions fix the paths at the ends of the time interval $(0, \beta)$ making the fluctuations vanish, and thus also their correlation functions:

$$G_{\mu\nu}^{(2)}(0, \tau') = G_{\mu\nu}^{(2)}(\beta, \tau') = 0, \quad G_{\mu\nu}^{(2)}(\tau, 0) = G_{\mu\nu}^{(2)}(\tau, \beta) = 0. \quad (10.390)$$

The first correlation function corresponding to (10.206) is now

$$G_{\mu\nu}^{(2)}(\tau, \tau') = \delta_{\mu\nu} \Delta(\tau, \tau') = \text{---} , \quad (10.391)$$

where

$$\Delta(\tau, \tau') = \Delta(\tau', \tau) = \frac{1}{\beta} (\beta - \tau_>) \tau_< = \frac{1}{2} [-\epsilon(\tau - \tau')(\tau - \tau') + \tau + \tau'] - \frac{\tau\tau'}{\beta}, \quad (10.392)$$

abbreviates the Euclidean version of $G_0(t, t')$ in Eq. (3.39). Being a Green function of the free equation of motion (10.213) for $\omega = 0$, this satisfies the inhomogeneous differential equations

$$\ddot{\Delta}(\tau, \tau') = \ddot{\Delta}(\tau, \tau') = -\delta(\tau - \tau'), \quad (10.393)$$

by analogy with Eq. (10.214) for $\omega = 0$. In addition, there is now an independent equation in which the two derivatives act on the different time arguments:

$$\dot{\Delta}(\tau, \tau') = \delta(\tau - \tau') - 1/\beta. \tag{10.394}$$

For a finite time interval, the correlation functions (10.203) (10.204) differ by more than just a sign [recall (10.210)]. We therefore must distinguish the derivatives depending on whether the left or the right argument are differentiated. In the following, we shall denote the derivatives with respect to τ or τ' by a dot on the left or right, respectively, writing

$$\dot{\Delta}(\tau, \tau') \equiv \frac{d}{d\tau} \Delta(\tau, \tau'), \quad \dot{\Delta}'(\tau, \tau') \equiv \frac{d}{d\tau'} \Delta(\tau, \tau'). \tag{10.395}$$

Differentiating (10.392) we obtain explicitly

$$\dot{\Delta}(\tau, \tau') = -\frac{1}{2}\epsilon(\tau - \tau') + \frac{1}{2} - \frac{\tau'}{\beta}, \quad \dot{\Delta}'(\tau, \tau') = \frac{1}{2}\epsilon(\tau - \tau') + \frac{1}{2} - \frac{\tau}{\beta} = \dot{\Delta}'(\tau', \tau). \tag{10.396}$$

The discontinuity at $\tau = \tau'$ which does not depend on the boundary condition is of course the same as before, The two correlation functions (10.208) and (10.210) and their diagrammatic symbols are now

$$\partial_\tau G_{\mu\nu}^{(2)}(\tau, \tau') \equiv \langle \dot{q}_\mu(\tau) q_\nu(\tau') \rangle = \delta_{\mu\nu} \dot{\Delta}(\tau, \tau') = \text{---} \text{---} \text{---}, \tag{10.397}$$

$$\partial_{\tau'} G_{\mu\nu}^{(2)}(\tau, \tau') \equiv \langle q_\mu(\tau) \dot{q}_\nu(\tau') \rangle = \delta_{\mu\nu} \dot{\Delta}'(\tau, \tau') = \text{---} \text{---} \text{---}. \tag{10.398}$$

The fourth correlation function (10.212) is now

$$\partial_\tau \partial_{\tau'} G_{\mu\nu}^{(2)}(\tau, \tau') = \delta_{\mu\nu} \dot{\Delta}'(\tau, \tau') = \text{---} \text{---} \text{---}, \tag{10.399}$$

with $\dot{\Delta}'(\tau, \tau')$ being given by (10.394). Note the close similarity but also the difference of this with respect to the equation of motion (10.393).

10.11.2 Cumulant Expansion of D -Dimensional Free-Particle Amplitude in Curvilinear Coordinates

We shall now calculate the partition function of a point particle in curved space for a finite time interval. Starting point is the integral over the diagonal amplitude of a free point particle of unit mass $(\mathbf{x}_a\beta|\mathbf{x}_a0)$ in flat D -dimensional space

$$Z = \int d^D x_a (\mathbf{x}_a\beta|\mathbf{x}_a0), \tag{10.400}$$

with the path integral representation

$$(\mathbf{x}_a\beta|\mathbf{x}_a0)_0 = \int \mathcal{D}^D x e^{-\mathcal{A}^{(0)}[\mathbf{x}]}, \tag{10.401}$$

where $\mathcal{A}^{(0)}[\mathbf{x}]$ is the free-particle action

$$\mathcal{A}^{(0)}[x] = \frac{1}{2} \int_0^\beta d\tau \dot{\mathbf{x}}^2(\tau). \tag{10.402}$$

Performing the Gaussian path integral leads to

$$(\mathbf{x}_a\beta|\mathbf{x}_a0)_0 = e^{-(D/2)\text{Tr} \log(-\partial^2)} = [2\pi\beta]^{-D/2}, \tag{10.403}$$

where the trace of the logarithm is evaluated with Dirichlet boundary conditions. The result is of course the D -dimensional imaginary-time version of the fluctuation factor (2.130) in natural units. A coordinate transformation $x^i(\tau) = x^i(q^\mu(\tau))$ mapping \mathbf{x}_a to q_a^μ brings the action (10.402) to the form (10.186) with $V(q(\tau)) = 0$:

$$\mathcal{A}[q] = \frac{1}{2} \int_0^\beta d\tau g_{\mu\nu}(q(\tau)) \dot{q}^\mu(\tau) \dot{q}^\nu(\tau), \quad \text{with } g_{\mu\nu}(q) \equiv \frac{\partial x^i(q)}{\partial q^\mu} \frac{\partial x^i(q)}{\partial q^\nu}. \quad (10.404)$$

In the formal notation (10.189), the measure transforms as follows:

$$\int \mathcal{D}^D x(\tau) \equiv \prod_\tau \int d^D x(\tau) = J \prod_\tau \int d^D q(\tau) \equiv J \int \mathcal{D}^D q \sqrt{g(q_a)}, \quad (10.405)$$

where $g(q) \equiv \det g_{\mu\nu}(q)$ and J is the Jacobian of the coordinate transformation generalizing (10.220) and (10.219)

$$J = \prod_\tau \left[\sqrt{\frac{\partial x^i(q(\tau))}{\delta q^\mu(\tau)}} \bigg/ \sqrt{\frac{\partial x^i(q_a)}{\delta q_0^\mu}} \right] = \exp \left[\frac{1}{2} \delta(0) \int_0^\beta d\tau \log \frac{g(q(\tau))}{g(q_a)} \right]. \quad (10.406)$$

Thus we may write the transformed path integral (10.401) in the form

$$(\mathbf{x}_a \beta | \mathbf{x}_a 0)_0 \equiv (q_a \beta | q_a 0)_0 = \int \mathcal{D}^D q e^{-\mathcal{A}_{\text{tot}}[q]}, \quad (10.407)$$

with the total action in the exponent

$$\mathcal{A}_{\text{tot}}[q] = \int_0^\beta d\tau \left[\frac{1}{2} g_{\mu\nu}(q(\tau)) \dot{q}^\mu(\tau) \dot{q}^\nu(\tau) - \frac{1}{2} \delta(0) \log \frac{g(q(\tau))}{g(q_a)} \right]. \quad (10.408)$$

Following the rules described in Subsection 10.6.1 we expand the action in powers of $\delta q^\mu(\tau) = q^\mu(\tau) - q_a^\mu$. The action can then be decomposed into a free part

$$\mathcal{A}^{(0)}[q_a, \delta q] = \frac{1}{2} \int_0^\beta d\tau g_{\mu\nu}(q_a) \delta \dot{q}^\mu(\tau) \delta \dot{q}^\nu(\tau) \quad (10.409)$$

and an interacting part written somewhat more explicitly than in (10.194) with (10.188) and (10.193):

$$\begin{aligned} \mathcal{A}_{\text{tot}}^{\text{int}}[q_a, \delta q] &= \int_0^\beta d\tau \frac{1}{2} [g_{\mu\nu}(q) - g_{\mu\nu}(q_a)] \delta \dot{q}^\mu \delta \dot{q}^\nu \\ &\quad - \int_0^\beta d\tau \frac{1}{2} \delta(0) \left\{ \left[\frac{g(q_a + \delta q)}{g(q_a)} - 1 \right] - \frac{1}{2} \left[\frac{g(q_a + \delta q)}{g(q_a)} - 1 \right]^2 + \dots \right\}. \end{aligned} \quad (10.410)$$

For simplicity, we assume the coordinates to be orthonormal at q_a^μ , i.e., $g_{\mu\nu}(q_a) = \delta_{\mu\nu}$. The path integral (10.407) is now formally defined by a perturbation expansion similar to (10.199):

$$\begin{aligned} (q_a \beta | q_a 0) &= \int \mathcal{D}^D q e^{\mathcal{A}^{(0)}[q] - \mathcal{A}_{\text{tot}}^{\text{int}}[q]} = \int \mathcal{D}^D q e^{-\mathcal{A}^{(0)}[q]} \left(1 - \mathcal{A}_{\text{tot}}^{\text{int}} + \frac{1}{2} \mathcal{A}_{\text{tot}}^{\text{int}2} - \dots \right) \\ &= (2\pi\beta)^{-D/2} \left[1 - \langle \mathcal{A}_{\text{tot}}^{\text{int}} \rangle + \frac{1}{2} \langle \mathcal{A}_{\text{tot}}^{\text{int}2} \rangle - \dots \right], \\ &= (2\pi\beta)^{-D/2} \exp \left\{ -\langle \mathcal{A}_{\text{tot}}^{\text{int}} \rangle_c + \frac{1}{2} \langle \mathcal{A}_{\text{tot}}^{\text{int}2} \rangle_c - \dots \right\} \equiv e^{-\beta f(q)}, \end{aligned} \quad (10.411)$$

with the harmonic expectation values

$$\langle \dots \rangle = (2\pi\beta)^{D/2} \int \mathcal{D}^D q(\tau) (\dots) e^{-\mathcal{A}^{(0)}[q]} \quad (10.412)$$

and their cumulants $\langle \mathcal{A}_{\text{tot}}^{\text{int}2} \rangle_c = \langle \mathcal{A}_{\text{tot}}^{\text{int}2} \rangle - \langle \mathcal{A}_{\text{tot}}^{\text{int}} \rangle^2, \dots$ [recall (3.485), (3.486)], containing only connected diagrams. To emphasize the analogy with the cumulant expansion of the free energy in (10.199), we have defined the exponent in (10.411) as $-\beta f(q)$. This q -dependent quantity $f(q)$ is closely related to the alternative effective classical potential discussed in Subsection 3.25.4, apart from a normalization factor:

$$e^{-\beta f(q)} = \frac{1}{\sqrt{2\pi\hbar^2/Mk_B T}} e^{-\beta \bar{V}_\omega^{\text{eff cl}}(q)}. \quad (10.413)$$

If our calculation procedure respects coordinate independence, all expansion terms of $\beta f(q)$ must vanish to yield the trivial exact results (10.401).

10.11.3 Propagator in $1 - \varepsilon$ Time Dimensions

In the dimensional regularization of the Feynman integrals on an infinite time interval in Subsection 10.7.2 we have continued all Feynman diagrams in momentum space to $d = 1 - \varepsilon$ time dimensions. For the present Dirichlet boundary conditions, this standard continuation of quantum field theory is not directly applicable since the integrals in momentum space become sums over discrete frequencies $\nu_n = \pi n/\beta$ [compare (3.64)]. For such sums one has to set up completely new rules for a continuation, and there are many possibilities for doing this. Fortunately, it will not be necessary to make a choice since we can use the method developed in Subsection 10.10 to avoid continuations altogether. and work in a single physical time dimension. For a better understanding of the final procedure it is, however, useful to see how a dimensional continuation could proceed. We extend the imaginary time coordinate τ to a d -dimensional spacetime vector whose zeroth component is τ : $z^\mu = (\tau, z^1, \dots, z^{d-1})$. In $d = 1 - \varepsilon$ dimensions, the extended correlation function reads

$$\Delta(\tau, \mathbf{z}; \tau', \mathbf{z}') = \int \frac{d^\varepsilon k}{(2\pi)^\varepsilon} e^{i\mathbf{k}(\mathbf{z}-\mathbf{z}')} \Delta_\omega(\tau, \tau'), \quad \text{where } \omega \equiv |\mathbf{k}|. \quad (10.414)$$

Here the extra ε -dimensional space coordinates \mathbf{z} are assumed to live on infinite axes with translational invariance along all directions. Only the original τ -coordinate lies in a finite interval $0 \leq \tau \leq \beta$, with Dirichlet boundary conditions. The Fourier component in the integrand $\Delta_\omega(\tau, \tau')$ is the usual one-dimensional correlation function of a harmonic oscillator with the \mathbf{k} -dependent frequency $\omega = |\mathbf{k}|$. It is the Green function which satisfies on the finite τ -interval the equation of motion

$$-\ddot{\Delta}_\omega(\tau, \tau') + \omega^2 \Delta_\omega(\tau, \tau') = \delta(\tau - \tau'), \quad (10.415)$$

with Dirichlet boundary conditions

$$\Delta_\omega(0, \tau) = \Delta_\omega(\beta, \tau) = 0. \quad (10.416)$$

The explicit form was given in Eq. (3.36) for real times. Its obvious continuation to imaginary-time is

$$\Delta_\omega(\tau, \tau') = \frac{\sinh \omega(\beta - \tau_>) \sinh \omega \tau_<}{\omega \sinh \omega \beta}, \quad (10.417)$$

where $\tau_>$ and $\tau_<$ denote the larger and smaller of the imaginary times τ and τ' , respectively.

In d time dimensions, the equation of motion (10.393) becomes a scalar field equation of the Klein-Gordon type. Using Eq. (10.415) we obtain

$$\begin{aligned} \mu\mu \Delta(\tau, \mathbf{z}; \tau', \mathbf{z}') &= \Delta_{\mu\mu}(\tau, \mathbf{z}; \tau', \mathbf{z}') = \ddot{\Delta}(\tau, \mathbf{z}; \tau', \mathbf{z}') + \mathbf{z}\mathbf{z} \Delta(\tau, \mathbf{z}; \tau', \mathbf{z}') \\ &= \int \frac{d^\varepsilon k}{(2\pi)^\varepsilon} e^{i\mathbf{k}(\mathbf{z}-\mathbf{z}')} [\ddot{\Delta}_\omega(\tau, \tau') - \omega^2 \Delta_\omega(\tau, \tau')] = \\ &= -\delta(\tau - \tau') \delta^{(\varepsilon)}(\mathbf{z} - \mathbf{z}') \equiv -\delta^{(d)}(z - z'). \end{aligned} \quad (10.418)$$

The important observation is now that for d spacetime dimensions, perturbation expansion of the path integral yields for the second correlation function $\Delta(\tau, \tau')$ in Eqs. (10.515) and (10.516) the extension ${}_{\mu}\Delta_{\nu}(z, z')$. This function differs from the contracted function ${}_{\mu}\Delta_{\mu}(z, z')$, and from ${}_{\mu\mu}\Delta(z, z')$ which satisfies the field equation (10.418). In fact, all correlation functions $\Delta(\tau, \tau')$ encountered in the diagrammatic expansion which have different time arguments always turn out to have the d -dimensional extension ${}_{\mu}\Delta_{\nu}(z, z')$. An important exception is the correlation function at *equal* times $\Delta(\tau, \tau)$ whose d -dimensional extension is always ${}_{\mu}\Delta_{\mu}(z, z)$, which satisfies the right-hand equation (10.393) in the $\varepsilon \rightarrow 0$ -limit. Indeed, it follows from Eq. (10.414) that

$${}_{\mu}\Delta_{\mu}(z, z) = \int \frac{d^{\varepsilon}k}{(2\pi)^{\varepsilon}} [\Delta_{\omega}(\tau, \tau) + \omega^2 \Delta_{\omega}(\tau, \tau)]. \quad (10.419)$$

With the help of Eq. (10.417), the integrand in Eq. (10.419) can be brought to

$$\Delta_{\omega}(\tau, \tau) + \omega^2 \Delta_{\omega}(\tau, \tau) = \delta(0) - \frac{\omega \cosh \omega(2\tau - \beta)}{\sinh \omega\beta}. \quad (10.420)$$

Substituting this into Eq. (10.419), we obtain

$${}_{\mu}\Delta_{\mu}(z, z) = \delta^{(d)}(z, z) - I^{\varepsilon}. \quad (10.421)$$

The integral I^{ε} is calculated as follows

$$\begin{aligned} I^{\varepsilon} &= \int \frac{d^{\varepsilon}k}{(2\pi)^{\varepsilon}} \frac{\omega \cosh \omega(2\tau - \beta)}{\sinh \omega\beta} = \frac{1}{\beta} \frac{S_{\varepsilon}}{(2\pi\beta)^{\varepsilon}} \int_0^{\infty} dz z^{\varepsilon} \frac{\cosh z(1 - 2\tau/\beta)}{\sinh z} \\ &= \frac{1}{\beta} \frac{S_{\varepsilon}}{(2\pi\beta)^{\varepsilon}} \frac{\Gamma(\varepsilon + 1)}{2^{\varepsilon+1}} [\zeta(\varepsilon + 1, 1 - \tau/\beta) + \zeta(\varepsilon + 1, \tau/\beta)], \end{aligned} \quad (10.422)$$

where $S_{\varepsilon} = 2\pi^{\varepsilon/2}/\Gamma(\varepsilon/2)$ is the surface of a unit sphere in ε dimension [recall Eq. (1.558)], and $\Gamma(z)$ and $\zeta(z, q)$ are gamma and zeta functions, respectively. For small $\varepsilon \rightarrow 0$, they have the limits $\zeta(\varepsilon + 1, q) \rightarrow 1/\varepsilon - \psi(q)$, and $\Gamma(\varepsilon/2) \rightarrow 2/\varepsilon$, so that $I^{\varepsilon} \rightarrow 1/\beta$, proving that the d -dimensional equation (10.421) at coinciding arguments reduces indeed to the one-dimensional equation (10.393). The explicit d -dimensional form will never be needed, since we can always treat ${}_{\mu}\Delta_{\mu}(z, z)$ as one-dimensional functions $\Delta(\tau, \tau)$, which can in turn be replaced everywhere by the right-hand side $\delta(0) - 1/\beta$ of (10.394).

10.11.4 Coordinate Independence for Dirichlet Boundary Conditions

Before calculating the path integral (10.411) in curved space with Dirichlet boundary conditions, let us first verify its coordinate independence following the procedure in Section 10.7. Thus we consider the perturbation expansion of the short-time amplitude of a free particle in one general coordinate. The free action is (10.221), and the interactions (10.222) and (10.224), all with $\omega = 0$. Taking the parameter $a = 1$, the actions are

$$\mathcal{A}^{(0)}[q] = \frac{1}{2} \int_0^{\beta} d\tau \dot{q}^2(\tau), \quad (10.423)$$

$$(10.424)$$

and

$$\mathcal{A}_{\text{tot}}^{\text{int}} = \int_0^{\beta} d\tau \left\{ \left[-\eta \dot{q}^2(\tau) + \frac{3}{2} \eta^2 q^4(\tau) \right] \dot{q}^2(\tau) - \delta(0) \left[-\eta \dot{q}^2(\tau) + \frac{1}{2} \eta^2 q^4(\tau) \right] \right\}. \quad (10.425)$$

We calculate the cumulants $\langle \mathcal{A}_{\text{tot}}^{\text{int}} \rangle_c = \langle \mathcal{A}_{\text{tot}}^{\text{int}} \rangle$, $\langle \mathcal{A}_{\text{tot}}^{\text{int}2} \rangle_c = \langle \mathcal{A}_{\text{tot}}^{\text{int}2} \rangle - \langle \mathcal{A}_{\text{tot}}^{\text{int}} \rangle^2, \dots$ [recall (3.485), (3.486)] contributing to the quantity βf in Eq. (10.411) order by order in η . For a better

comparison with the previous expansion in Subsection 10.7.1 we shall denote the diagrammatic contributions which are analogous to the different free energy terms $\beta F_n^{(m)}$ of order n by corresponding symbols $\beta f_n^{(m)}$. There are two main differences with respect to Subsection 10.7.1: All diagrams with a prefactor ω are absent, and there are new diagrams involving the correlation functions at equal times $\langle \dot{q}^\mu(\tau)q^\nu(\tau) \rangle$ and $\langle q^\mu(\tau)\dot{q}^\nu(\tau) \rangle$ which previously vanished because of (10.211). Here they have the nonzero value $\Delta(\tau, \tau) = \dot{\Delta}(\tau, \tau) = 1/2 - \tau/\beta$ by Eq. (10.396). To first order in η , the quantity $f(q)$ in Eq. (10.411) receives a contribution from the first cumulant of the linear terms in η of the interaction (10.425):

$$\beta f_1 = \langle \mathcal{A}_{\text{tot}}^{\text{int}} \rangle_c = \eta \int_0^\beta d\tau \langle -q^2(\tau)\dot{q}^2(\tau) + \delta(0)q^2(\tau) \rangle + \mathcal{O}(\eta^2). \tag{10.426}$$

There exists only three diagrams, two originating from the kinetic term and one from the Jacobian action:

$$\beta f_1 = -\eta \text{ (diagram 1)} - 2\eta \text{ (diagram 2)} + \eta \delta(0) \text{ (diagram 3)}. \tag{10.427}$$

Note the difference with respect to the diagrams (10.227) for infinite time interval with ω^2 -term in the action.

The omitted η^2 -terms in (10.426) yield the second-order contribution

$$\beta f_2^{(1)} = \eta^2 \int_0^\beta d\tau \left\langle \frac{3}{2} q^4(\tau)\dot{q}^2(\tau) - \delta(0)\frac{1}{2} q^4(\tau) \right\rangle_c. \tag{10.428}$$

The associated local diagrams are [compare (10.228)]:

$$\beta f_2^{(1)} = \eta^2 \left[\frac{9}{2} \text{ (diagram 1)} + 18 \text{ (diagram 2)} - \frac{3}{2} \delta(0) \text{ (diagram 3)} \right]. \tag{10.429}$$

The second cumulant to order η^2 reads

$$-\frac{1}{2!} \eta^2 \int_0^\beta d\tau \int_0^\beta d\tau' \langle [-q^2(\tau)\dot{q}^2(\tau) + \delta(0)q^2(\tau)] [-q^2(\tau')\dot{q}^2(\tau') + \delta(0)q^2(\tau')] \rangle_c,$$

leading to diagrams containing $\delta(0)$:

$$\beta f_2^{(2)} = -\frac{\eta^2}{2!} \left\{ 2 \delta^2(0) \text{ (diagram 1)} - 4 \delta(0) [\text{diagram 2} + 4 \text{ (diagram 3)} + \text{diagram 4}] \right\}. \tag{10.430}$$

The remaining diagrams are either of the three-bubble type, or of the watermelon type, each with all possible combinations of the four line types (10.391) and (10.397)–(10.399). The three-bubbles diagrams yield [compare (10.231)]

$$\beta f_2^{(3)} = -\frac{\eta^2}{2!} \left[4 \text{ (diagram 1)} + 2 \text{ (diagram 2)} - 8 \text{ (diagram 3)} + 4 \text{ (diagram 4)} + 4 \text{ (diagram 5)} + 2 \text{ (diagram 6)} - 8 \text{ (diagram 7)} \right]. \tag{10.431}$$

The watermelon-type diagrams contribute the same diagrams as in (10.232) for $\omega = 0$:

$$\beta f_2^{(4)} = -\frac{\eta^2}{2!} 4 \left[\text{diagram 1} + 4 \text{ (diagram 2)} + \text{diagram 3} \right]. \tag{10.432}$$

For coordinate independence, the sum of the first-order diagrams (10.427) has to vanish. Analytically, this amounts to the equation

$$\beta f_1 = -\eta \int_0^\beta d\tau [\Delta(\tau, \tau)\dot{\Delta}(\tau, \tau) + 2\dot{\Delta}^2(\tau, \tau) - \delta(0)\Delta(\tau, \tau)] = 0. \tag{10.433}$$

In the d -dimensional extension, the correlation function $\dot{\Delta}(\tau, \tau)$ at equal times is the limit $d \rightarrow 1$ of the contracted correlation function ${}_{\mu}\Delta_{\mu}(x, x)$ which satisfies the d -dimensional field equation (10.418). Thus we can use Eq. (10.394) to replace $\dot{\Delta}(\tau, \tau)$ by $\delta(0) - 1/\beta$. This removes the infinite factor $\delta(0)$ in Eq. (10.433) coming from the measure. The remainder is calculated directly:

$$\int_0^{\beta} d\tau \left[-\frac{1}{\beta} \Delta(\tau, \tau) + 2 \dot{\Delta}^2(\tau, \tau) \right] = 0. \quad (10.434)$$

This result is obtained without subtleties, since by Eqs. (10.392) and (10.396)

$$\Delta(\tau, \tau) = \tau - \frac{\tau^2}{\beta}, \quad \dot{\Delta}^2(\tau, \tau) = \frac{1}{4} - \frac{\Delta(\tau, \tau)}{\beta}, \quad (10.435)$$

whose integrals yield

$$\frac{1}{2\beta} \int_0^{\beta} d\tau \Delta(\tau, \tau) = \int_0^{\beta} d\tau \dot{\Delta}^2(\tau, \tau) = \frac{\beta}{12}. \quad (10.436)$$

Let us evaluate the second-order diagrams in $\beta f_2^{(i)}$, $i = 1, 2, 3, 4$. The sum of the local diagrams in (10.429) consists of the integrals by

$$\beta f_2^{(1)} = \frac{3}{2} \eta^2 \int_0^{\beta} d\tau [3\Delta^2(\tau, \tau) \dot{\Delta}(\tau, \tau) + 12\Delta(\tau, \tau) \dot{\Delta}^2(\tau, \tau) - \delta(0)\Delta^2(\tau, \tau)]. \quad (10.437)$$

Replacing $\dot{\Delta}(\tau, \tau)$ in Eq. (10.437) again by $\delta(0) - 1/\beta$, on account of the equation of motion (10.394), and taking into account the right-hand equation (10.435),

$$\beta f_2^{(1)} = \eta^2 \left[3\delta(0) \int_0^{\beta} d\tau \Delta^2(\tau, \tau) \right] = \eta^2 \frac{\beta^3}{10} \delta(0). \quad (10.438)$$

We now calculate the sum of bubble diagrams (10.430)–(10.432), beginning with (10.430) whose analytic form is

$$\begin{aligned} \beta f_2^{(2)} = & -\frac{\eta^2}{2} \int_0^{\beta} \int_0^{\beta} d\tau d\tau' \{ 2\delta^2(0)\Delta^2(\tau, \tau') \\ & - 4\delta(0) [\Delta(\tau, \tau) \dot{\Delta}^2(\tau, \tau') + 4\dot{\Delta}(\tau, \tau)\Delta(\tau, \tau') \dot{\Delta}(\tau, \tau') + \Delta^2(\tau, \tau') \dot{\Delta}(\tau, \tau)] \}. \end{aligned} \quad (10.439)$$

Inserting Eq. (10.394) into the last equal-time term, we obtain

$$\begin{aligned} \beta f_2^{(2)} = & -\frac{\eta^2}{2} \int_0^{\beta} \int_0^{\beta} d\tau d\tau' \{ -2\delta^2(0)\Delta^2(\tau, \tau') \\ & - 4\delta(0) [\Delta(\tau, \tau) \dot{\Delta}^2(\tau, \tau') + 4\dot{\Delta}(\tau, \tau)\Delta(\tau, \tau') \dot{\Delta}(\tau, \tau') - \Delta^2(\tau, \tau')/\beta] \}. \end{aligned} \quad (10.440)$$

As we shall see below, the explicit evaluation of the integrals in this sum is not necessary. Just for completeness, we give the result:

$$\begin{aligned} \beta f_2^{(2)} &= \frac{\eta^2}{2} \left\{ 2\delta^2(0) \frac{\beta^4}{90} + 4\delta(0) \left[\frac{\beta^3}{45} + 4 \frac{\beta^3}{180} - \frac{\beta^3}{90} \right] \right\} \\ &= \eta^2 \left\{ \frac{\beta^4}{90} \delta^2(0) + \frac{\beta^3}{15} \delta(0) \right\}. \end{aligned} \quad (10.441)$$

We now turn to the three-bubbles diagrams (10.432). Only three of these contain the correlation function ${}_{\mu}\Delta_{\nu}(x, x') \rightarrow \dot{\Delta}(\tau, \tau')$ for which Eq. (10.394) is not applicable: the second, fourth,

and sixth diagram. The other three-bubble diagrams in (10.432) containing the generalization ${}_{\mu}\Delta_{\mu}(x, x)$ of the equal-time propagator $\Delta(\tau, \tau)$ can be calculated using Eq. (10.394).

Consider first a partial sum consisting of the first three three-bubble diagrams in the sum (10.432). This has the analytic form

$$\begin{aligned} \beta f_2^{(3)} \Big|_{1,2,3} &= -\frac{\eta^2}{2} \int_0^{\beta} \int_0^{\beta} d\tau d\tau' \{ 4 \Delta(\tau, \tau) \Delta^2(\tau, \tau') \Delta(\tau', \tau') \\ &\quad + 2 \Delta(\tau, \tau) \Delta^2(\tau, \tau') \Delta(\tau', \tau') + 16 \Delta(\tau, \tau) \Delta(\tau, \tau') \Delta(\tau, \tau') \Delta(\tau', \tau') \}. \end{aligned} \quad (10.442)$$

Replacing $\Delta(\tau, \tau)$ and $\Delta(\tau', \tau')$ by $\delta(0) - 1/\beta$, according to of (10.394), we see that Eq. (10.442) contains, with opposite sign, precisely the previous sum (10.439) of all one- and two-bubble diagrams. Together they give

$$\begin{aligned} \beta f_2^{(2)} + \beta f_2^{(3)} \Big|_{1,2,3} &= -\frac{\eta^2}{2} \int_0^{\beta} \int_0^{\beta} d\tau d\tau' \left\{ -\frac{4}{\beta} \Delta(\tau, \tau) \Delta^2(\tau, \tau') \right. \\ &\quad \left. + \frac{2}{\beta^2} \Delta^2(\tau, \tau') - \frac{16}{\beta} \Delta(\tau, \tau) \Delta(\tau, \tau') \Delta(\tau, \tau') \right\}, \end{aligned} \quad (10.443)$$

and can be evaluated directly to

$$\beta f_2^{(2)} + \beta f_2^{(3)} \Big|_{1,2,3} = \frac{\eta^2}{2} \left(\frac{4}{\beta} \frac{\beta^2}{45} - \frac{2}{\beta^2} \frac{\beta^4}{90} + \frac{16}{\beta} \frac{\beta^3}{180} \right) = \frac{\eta^2}{2} \frac{7}{45} \beta^2. \quad (10.444)$$

By the same direct calculation, the Feynman integral in the fifth three-bubble diagram in (10.432) yields

$$\text{Diagram 5}: I_5 = \int_0^{\beta} \int_0^{\beta} d\tau d\tau' \Delta(\tau, \tau) \Delta(\tau, \tau') \Delta(\tau, \tau') \Delta(\tau', \tau') = -\frac{\beta^2}{720}. \quad (10.445)$$

The explicit results (10.444) and (10.445) are again not needed, since the last term in Eq. (10.443) is equal, with opposite sign, to the partial sum of the fourth and fifth three-bubble diagrams in Eq. (10.432). To see this, consider the Feynman integral associated with the sixth three-bubble diagram in Eq. (10.432):

$$\text{Diagram 6}: I_4 = \int_0^{\beta} \int_0^{\beta} d\tau d\tau' \Delta(\tau, \tau) \Delta(\tau, \tau') \Delta(\tau, \tau') \Delta(\tau', \tau'), \quad (10.446)$$

whose d -dimensional extension is

$$I_4^d = \int_0^{\beta} \int_0^{\beta} d^d\tau d^d\tau' \alpha \Delta(\tau, \tau) \Delta(\tau, \tau') \alpha \Delta_{\beta}(\tau, \tau') \Delta_{\beta}(\tau', \tau'). \quad (10.447)$$

Adding this to the fifth Feynman integral (10.445) and performing a partial integration, we find in one dimension

$$\begin{aligned} \beta f_2^{(3)} \Big|_{4,5} &= -\frac{\eta^2}{2} 16 (I_4 + I_5) = -\frac{\eta^2}{2} \int_0^{\beta} \int_0^{\beta} d\tau d\tau' \frac{16}{\beta} \Delta(\tau, \tau) \Delta(\tau, \tau') \Delta(\tau, \tau') \\ &= -\eta^2 \frac{4}{45} \beta^2, \end{aligned} \quad (10.448)$$

where we have used $d[\Delta(\tau, \tau)]/d\tau = -1/\beta$ obtained by differentiating (10.435). Comparing (10.448) with (10.443), we find the sum of all bubbles diagrams, except for the sixth and seventh three-bubble diagrams in Eq. (10.432), to be given by

$$\beta f_2^{(2)} + \beta f_2^{(3)} \Big|_{6,7} = \frac{\eta^2}{2} \frac{2}{15} \beta^2. \quad (10.449)$$

The prime on the sum denotes the exclusion of the diagrams indicated by subscripts. The correlation function $\dot{\Delta}(\tau, \tau')$ in the two remaining diagrams of Eq. (10.432), whose d -dimensional extension is ${}_{\alpha}\Delta_{\beta}(x, x')$, cannot be replaced via Eq. (10.394), and the expression can only be simplified by applying partial integration to the seventh diagram in Eq. (10.432), yielding

$$\begin{aligned}
 \text{Diagram 7} : I_7 &= \int_0^{\beta} \int_0^{\beta} d\tau d\tau' \Delta(\tau, \tau) \dot{\Delta}(\tau, \tau') \dot{\Delta}(\tau, \tau') \dot{\Delta}(\tau', \tau') \\
 &\rightarrow \int_0^{\beta} \int_0^{\beta} d^d\tau d^d\tau' \Delta(\tau, \tau) {}_{\alpha}\Delta(\tau, \tau') {}_{\alpha}\Delta_{\beta}(\tau, \tau') \Delta_{\beta}(\tau', \tau') \\
 &= \frac{1}{2} \int_0^{\beta} \int_0^{\beta} d^d\tau d^d\tau' \Delta(\tau, \tau) \Delta_{\beta}(\tau', \tau') \partial'_{\beta} [{}_{\alpha}\Delta(\tau, \tau')]^2 \\
 &\rightarrow \frac{1}{2} \int_0^{\beta} \int_0^{\beta} d\tau d\tau' \Delta(\tau, \tau) \dot{\Delta}(\tau', \tau') \frac{d}{d\tau'} [\dot{\Delta}^2(\tau, \tau')] \\
 &= \frac{1}{2\beta} \int_0^{\beta} \int_0^{\beta} d\tau d\tau' \Delta(\tau, \tau) \dot{\Delta}^2(\tau, \tau') = \frac{\beta^2}{90}.
 \end{aligned}
 \tag{10.450}$$

The sixth diagram in the sum (10.432) diverges linearly. As before, we add and subtract the divergence

$$\begin{aligned}
 \text{Diagram 6} : I_6 &= \int_0^{\beta} \int_0^{\beta} d\tau d\tau' \Delta(\tau, \tau) \dot{\Delta}^2(\tau, \tau') \Delta(\tau', \tau') \\
 &= \int_0^{\beta} \int_0^{\beta} d\tau d\tau' \Delta(\tau, \tau) [\dot{\Delta}^2(\tau, \tau') - \delta^2(\tau - \tau')] \Delta(\tau', \tau') \\
 &+ \int_0^{\beta} \int_0^{\beta} d\tau d\tau' \Delta^2(\tau, \tau) \delta^2(\tau - \tau').
 \end{aligned}
 \tag{10.451}$$

In the first, finite term we go to d dimensions and replace $\delta(\tau - \tau') \rightarrow \delta^{(d)}(\tau - \tau') = -\Delta_{\beta\beta}(\tau, \tau')$ using the field equation (10.418). After this, we apply partial integration and find

$$\begin{aligned}
 I_6^R &\rightarrow \int_0^{\beta} \int_0^{\beta} d^d\tau d^d\tau' \Delta(\tau, \tau) [{}_{\alpha}\Delta_{\beta}^2(\tau, \tau') - \Delta_{\gamma\gamma}^2(\tau, \tau')] \Delta(\tau', \tau') \\
 &= \int_0^{\beta} \int_0^{\beta} d^d\tau d^d\tau' \{ -\partial_{\alpha} [\Delta(\tau, \tau)] \Delta_{\beta}(\tau, \tau') {}_{\alpha}\Delta_{\beta}(\tau, \tau') \Delta(\tau', \tau') \\
 &\quad + \Delta(\tau, \tau) \Delta_{\beta}(\tau, \tau') \Delta_{\gamma\gamma}(\tau, \tau') \partial'_{\beta} [\Delta(\tau', \tau')] \} \\
 &\rightarrow \int_0^{\beta} \int_0^{\beta} d\tau d\tau' 2 \{ -\dot{\Delta}(\tau, \tau) \dot{\Delta}(\tau, \tau') \dot{\Delta}(\tau, \tau') \Delta(\tau', \tau') + \\
 &\quad \Delta(\tau, \tau) \dot{\Delta}(\tau, \tau') \dot{\Delta}(\tau', \tau') \dot{\Delta}(\tau, \tau') \}.
 \end{aligned}
 \tag{10.452}$$

In going to the last line we have used $d[\Delta(\tau, \tau)]/d\tau = 2 \dot{\Delta}(\tau, \tau)$ following from (10.435). By interchanging the order of integration $\tau \leftrightarrow \tau'$, the first term in Eq. (10.452) reduces to the integral (10.450). In the last term we replace $\dot{\Delta}(\tau, \tau')$ using the field equation (10.393) and the trivial equation (10.376). Thus we obtain

$$I_6 = I_6^R + I_6^{\text{div}}
 \tag{10.453}$$

with

$$I_6^R = 2 \left(-\frac{\beta^2}{90} - \frac{\beta^2}{120} \right) = \frac{1}{2} \left(-\frac{7\beta^2}{90} \right),
 \tag{10.454}$$

$$I_6^{\text{div}} = \int_0^{\beta} \int_0^{\beta} d\tau d\tau' \Delta^2(\tau, \tau) \delta^2(\tau - \tau').
 \tag{10.455}$$

With the help of the identity for distributions (10.369), the divergent part is calculated to be

$$I_6^{\text{div}} = \delta(0) \int_0^\beta d\tau \Delta^2(\tau, \tau) = \delta(0) \frac{\beta^3}{30}. \tag{10.456}$$

Using Eqs. (10.450) and (10.453) yields the sum of the sixth and seventh three-bubble diagrams in Eq. (10.432):

$$\beta f_2^{(3)} \Big|_{6,7} = -\frac{\eta^2}{2} (2I_6 + 16I_7) = -\frac{\eta^2}{2} \left[2\delta(0) \frac{\beta^3}{30} + \frac{\beta^2}{10} \right]. \tag{10.457}$$

Adding this to (10.449), we obtain the sum of all bubble diagrams

$$\beta f_2^{(2)} + \beta f_2^{(3)} = -\frac{\eta^2}{2} \left[2\delta(0) \frac{\beta^3}{30} + \frac{\beta^2}{30} \right]. \tag{10.458}$$

The contributions of the watermelon diagrams (10.432) correspond to the Feynman integrals

$$\begin{aligned} \beta f_2^{(4)} &= -2\eta^2 \int_0^\beta \int_0^\beta d\tau d\tau' [\Delta^2(\tau, \tau') \dot{\Delta}^2(\tau, \tau') \\ &\quad + 4\Delta(\tau, \tau') \dot{\Delta}(\tau, \tau') \ddot{\Delta}(\tau, \tau') \dot{\Delta}(\tau, \tau') + \dot{\Delta}^2(\tau, \tau') \Delta^2(\tau, \tau')]. \end{aligned} \tag{10.459}$$

The third integral is unique and can be calculated directly:

$$\text{⊖} : I_{10} = \int_0^\beta d\tau \int_0^\beta d\tau' \dot{\Delta}^2(\tau, \tau') \Delta^2(\tau, \tau') = \frac{\beta^2}{90}. \tag{10.460}$$

The second integral reads in d dimensions

$$\text{⊖} : I_9 = \int \int d^d\tau d^d\tau' \Delta(\tau, \tau')_\alpha \Delta(\tau, \tau')_\beta \Delta_\beta(\tau, \tau')_\alpha \Delta_\beta(\tau, \tau'). \tag{10.461}$$

This is integrated partially to yield, in one dimension,

$$I_9 = -\frac{1}{2} I_{10} + I_{9'} \equiv -\frac{1}{2} I_{10} - \frac{1}{2} \int \int d\tau d\tau' \Delta(\tau, \tau') \dot{\Delta}^2(\tau, \tau') \ddot{\Delta}(\tau, \tau'). \tag{10.462}$$

The integral on the right-hand side is the one-dimensional version of

$$I_{9'} = -\frac{1}{2} \int \int d^d\tau d^d\tau' \Delta(\tau, \tau') \Delta_\beta^2(\tau, \tau') \alpha_\alpha \Delta(\tau, \tau'). \tag{10.463}$$

Using the field equation (10.418), going back to one dimension, and inserting $\Delta(\tau, \tau')$, $\dot{\Delta}(\tau, \tau')$, and $\ddot{\Delta}(\tau, \tau')$ from (10.392), (10.396), and (10.393), we perform all unique integrals and obtain

$$I_{9'} = \beta^2 \left\{ \frac{1}{48} \int d\tau \epsilon^2(\tau) \delta(\tau) + \frac{1}{240} \right\}. \tag{10.464}$$

According to Eq. (10.375), the integral over the product of distributions vanishes. Inserting the remainder and (10.460) into Eq. (10.462) gives:

$$I_9 = -\frac{\beta^2}{720}. \tag{10.465}$$

We now evaluate the first integral in Eq. (10.459). Adding and subtracting the linear divergence yields

$$\begin{aligned} \text{⊖} : I_8 &= \int_0^\beta \int_0^\beta d\tau d\tau' \Delta^2(\tau, \tau') \dot{\Delta}^2(\tau, \tau') = \int_0^\beta \int_0^\beta d\tau d\tau' \Delta^2(\tau, \tau) \delta^2(\tau - \tau') \\ &\quad + \int_0^\beta \int_0^\beta d\tau d\tau' \Delta^2(\tau, \tau') [\dot{\Delta}^2(\tau, \tau') - \delta^2(\tau - \tau')]. \end{aligned} \tag{10.466}$$

The finite second part of the integral (10.466) has the d -dimensional extension

$$I_8^R = \int \int d^d\tau d^d\tau' \Delta^2(\tau, \tau') [\alpha \Delta_\beta^2(\tau, \tau') - \Delta_{\gamma\gamma}^2(\tau, \tau')], \quad (10.467)$$

which after partial integration and going back to one dimension reduces to a combination of integrals Eqs. (10.465) and (10.464):

$$I_8^R = -2I_9 + 2I_{9'} = -\frac{\beta^2}{72}. \quad (10.468)$$

The divergent part of I_8 coincides with I_6^{div} in Eq. (10.455):

$$I_8^{\text{div}} = \int_0^\beta \int_0^\beta d\tau d\tau' \Delta^2(\tau, \tau) \delta^2(\tau - \tau') = I_6^{\text{div}} = \delta(0) \frac{\beta^3}{30}. \quad (10.469)$$

Inserting this together with (10.460) and (10.465) into Eq. (10.459), we obtain the sum of watermelon diagrams

$$\beta f_2^{(4)} = -2\eta^2(I_8 + 4I_9 + I_{10}) = -\frac{\eta^2}{2} \left\{ 4\delta(0) \frac{\beta^2}{30} - \frac{\beta^2}{30} \right\}. \quad (10.470)$$

For a flat space in curvilinear coordinates, the sum of the first-order diagrams vanish. To second order, the requirement of coordinate independence implies a vanishing sum of all connected diagrams (10.429)–(10.432). By adding the sum of terms in Eqs. (10.438), (10.458), and (10.470), we find indeed zero, thus confirming coordinate independence. It is not surprising that the integration rules for products of distributions derived in an infinite time interval $\tau \in [0, \infty)$ are applicable for finite time intervals. The singularities in the distributions come in only at a single point of the time axis, so that its total length is irrelevant.

The procedure can easily be continued to higher-loop diagrams to define integrals over higher singular products of ϵ - and δ -functions. At the one-loop level, the cancellation of $\delta(0)$ s requires

$$\int d\tau \Delta(\tau, \tau) \delta(0) = \delta(0) \int d\tau \Delta(\tau, \tau). \quad (10.471)$$

The second-order gave, in addition, the rule

$$\int_0^\beta \int_0^\beta d\tau d\tau' \Delta^2(\tau, \tau) \delta^2(\tau - \tau') = \delta(0) \int d\tau \Delta^2(\tau, \tau), \quad (10.472)$$

To n -order we can derive the equation

$$\int d\tau_1 \dots d\tau_n \Delta(\tau_1, \tau_2) \delta(\tau_1, \tau_2) \cdots \Delta(\tau_n, \tau_1) \delta(\tau_n, \tau_1) = \delta(0) \int d\tau \Delta^n(\tau, \tau), \quad (10.473)$$

which reduces to

$$\int \int d\tau_1 d\tau_n \Delta^n(\tau_1, \tau_1) \delta^2(\tau_1 - \tau_n) = \delta(0) \int d\tau \Delta^n(\tau, \tau), \quad (10.474)$$

which is satisfied due to the integration rule (10.369). See Appendix 10C for a general derivation of (10.473).

10.11.5 Time Evolution Amplitude in Curved Space

The same Feynman diagrams which we calculated to verify coordinate independence appear also in the perturbation expansion of the time evolution amplitude in curved space if this is performed in normal or geodesic coordinates.

The path integral in curved space is derived by making the mapping from x^i to q_a^μ in Subsection 10.11.2 nonholonomic, so that it can no longer be written as $x^i(\tau) = x^i(q^\mu(\tau))$ but only as $dx^i(\tau) = e^i_\mu(q)dq^\mu(\tau)$. Then the q -space may contain curvature and torsion, and the result of the path integral will not longer be trivial one in Eq. (10.403) but depend on $R_{\mu\nu\lambda}{}^\kappa(q_a)$ and $S_{\mu\nu}{}^\lambda(q_a)$. For simplicity, we shall ignore torsion.

Then the action becomes (10.404) with the metric $g_{\mu\nu}(q) = e^i_\mu(q)e^i_\nu(q)$. It was shown in Subsection 10.3.2 that under nonholonomic coordinate transformations, the measure of a time-sliced path integral transforms from the flat-space form $\prod_n d^D x_n$ to $\prod_n d^D q \sqrt{g_n} \exp(\Delta t \bar{R}_n/6)$. This had the consequence, in Section 10.4, that the time evolution amplitude for a particle on the surface of a sphere has an energy (10.165) corresponding to the Hamiltonian (1.418) which governs the Schrödinger equation (1.424). It contains a pure Laplace-Beltrami operator in the kinetic part. There is no extra R -term, which would be allowed if only covariance under ordinary coordinate transformations is required. This issue will be discussed in more detail in Subsection 11.1.1.

Below we shall see that for perturbatively defined path integrals, the nonholonomic transformation must carry the flat-space measure into curved space as follows:

$$\mathcal{D}^D x \rightarrow \mathcal{D}^D q \sqrt{g} \exp\left(\int_0^\beta d\tau \bar{R}/8\right). \tag{10.475}$$

For a D -dimensional space with a general metric $g_{\mu\nu}(q)$ we can make use of the above proven coordinate invariance to bring the metric to the most convenient normal or geodesic coordinates (10.98) around some point q_a . The advantage of these coordinates is that the derivatives and thus the affine connection vanish at this point. Its derivatives can directly be expressed in terms of the curvature tensor:

$$\partial_\kappa \bar{\Gamma}_{\tau\kappa}{}^\mu(q_a) = -\frac{1}{3} [\bar{R}_{\tau\kappa\sigma}{}^\mu(q_a) + \bar{R}_{\sigma\kappa\tau}{}^\mu(q_a)], \quad \text{for normal coordinates.} \tag{10.476}$$

Assuming q_a to lie at the origin, we expand the metric and its determinant in powers of normal coordinates $\Delta\xi^\mu$ around the origin and find, dropping the smallness symbols Δ in front of q and ξ in the transformation (10.98):

$$g_{\mu\nu}(\xi) = \delta_{\mu\nu} + \eta \frac{1}{3} \bar{R}_{\mu\lambda\nu\kappa} \xi^\lambda \xi^\kappa + \eta^2 \frac{2}{45} \bar{R}_{\lambda\nu\kappa}{}^\delta \bar{R}_{\sigma\mu\tau\delta} \xi^\lambda \xi^\kappa \xi^\sigma \xi^\tau + \dots, \tag{10.477}$$

$$g(\xi) = 1 - \eta \frac{1}{3} \bar{R}_{\mu\nu} \xi^\mu \xi^\nu + \eta^2 \frac{1}{18} \left(\bar{R}_{\mu\nu} \bar{R}_{\lambda\kappa} + \frac{1}{5} \bar{R}_{\mu\sigma\nu}{}^\tau \bar{R}_{\lambda\tau\kappa}{}^\sigma \right) \xi^\mu \xi^\nu \xi^\lambda \xi^\kappa + \dots \tag{10.478}$$

These expansions have obviously the same power content in ξ^μ as the previous one-dimensional expansions (10.223) had in q . The interaction (10.410) becomes in normal coordinates, up to order η^2 :

$$\begin{aligned} \mathcal{A}_{\text{tot}}^{\text{int}}[\xi] = & \int_0^\beta d\tau \left\{ \left[\eta \frac{1}{6} \bar{R}_{\mu\lambda\nu\kappa} \xi^\lambda \xi^\kappa + \eta^2 \frac{1}{45} \bar{R}_{\lambda\mu\kappa}{}^\delta \bar{R}_{\sigma\nu\tau\delta} \xi^\lambda \xi^\kappa \xi^\sigma \xi^\tau \right] \dot{\xi}^\mu \dot{\xi}^\nu \right. \\ & \left. + \eta \frac{1}{6} \delta(0) \bar{R}_{\mu\nu} \xi^\mu \xi^\nu + \eta^2 \frac{1}{180} \delta(0) \bar{R}_{\mu\delta\nu}{}^\sigma \bar{R}_{\lambda\sigma\kappa}{}^\delta \xi^\mu \xi^\nu \xi^\lambda \xi^\kappa \right\}. \end{aligned} \tag{10.479}$$

This has again the same powers in ξ^μ as the one-dimensional interaction (10.425), leading to the same Feynman diagrams, differing only by the factors associated with the vertices. In one dimension, with the trivial vertices of the interaction (10.425), the sum of all diagrams vanishes. In curved space with the more complicated vertices proportional to $\bar{R}_{\mu\nu\kappa\lambda}$ and $\bar{R}_{\mu\nu}$, the result is nonzero but depends on contractions of the curvature tensor $\bar{R}_{\mu\nu\kappa\lambda}$. The dependence is easily identified for each diagram. All bubble diagrams in (10.430)–(10.432) yield results proportional to $\bar{R}_{\mu\nu}^2$, while the watermelon-like diagrams (10.432) carry a factor $\bar{R}_{\mu\nu\kappa\lambda}^2$.

When calculating the contributions of the first expectation value $\langle \mathcal{A}_{\text{tot}}^{\text{int}}[\xi] \rangle$ to the time evolution amplitude it is useful to reduce the D -dimensional expectation values of (10.479) to one-dimensional ones of (10.425) as follows using the contraction rules (8.63) and (8.64):

$$\langle \xi^\mu \xi^\nu \rangle = \delta^{\mu\nu} \langle \xi \xi \rangle, \quad (10.480)$$

$$\langle \xi^\lambda \xi^\kappa \xi^\mu \xi^\nu \rangle = (\delta^{\lambda\kappa} \delta^{\mu\nu} + \delta^{\lambda\mu} \delta^{\nu\kappa} + \delta^{\lambda\nu} \delta^{\kappa\mu}) \langle \xi \xi \xi \xi \rangle, \quad (10.481)$$

$$\langle \xi^\lambda \xi^\kappa \dot{\xi}^\mu \dot{\xi}^\nu \rangle = \delta^{\lambda\kappa} \delta^{\mu\nu} \langle \xi \xi \rangle \langle \dot{\xi} \dot{\xi} \rangle + (\delta^{\lambda\mu} \delta^{\kappa\nu} + \delta^{\lambda\nu} \delta^{\kappa\mu}) \langle \xi \dot{\xi} \rangle \langle \xi \dot{\xi} \rangle, \quad (10.482)$$

$$\begin{aligned} \langle \xi^\lambda \xi^\kappa \xi^\sigma \xi^\tau \dot{\xi}^\mu \dot{\xi}^\nu \rangle &= (\delta^{\lambda\kappa} \delta^{\sigma\tau} + \delta^{\lambda\sigma} \delta^{\kappa\tau} + \delta^{\lambda\tau} \delta^{\kappa\sigma}) \delta^{\mu\nu} \langle \xi \xi \rangle \langle \xi \xi \rangle \langle \dot{\xi} \dot{\xi} \rangle \\ &+ [\delta^{\lambda\mu} (\delta^{\kappa\nu} \delta^{\sigma\tau} + \delta^{\sigma\nu} \delta^{\tau\kappa} + \delta^{\tau\nu} \delta^{\kappa\sigma}) + \delta^{\kappa\mu} (\delta^{\sigma\nu} \delta^{\lambda\tau} + \delta^{\lambda\nu} \delta^{\tau\sigma} + \delta^{\tau\nu} \delta^{\sigma\lambda}) \\ &+ \delta^{\sigma\mu} (\delta^{\tau\nu} \delta^{\lambda\kappa} + \delta^{\lambda\nu} \delta^{\kappa\tau} + \delta^{\kappa\nu} \delta^{\tau\lambda}) + \delta^{\tau\mu} (\delta^{\lambda\nu} \delta^{\kappa\sigma} + \delta^{\kappa\nu} \delta^{\sigma\lambda} + \delta^{\sigma\nu} \delta^{\lambda\kappa})] \\ &\times \langle \xi \xi \rangle \langle \xi \dot{\xi} \rangle \langle \xi \dot{\xi} \rangle. \end{aligned} \quad (10.483)$$

Inserting these into the expectation value of (10.479) and performing the tensor contractions, we obtain

$$\begin{aligned} \langle \mathcal{A}_{\text{tot}}^{\text{int}}[\xi] \rangle &= \int_0^\beta d\tau \left\{ \eta \frac{1}{6} \bar{R} \left[-\langle \xi \xi \rangle \langle \dot{\xi} \dot{\xi} \rangle + \langle \xi \dot{\xi} \rangle \langle \xi \dot{\xi} \rangle + \eta \delta(0) \langle \xi \xi \rangle \right] \right. \\ &+ \eta^2 \frac{1}{45} \left[(\bar{R}_{\mu\nu}^2 + \bar{R}_{\mu\nu\lambda\kappa} \bar{R}^{\mu\nu\lambda\kappa} + \bar{R}_{\mu\nu\lambda\kappa} \bar{R}^{\lambda\nu\mu\kappa}) \left(\langle \xi \xi \rangle^2 \langle \dot{\xi} \dot{\xi} \rangle - \langle \xi \xi \rangle \langle \xi \dot{\xi} \rangle^2 \right) \right] \\ &\left. + \eta^2 \frac{1}{180} \delta(0) (\bar{R}_{\mu\nu}^2 + \bar{R}_{\mu\nu\lambda\kappa} \bar{R}^{\mu\nu\lambda\kappa} + \bar{R}_{\mu\nu\lambda\kappa} \bar{R}^{\lambda\nu\mu\kappa}) \langle \xi \xi \rangle \langle \xi \xi \rangle \right\}. \end{aligned} \quad (10.484)$$

Individually, the four tensors in the brackets of (10.483) contribute the tensor contractions, using the antisymmetry of $\bar{R}_{\mu\nu\lambda\kappa}$ in $\mu\nu$ and the contraction to the Ricci tensor $\bar{R}_{\lambda\mu\kappa}{}^\delta \delta^{\mu\kappa} = \bar{R}_\lambda{}^\delta$:

$$\begin{aligned} \bar{R}_{\lambda\mu\kappa}{}^\delta \bar{R}_{\sigma\nu\tau\delta} \delta^{\lambda\mu} (\delta^{\kappa\nu} \delta^{\sigma\tau} + \delta^{\sigma\nu} \delta^{\tau\kappa} + \delta^{\tau\nu} \delta^{\kappa\sigma}) &= 0, \\ \bar{R}_{\lambda\mu\kappa}{}^\delta \bar{R}_{\sigma\nu\tau\delta} \delta^{\kappa\mu} (\delta^{\sigma\nu} \delta^{\lambda\tau} + \delta^{\lambda\nu} \delta^{\tau\sigma} + \delta^{\tau\nu} \delta^{\sigma\lambda}) &= \bar{R}_\lambda{}^\delta (-\bar{R}^\lambda{}_\delta + \bar{R}^\lambda{}_\delta) = 0, \\ \bar{R}_{\lambda\mu\kappa}{}^\delta \bar{R}_{\sigma\nu\tau\delta} \delta^{\sigma\mu} (\delta^{\tau\nu} \delta^{\lambda\kappa} + \delta^{\lambda\nu} \delta^{\kappa\tau} + \delta^{\kappa\nu} \delta^{\tau\lambda}) &= \bar{R}_{\lambda\mu\kappa}{}^\delta (\bar{R}^\sigma{}_\delta \delta^{\lambda\kappa} + \bar{R}_{\sigma\lambda\kappa\delta} + \bar{R}_{\sigma\kappa\lambda\delta}) \\ &= -(\bar{R}_{\mu\nu}^2 + \bar{R}_{\mu\nu\lambda\kappa} \bar{R}^{\mu\nu\lambda\kappa} + \bar{R}_{\mu\nu\lambda\kappa} \bar{R}^{\lambda\nu\mu\kappa}) \\ \bar{R}_{\lambda\mu\kappa}{}^\delta \bar{R}_{\sigma\nu\tau\delta} \delta^{\tau\mu} (\delta^{\lambda\nu} \delta^{\kappa\sigma} + \delta^{\kappa\nu} \delta^{\sigma\lambda} + \delta^{\sigma\nu} \delta^{\lambda\kappa}) &= \bar{R}_{\lambda\tau\kappa}{}^\delta (R_{\kappa\lambda\tau\delta} + R_{\lambda\kappa\tau\delta}) = 0. \end{aligned} \quad (10.485)$$

We now use the *fundamental identity* of Riemannian spaces

$$\bar{R}_{\mu\nu\lambda\kappa} + \bar{R}_{\mu\lambda\kappa\nu} + \bar{R}_{\mu\kappa\nu\lambda} = 0. \quad (10.486)$$

By expressing the curvature tensor (10.31) in Riemannian space in terms of the Christoffel symbol (1.70) as

$$R_{\mu\nu\lambda\kappa} = \frac{1}{2} (\partial_\mu \partial_\lambda g_{\nu\kappa} - \partial_\mu \partial_\kappa g_{\nu\lambda} - \partial_\nu \partial_\lambda g_{\mu\kappa} + \partial_\nu \partial_\kappa g_{\mu\lambda}) - [\bar{\Gamma}_\mu, \bar{\Gamma}_\nu]_{\lambda\kappa}, \quad (10.487)$$

we see that the identity (10.486) is a consequence of the symmetry of the metric and the single-valuedness of the metric expressed by the integrability condition⁸ $(\partial_\lambda \partial_\kappa - \partial_\kappa \partial_\lambda) g_{\mu\nu} = 0$. Indeed, due to the symmetry of $g_{\mu\nu}$ we find

$$\bar{R}_{\mu\nu\lambda\kappa} + \bar{R}_{\mu\lambda\kappa\nu} + \bar{R}_{\mu\kappa\nu\lambda} = \frac{1}{2} [(\partial_\nu \partial_\kappa - \partial_\kappa \partial_\nu) g_{\mu\lambda} - (\partial_\nu \partial_\lambda - \partial_\lambda \partial_\nu) g_{\mu\kappa} - (\partial_\lambda \partial_\kappa - \partial_\kappa \partial_\lambda) g_{\mu\nu}] = 0.$$

The integrability has also the consequence that

$$R_{\mu\nu\lambda\kappa} = -R_{\mu\nu\kappa\lambda}, \quad R_{\mu\nu\lambda\kappa} = R_{\lambda\kappa\mu\nu}. \quad (10.488)$$

⁸For the derivation see p. 1353 in the textbook [2].

Using (10.486) and (10.488) we find that

$$\bar{R}_{\mu\nu\lambda\kappa}\bar{R}^{\lambda\nu\mu\kappa} = \frac{1}{2}\bar{R}_{\mu\nu\lambda\kappa}\bar{R}^{\mu\nu\lambda\kappa}, \tag{10.489}$$

so that the contracted curvature tensors in the parentheses of (10.484) can be replaced by $\bar{R}_{\mu\nu}^2 + \frac{3}{2}\bar{R}_{\mu\nu\lambda\kappa}\bar{R}^{\mu\nu\lambda\kappa}$.

We now calculate explicitly the contribution of the first-order diagrams in (10.484) [compare (10.427)]:

$$\beta f_1 = \frac{1}{6}\bar{R} \left[-\eta \text{ (diagram 1)} + \eta \text{ (diagram 2)} + \eta \delta(0) \text{ (diagram 3)} \right]. \tag{10.490}$$

corresponding to the analytic expression [compare (10.433)]:

$$\beta f_1 = -\eta \frac{1}{6}\bar{R} \int_0^\beta d\tau [\Delta(\tau, \tau)\dot{\Delta}(\tau, \tau) - \dot{\Delta}^2(\tau, \tau) - \delta(0)\Delta(\tau, \tau)]. \tag{10.491}$$

Note that the combination of propagators in the brackets is different from the previous one in (10.433). Using the integrals (10.436) we find, setting $\eta = 1$:

$$\beta f_1 = -\frac{1}{6}\bar{R} \int_0^\beta d\tau \left[-\frac{1}{\beta}\Delta(\tau, \tau) - \dot{\Delta}^2(\tau, \tau) \right]. \tag{10.492}$$

Using Eq. (10.436), this becomes

$$\beta f_1 = \frac{1}{6}\bar{R} \int_0^\beta d\tau \frac{3}{2\beta}\Delta(\tau, \tau) = \frac{\beta}{24}\bar{R}. \tag{10.493}$$

Adding to this the similar contribution coming from the nonholonomically transformed measure (10.475), we obtain the first-order expansion of the imaginary-time evolution amplitude

$$(q_a \beta | q_a 0) = \frac{1}{\sqrt{2\pi\beta^D}} \exp \left[\frac{\beta}{12}\bar{R}(q_a) + \dots \right]. \tag{10.494}$$

We now turn to the second-order contributions in η . The sum of the local diagrams (10.429) reads now

$$\beta f_2^{(1)} = \eta^2 \frac{1}{45} \left(\bar{R}_{\mu\nu}\bar{R}^{\mu\nu} + \frac{3}{2}\bar{R}_{\mu\nu\lambda\kappa}\bar{R}^{\mu\nu\lambda\kappa} \right) \left[\text{ (diagram 1)} - \text{ (diagram 2)} + \frac{1}{4}\delta(0) \text{ (diagram 3)} \right]. \tag{10.495}$$

In terms of the Feynman integrals, the brackets are equal to [compare (10.437)]

$$\int_0^\beta d\tau \left[\Delta^2(\tau, \tau)\dot{\Delta}(\tau, \tau) - \Delta(\tau, \tau)\dot{\Delta}^2(\tau, \tau) + \frac{1}{4}\delta(0)\Delta^2(\tau, \tau) \right]. \tag{10.496}$$

Inserting the equation of motion (10.394) and the right-hand equation (10.435), this becomes

$$\int_0^\beta d\tau \left[-\frac{5}{4\beta}\Delta^2(\tau, \tau) + \frac{5}{4}\delta(0)\Delta^2(\tau, \tau) \right] = \frac{5}{4} \frac{1}{30} [1 - \delta(0)]. \tag{10.497}$$

Thus we find

$$\beta f_2^{(1)} = -\eta^2 \frac{\beta^2}{1080} \left(\bar{R}_{\mu\nu}^2 + \frac{3}{2}\bar{R}_{\mu\nu\kappa\lambda}^2 \right) [1 - \delta(0)]. \tag{10.498}$$

Next we calculate the nonlocal contributions of order \hbar^2 to βf coming from the cumulant

$$\begin{aligned}
-\frac{1}{2} \langle \mathcal{A}_{\text{tot}}^{\text{int}2} \rangle_c = & -\frac{\eta^2}{2} \frac{1}{36} \int_0^\beta d\tau \int_0^\beta d\tau' \left\langle \left[\delta^2(0) \bar{R}_{\mu\nu} \bar{R}_{\mu'\nu'} \xi^\mu(\tau) \xi^\nu(\tau) \xi^{\mu'}(\tau') \xi^{\nu'}(\tau') \right. \right. \\
& + 2\delta(0) \bar{R}_{\mu\lambda\nu\kappa} \bar{R}_{\mu'\nu'} \xi^\lambda(\tau) \xi^\kappa(\tau) \dot{\xi}^\mu(\tau) \dot{\xi}^\nu(\tau) \xi^{\mu'}(\tau') \xi^{\nu'}(\tau') \\
& \left. \left. + \bar{R}_{\mu\lambda\nu\kappa} \bar{R}_{\mu'\lambda'\nu'\kappa'} \xi^\lambda(\tau) \xi^{\kappa'}(\tau) \dot{\xi}^\mu(\tau) \dot{\xi}^\nu(\tau) \xi^{\lambda'}(\tau') \xi^{\kappa'}(\tau') \dot{\xi}^{\mu'}(\tau') \dot{\xi}^{\nu'}(\tau') \right] \right\rangle_c.
\end{aligned} \tag{10.499}$$

The first two terms yield the connected diagrams [compare (10.430)]

$$\beta f_2^{(2)} = -\frac{\eta^2}{2} \frac{\bar{R}_{\mu\nu} \bar{R}^{\mu\nu}}{36} \left\{ 2\delta^2(0) \text{---} \text{---} \text{---} - 4\delta(0) \left[\text{---} \text{---} \text{---} - 2 \text{---} \text{---} \text{---} + \text{---} \text{---} \text{---} \right] \right\}, \tag{10.500}$$

and the analytic expression diagrams [compare (10.439)]

$$\begin{aligned}
\beta f_2^{(2)} = & -\frac{\eta^2}{2} \frac{\bar{R}_{\mu\nu} \bar{R}^{\mu\nu}}{36} \int_0^\beta \int_0^\beta d\tau d\tau' \left\{ 2\delta^2(0) \Delta^2(\tau, \tau') \right. \\
& \left. - 4\delta(0) \left[\Delta(\tau, \tau) \Delta^2(\tau, \tau') - 2\Delta(\tau, \tau) \Delta(\tau, \tau') \Delta(\tau, \tau') + \Delta^2(\tau, \tau') \Delta(\tau, \tau') \right] \right\}.
\end{aligned} \tag{10.501}$$

The third term in (10.499) leads to the three-bubble diagrams [compare (10.439)]

$$\beta f_2^{(3)} = -\frac{\eta^2}{2} \frac{\bar{R}_{\mu\nu} \bar{R}^{\mu\nu}}{36} \left[4 \text{---} \text{---} \text{---} + 2 \text{---} \text{---} \text{---} - 8 \text{---} \text{---} \text{---} + 4 \text{---} \text{---} \text{---} + 4 \text{---} \text{---} \text{---} + 2 \text{---} \text{---} \text{---} - 8 \text{---} \text{---} \text{---} \right]. \tag{10.502}$$

The analytic expression for the diagrams 1,2,3 is [compare (10.442)]

$$\begin{aligned}
\beta f_2^{(3)} \Big|_{1,2,3} = & -\frac{\eta^2}{2} \frac{\bar{R}_{\mu\nu} \bar{R}^{\mu\nu}}{36} \int_0^\beta \int_0^\beta d\tau d\tau' \left\{ 4\Delta(\tau, \tau) \Delta^2(\tau, \tau') \Delta(\tau', \tau') \right. \\
& \left. + 2\Delta(\tau, \tau) \Delta^2(\tau, \tau') \Delta(\tau', \tau') - 8\Delta(\tau, \tau) \Delta(\tau, \tau') \Delta(\tau, \tau') \Delta(\tau', \tau') \right\}.
\end{aligned} \tag{10.503}$$

and for 4 and 5 [compare (10.448)]:

$$\begin{aligned}
\beta f_2^{(3)} \Big|_{4,5} = & -\frac{\eta^2}{2} \frac{\bar{R}_{\mu\nu} \bar{R}^{\mu\nu}}{36} (I_4 + I_5) = -\frac{\eta^2}{2} \frac{\bar{R}_{\mu\nu} \bar{R}^{\mu\nu}}{36} \int_0^\beta \int_0^\beta d\tau d\tau' \frac{4}{\beta} \Delta(\tau, \tau) \Delta(\tau, \tau') \Delta(\tau, \tau') \\
= & -\frac{\eta^2}{2} \frac{\bar{R}_{\mu\nu} \bar{R}^{\mu\nu}}{36} \frac{1}{45} \beta^2.
\end{aligned} \tag{10.504}$$

For the diagrams 6 and 7, finally, we obtain [compare (10.458)]

$$\beta f_2^{(3)} \Big|_{6,7} = -\frac{\eta^2}{2} \frac{\bar{R}_{\mu\nu} \bar{R}^{\mu\nu}}{36} (2I_6 - 8I_7) = -\frac{\eta^2}{2} \frac{\bar{R}_{\mu\nu} \bar{R}^{\mu\nu}}{36} \left[2\delta(0) \frac{\beta^3}{30} - \frac{\beta^2}{6} \right]. \tag{10.505}$$

The sum of all bubbles diagrams (10.501) and (10.503) is therefore

$$\beta f_2^{(2)} + \beta f_2^{(3)} = \eta^2 \frac{\beta^2}{432} \bar{R}_{\mu\nu}^2 - \eta^2 \delta(0) \frac{\beta^3}{1080} \bar{R}_{\mu\nu}^2. \tag{10.506}$$

This compensates exactly the $\delta(0)$ -term proportional to $\bar{R}_{\mu\nu}^2$ in Eq. (10.498), leaving only a finite second-order term

$$\beta f_1^{(2)} + \beta f_2^{(2)} + \beta f_2^{(3)} = \eta^2 \frac{\beta^2}{720} (\bar{R}_{\mu\nu}^2 - \bar{R}_{\mu\nu\kappa\lambda}^2) + \eta^2 \delta(0) \frac{\beta^3}{1080} \bar{R}_{\mu\nu\kappa\lambda}^2. \tag{10.507}$$

Finally we calculate the second-order watermelon diagrams (10.432) which contain the initially ambiguous Feynman integrals we make the following observation. Their sum is [compare (10.432)]

$$\beta f_2^{(4)} = -\frac{\eta^2}{2} 2 \frac{1}{36} (\bar{R}_{\mu\nu\lambda\kappa} \bar{R}^{\mu\nu\lambda\kappa} + \bar{R}_{\mu\nu\lambda\kappa} \bar{R}^{\mu\lambda\nu\kappa}) \left[\text{diagram 1} - 2 \text{diagram 2} + \text{diagram 3} \right], \quad (10.508)$$

corresponding to the analytic expression

$$\begin{aligned} \beta f_2^{(3)} &= -\frac{\eta^2}{2} 2 \frac{3}{2} \frac{1}{36} \bar{R}_{\mu\nu\kappa\lambda}^2 \int_0^\beta \int_0^\beta d\tau d\tau' [\Delta^2(\tau, \tau') \Delta^2(\tau, \tau') \\ &\quad - 2 \Delta(\tau, \tau') \Delta(\tau, \tau') \Delta(\tau, \tau') \Delta(\tau, \tau') + \Delta^2(\tau, \tau') \Delta^2(\tau, \tau')] \\ &= -\frac{\eta^2}{24} \bar{R}_{\mu\nu\kappa\lambda}^2 (I_8 - 2I_9 + I_{10}), \end{aligned} \quad (10.509)$$

where the integrals I_8, I_9 , and I_{10} were evaluated before in Eqs. (10.469), (10.468), (10.465), and (10.460). Substituting the results into Eq. (10.509) and using the rules (10.369) and (10.375), we obtain

$$\beta f_2^{(3)} = -\frac{\eta^2}{24} \bar{R}_{\mu\nu\kappa\lambda}^2 \int_0^\beta \int_0^\beta d\tau d\tau' \Delta^2(\tau, \tau) \delta^2(\tau - \tau') = -\eta^2 \frac{\beta^3}{720} \bar{R}_{\mu\nu\kappa\lambda}^2 \delta(0). \quad (10.510)$$

Thus the only role of the watermelon diagrams is to cancel the remaining $\delta(0)$ -term proportional to $\bar{R}_{\mu\nu\kappa\lambda}^2$ in Eq. (10.507). It gives no finite contribution.

The remaining total sum of all second-order contribution in Eq. (10.507). changes the diagonal time evolution amplitude (10.494) to

$$(q_a \beta | q_a 0) = \frac{1}{\sqrt{2\pi\beta^D}} \exp \left[\frac{\beta}{12} \bar{R}(q_a) + \frac{\beta^2}{720} (\bar{R}_{\mu\nu\kappa\lambda}^2 - \bar{R}_{\mu\nu}^2) + \dots \right]. \quad (10.511)$$

In Chapter 11 we shall see that this expression agrees with what has been derived in Schrödinger quantum mechanics from a Hamiltonian operator $\hat{H} = -\Delta/2$ which contains only is the Laplace-Beltrami operator $\Delta = g^{-1/2} \partial_\mu g^{1/2} g^{\mu\nu}(q) \partial_\nu$ of Eq. (1.381) and no extra R -term:

$$\begin{aligned} (q_a \beta | q_a 0) &\equiv \langle e^{\beta\Delta/2} \rangle = (q_a | e^{\beta\Delta/2} | q_a) \\ &= \frac{1}{\sqrt{2\pi\beta^D}} \left\{ 1 + \frac{\beta}{12} \bar{R} + \frac{\beta^2}{2} \left[\frac{1}{144} \bar{R}^2 + \frac{1}{360} (\bar{R}^{\mu\nu\kappa\lambda} \bar{R}_{\mu\nu\kappa\lambda} - \bar{R}^{\mu\nu} \bar{R}_{\mu\nu}) \right] + \dots \right\}. \end{aligned} \quad (10.512)$$

This expansion due to DeWitt and Seeley will be derived in Section 11.6, the relevant equation being (11.110).

Summarizing the results we have found that for one-dimensional q -space as well as for a D -dimensional curved space in normal coordinates, our calculation procedure on a one-dimensional τ -axis yields unique results. The procedure uses only the essence of the d -dimensional extension, together with the rules (10.369) and (10.375). The results guarantee the coordinate independence of path integrals. They also agree with the DeWitt-Seeley expansion of the short-time amplitude to be derived in Eq. (11.110). The agreement is ensured by the initially ambiguous integrals I_8 and I_9 satisfying the equations

$$I_8^R + 4I_9 + I_{10} = -\frac{\beta^2}{120}, \quad (10.513)$$

$$I_8^R - 2I_9 + I_{10} = 0, \quad (10.514)$$

as we can see from Eqs. (10.470) and (10.509). Since the integral $I_{10} = \beta^2/90$ is unique, we must have $I_9 = -\beta^2/720$ and $I_8^R = -\beta^2/72$, and this is indeed what we found from our integration rules.

The main role of the d -dimensional extension of the τ -axis is, in this context, to forbid the application of the equation of motion (10.394) to correlation functions $\Delta(\tau, \tau')$. This would

fix immediately the finite part of the integral I_8 to the wrong value $I_8^R = -\beta^2/18$, leaving the integral I_9 which fixes the integral over distributions (10.375). In this way, however, we could only satisfy one of the equations (10.513) and (10.514), the other would always be violated. Thus, any regularization different from ours will ruin immediately coordinate independence.

10.11.6 Covariant Results for Arbitrary Coordinates

It must be noted that if we were to use arbitrary rather than Riemann normal coordinates, we would find ambiguous integrals already at the two-loop level:

$$\textcircled{\text{---}} : I_{14} = \int_0^\beta \int_0^\beta d\tau d\tau' \Delta(\tau, \tau') \Delta(\tau, \tau') \Delta(\tau, \tau'), \quad (10.515)$$

$$\textcircled{\text{---}} : I_{15} = \int_0^\beta \int_0^\beta d\tau d\tau' \Delta(\tau, \tau') \Delta^2(\tau, \tau'). \quad (10.516)$$

Let us show that coordinate independence requires these integrals to have the values

$$I_{14} = \beta/24, \quad I_{15}^R = -\beta/8, \quad (10.517)$$

where the superscript R denotes the finite part of an integral. We study first the ambiguities arising in one dimension. Without dimensional extension, the values (10.517) would be incompatible with partial integration and the equation of motion (10.393). In the integral (10.515), we use the symmetry $\Delta(\tau, \tau') = \Delta(\tau', \tau)$, apply partial integration twice taking care of nonzero boundary terms, and obtain on the one hand

$$\begin{aligned} I_{14} &= \frac{1}{2} \int_0^\beta \int_0^\beta d\tau d\tau' \Delta(\tau, \tau') \frac{d}{d\tau} [\Delta^2(\tau, \tau')] = -\frac{1}{2} \int_0^\beta \int_0^\beta d\tau d\tau' \Delta^2(\tau, \tau') \Delta(\tau, \tau') \\ &= -\frac{1}{6} \int_0^\beta \int_0^\beta d\tau d\tau' \frac{d}{d\tau'} [\Delta^3(\tau, \tau')] = \frac{1}{6} \int_0^\beta d\tau [\Delta^3(\tau, 0) - \Delta^3(\tau, \beta)] = \frac{\beta}{12}. \end{aligned} \quad (10.518)$$

On the other hand, we apply Eq. (10.394) and perform two regular integrals, reducing I_{14} to a form containing an undefined integral over a product of distributions:

$$\begin{aligned} I_{14} &= \int_0^\beta \int_0^\beta d\tau d\tau' \Delta(\tau, \tau') \Delta(\tau, \tau') \delta(\tau - \tau') - \frac{1}{\beta} \int_0^\beta \int_0^\beta d\tau d\tau' \Delta(\tau, \tau') \Delta(\tau, \tau') \\ &= \int_0^\beta \int_0^\beta d\tau d\tau' \left[-\frac{1}{4} \epsilon^2(\tau - \tau') \delta(\tau - \tau') \right] + \int_0^\beta d\tau \Delta^2(\tau, \tau) + \frac{\beta}{12} \\ &= \beta \left[-\frac{1}{4} \int d\tau \epsilon^2(\tau) \delta(\tau) + \frac{1}{6} \right]. \end{aligned} \quad (10.519)$$

A third, mixed way of evaluating I_{14} employs one partial integration as in the first line of Eq. (10.518), then the equation of motion (10.393) to reduce I_{14} to yet another form

$$\begin{aligned} I_{14} &= \frac{1}{2} \int_0^\beta \int_0^\beta d\tau d\tau' \Delta^2(\tau, \tau') \delta(\tau - \tau') = \\ &= \frac{1}{8} \int_0^\beta \int_0^\beta d\tau d\tau' \epsilon^2(\tau - \tau') \delta(\tau - \tau') + \frac{1}{2} \int_0^\beta d\tau \Delta^2(\tau, \tau) \\ &= \beta \left[\frac{1}{8} \int d\tau \epsilon^2(\tau) \delta(\tau) + \frac{1}{24} \right]. \end{aligned} \quad (10.520)$$

We now see that if we set [compare with the correct equation (10.375)]

$$\int d\tau [\epsilon(\tau)]^2 \delta(\tau) \equiv \frac{1}{3}, \quad (\text{false}), \quad (10.521)$$

the last two results (10.520) and (10.519) coincide with the first in Eq. (10.518). The definition (10.521) would obviously be consistent with partial integration if we insert $\delta(\tau) = \dot{\epsilon}(\tau)/2$:

$$\int d\tau [\epsilon(\tau)]^2 \delta(\tau) = \frac{1}{2} \int d\tau [\epsilon(\tau)]^2 \dot{\epsilon}(\tau) = \frac{1}{6} \int d\tau \frac{d}{d\tau} [\epsilon(\tau)]^3 = \frac{1}{3}. \tag{10.522}$$

In spite of this consistency with partial integration and the equation of motion, Eq. (10.521) is incompatible with the requirement of coordinate independence. This can be seen from the discrepancy between the resulting value $I_{14} = \beta/12$ and the necessary (10.517). In earlier work on the subject by other authors [31]– [36], this discrepancy was compensated by adding the above-mentioned (on p. 817) noncovariant term to the classical action, in violation of Feynman’s construction rules for path integrals.

A similar problem appears with the other Feynman integral (10.516). Applying first Eq. (10.394) we obtain

$$I_{15} = \int_0^\beta \int_0^\beta d\tau d\tau' \Delta(\tau, \tau') \delta^2(\tau - \tau') - \frac{2}{\beta} \int_0^\beta d\tau \Delta(\tau, \tau) + \frac{1}{\beta^2} \int_0^\beta \int_0^\beta d\tau d\tau' \Delta(\tau, \tau'). \tag{10.523}$$

For the integral containing the square of the δ -function we must postulate the integration rule (10.369) to obtain a divergent term

$$I_{15}^{\text{div}} = \delta(0) \int_0^\beta d\tau \Delta(\tau, \tau) = \delta(0) \frac{\beta^2}{6}, \tag{10.524}$$

which is proportional to $\delta(0)$, and compensates a similar term from the measure. The remaining integrals in (10.523) are finite and yield the regular part $I_{15}^R = -\beta/4$, which we shall see to be inconsistent with coordinate invariance. In another calculation of I_{15} , we first add and subtract the UV-divergent term, writing

$$I_{15} = \int_0^\beta \int_0^\beta d\tau d\tau' \Delta(\tau, \tau') [\dot{\Delta}^2(\tau, \tau') - \delta^2(\tau - \tau')] + \delta(0) \frac{\beta^2}{6}. \tag{10.525}$$

Replacing $\delta^2(\tau - \tau')$ by the square of the left-hand side of the equation of motion (10.393), and integrating the terms in brackets by parts, we obtain

$$\begin{aligned} I_{15}^R &= \int_0^\beta \int_0^\beta d\tau d\tau' \Delta(\tau, \tau') [\dot{\Delta}^2(\tau, \tau') - \Delta^{\cdot 2}(\tau, \tau')] \\ &= \int_0^\beta \int_0^\beta d\tau d\tau' [-\dot{\Delta}(\tau, \tau') \dot{\Delta}(\tau, \tau') \dot{\Delta}(\tau, \tau') - \Delta(\tau, \tau') \dot{\Delta}(\tau, \tau') \ddot{\Delta}(\tau, \tau')] \\ &\quad - \int_0^\beta \int_0^\beta d\tau d\tau' [-\Delta^{\cdot 2}(\tau, \tau') \ddot{\Delta}(\tau, \tau') - \Delta(\tau, \tau') \dot{\Delta}(\tau, \tau') \Delta^{\cdot 2}(\tau, \tau')] \\ &= -I_{14} + \int_0^\beta \int_0^\beta d\tau d\tau' \Delta^{\cdot 2}(\tau, \tau') \ddot{\Delta}(\tau, \tau') = -I_{14} - \beta/6. \end{aligned} \tag{10.526}$$

The value of the last integral follows from partial integration.

For a third evaluation of I_{15} we insert the equation of motion (10.393) and bring the last integral in the fourth line of (10.526) to

$$- \int_0^\beta \int_0^\beta d\tau d\tau' \Delta^{\cdot 2}(\tau, \tau') \delta(\tau - \tau') = -\beta \left[\frac{1}{4} \int d\tau \epsilon^2(\tau) \delta(\tau) + \frac{1}{12} \right]. \tag{10.527}$$

All three ways of calculation lead, with the assignment (10.521) to the singular integral, to the same result $I_{15}^R = -\beta/4$ using the rule (10.521). This, however, is again in disagreement with the

coordinate-independent value in Eq. (10.517). Note that both integrals I_{14} and I_{15}^R are too large by a factor 2 with respect to the necessary (10.517) for coordinate independence.

How can we save coordinate independence while maintaining the equation of motion and partial integration? The direction in which the answer lies is suggested by the last line of Eq. (10.520): we must find a consistent way to have an integral $\int d\tau [\epsilon(\tau)]^2 \delta(\tau) = 0$, as in Eq. (10.375), instead of the false value (10.521), which means that we need a reason for forbidding the application of partial integration to this singular integral. For the calculation at the infinite time interval, this problem was solved in Refs. [23]–[25] with the help of dimensional regularization.

In dimensional regularization, we would write the Feynman integral (10.515) in d dimensions as

$$I_{14}^d = \int \int d^d x d^d x' {}_{\mu} \Delta(x, x') \Delta_{\nu}(x, x') {}_{\mu} \Delta_{\nu}(x, x'), \quad (10.528)$$

and see that the different derivatives on ${}_{\mu} \Delta_{\nu}(x, x')$ prevent us from applying the field equation (10.418), in contrast to the one-dimensional calculation. We can, however, apply partial integration as in the first line of Eq. (10.518), and arrive at

$$I_{14}^d = -\frac{1}{2} \int \int d^d x d^d x' \Delta_{\nu}^2(x, x') \Delta_{\mu\mu}(x, x'). \quad (10.529)$$

In contrast to the one-dimensional expression (10.518), a further partial integration is impossible. Instead, we may apply the field equation (10.418), go back to one dimension, and apply the integration rule (10.375) as in Eq. (10.520) to obtain the correct result $I_{14} = \beta/24$ guaranteeing coordinate independence.

The Feynman integral (10.516) for I_{15} is treated likewise. Its d -dimensional extension is

$$I_{15}^d = \int \int d^d x d^d x' \Delta(x, x') [{}_{\mu} \Delta_{\nu}(x, x')]^2. \quad (10.530)$$

The different derivatives on ${}_{\mu} \Delta_{\nu}(x, x')$ make it impossible to apply a dimensionally extended version of equation (10.394) as in Eq. (10.523). We can, however, extract the UV-divergence as in Eq. (10.525), and perform a partial integration on the finite part which brings it to a dimensionally extended version of Eq. (10.526):

$$I_{15}^R = -I_{14} + \int \int d^d x d^d x' \Delta_{\nu}^2(x, x') \Delta_{\mu\mu}(x, x'). \quad (10.531)$$

On the right-hand side we use the field equation (10.418), as in Eq. (10.527), return to $d = 1$, and use the rule (10.375) to obtain the result $I_{15}^R = -I_{14} - \beta/12 = -\beta/8$, again guaranteeing coordinate independence.

Thus, by keeping only track of a few essential properties of the theory in d dimensions we indeed obtain a simple consistent procedure for calculating singular Feynman integrals. All results obtained in this way ensure coordinate independence. They agree with what we would obtain using the one-dimensional integration rule (10.375) for the product of two ϵ - and one δ -distribution.

Our procedure gives us unique rules telling us where we are allowed to apply partial integration and the equation of motion in one-dimensional expressions. Ultimately, all integrals are brought to a regular form, which can be continued back to one time dimension for a direct evaluation. This procedure is obviously much simpler than the previous explicit calculations in d dimensions with the limit $d \rightarrow 1$ taken at the end.

The coordinate independence would require the equations (10.517). Thus, although the calculation in normal coordinates are simpler and can be carried more easily to higher orders, the perturbation in arbitrary coordinates help to fix more ambiguous integrals.

Let us see how the integrals I_{14} and I_{15} arise in the perturbation expansion of the time evolution amplitude in arbitrary coordinates up to the order η , and that the values in (10.517) are necessary

to guarantee a covariant result. We use arbitrary coordinates and expand the metric around the origin. Dropping the increment symbol δ in front of δq^μ , we write:

$$g_{\mu\nu}(q) = \delta_{\mu\nu} + \sqrt{\eta}(\partial_\lambda g_{\mu\nu})q^\lambda + \eta \frac{1}{2}(\partial_\lambda \partial_\kappa g_{\mu\nu})q^\lambda q^\kappa, \quad (10.532)$$

with the expansion parameter η keeping track of the orders of the perturbation series. At the end it will be set equal to unity. The determinant has the expansion to order η :

$$\log g(q) = \sqrt{\eta} g^{\mu\nu}(\partial_\lambda g_{\mu\nu})q^\lambda + \eta \frac{1}{2} g^{\mu\nu} [(\partial_\lambda \partial_\kappa g_{\mu\nu}) - g^{\sigma\tau}(\partial_\lambda g_{\mu\sigma})(\partial_\kappa g_{\nu\tau})]q^\lambda q^\kappa. \quad (10.533)$$

The total interaction (10.410) becomes

$$\begin{aligned} \mathcal{A}_{\text{tot}}^{\text{int}}[q] &= \int_0^\beta d\tau \left\{ \left[\frac{1}{2} \sqrt{\eta} (\partial_\kappa g_{\mu\nu}) q^\kappa + \frac{1}{4} \eta (\partial_\lambda \partial_\kappa g_{\mu\nu}) q^\lambda q^\kappa \right] \dot{q}^\mu \dot{q}^\nu \right. \\ &\quad \left. - \frac{1}{2} \sqrt{\eta} \delta(0) g^{\mu\nu} (\partial_\kappa g_{\mu\nu}) q^\kappa - \frac{1}{4} \eta \delta(0) g^{\mu\nu} [(\partial_\lambda \partial_\kappa g_{\mu\nu}) - g^{\sigma\tau} (\partial_\lambda g_{\mu\sigma})(\partial_\kappa g_{\nu\tau})] q^\lambda q^\kappa \right\}. \end{aligned} \quad (10.534)$$

Using the relations following directly from the definition of the Christoffel symbols (1.70) and (1.71),

$$\begin{aligned} \partial_\kappa g_{\mu\nu} &= -g_{\mu\sigma} g_{\nu\tau} \partial_\kappa g^{\sigma\tau} = \Gamma_{\kappa\mu\nu} + \Gamma_{\kappa\nu\mu} = 2\Gamma_{\kappa\{\mu\nu\}}, & g^{\mu\nu} (\partial_\kappa g_{\mu\nu}) &= 2\Gamma_{\kappa\mu}{}^\mu, \\ \partial_\lambda \partial_\kappa g_{\mu\nu} &= \partial_\lambda \Gamma_{\kappa\mu\nu} + \partial_\lambda \Gamma_{\kappa\nu\mu} = \partial_\lambda \Gamma_{\kappa\{\mu\nu\}}, \\ g^{\mu\nu} (\partial_\tau \partial_\lambda g_{\mu\nu}) &= 2g^{\mu\nu} \partial_\kappa \Gamma_{\sigma\mu\nu} = 2\partial_\kappa (g^{\mu\nu} \Gamma_{\sigma\mu\nu}) - 2\Gamma_{\sigma\mu\nu} \partial_\kappa g^{\mu\nu} \\ &= 2(\partial_\kappa \Gamma_{\sigma\mu}{}^\mu + g^{\mu\nu} \Gamma_{\sigma\mu\tau} \Gamma_{\lambda\nu}{}^\tau + \Gamma_{\sigma\mu}{}^\nu \Gamma_{\lambda\nu}{}^\mu), \end{aligned} \quad (10.535)$$

this becomes

$$\begin{aligned} \mathcal{A}_{\text{tot}}^{\text{int}}[q] &= \int_0^\beta d\tau \left\{ \left[\sqrt{\eta} \Gamma_{\kappa\mu\nu} q^\kappa + \frac{\eta}{2} \partial_\lambda \Gamma_{\kappa\mu\nu} q^\lambda q^\kappa \right] \dot{q}^\mu \dot{q}^\nu \right. \\ &\quad \left. - \delta(0) \left[\sqrt{\eta} \Gamma_{\mu\kappa}{}^\mu q^\kappa + \frac{\eta}{2} \partial_\lambda \Gamma_{\tau\mu}{}^\mu q^\lambda q^\tau \right] \right\}. \end{aligned} \quad (10.536)$$

The derivative of the Christoffel symbol in the last term can also be written differently using the identity $\partial_\lambda g^{\mu\nu} = -g^{\mu\sigma} g^{\nu\tau} \partial_\lambda g_{\sigma\tau}$ as follows:

$$\begin{aligned} \partial_\lambda \Gamma_{\tau\mu}{}^\mu &= \partial_\lambda g^{\mu\nu} \Gamma_{\tau\mu\nu} = g^{\mu\nu} \partial_\lambda \Gamma_{\tau\mu\nu} = g^{\mu\nu} \partial_\lambda \Gamma_{\tau\mu\nu} - g^{\mu\sigma} g^{\nu\tau} (\partial_\lambda g_{\sigma\tau}) \Gamma_{\tau\mu\nu} \\ &= \partial_\lambda \Gamma_{\tau\mu\nu} - (\Gamma_{\lambda\mu\nu} + \Gamma_{\lambda\nu\mu}) \Gamma_{\tau\mu}{}^\nu. \end{aligned} \quad (10.537)$$

To first order in η , we obtain from the first cumulant $\langle \mathcal{A}_{\text{tot}}^{\text{int}}[q] \rangle_c$:

$$\beta f_1^{(1)} = \eta \int_0^\beta d\tau \left\langle \frac{1}{2} \partial_\lambda \Gamma_{\kappa\mu\nu} q^\lambda q^\kappa \dot{q}^\mu \dot{q}^\nu - \delta(0) \frac{1}{2} \partial_\lambda \Gamma_{\tau\mu}{}^\mu q^\lambda q^\tau \right\rangle_c, \quad (10.538)$$

the diagrams (10.490) corresponding to the analytic expression [compare (10.491)]

$$\begin{aligned} \beta f_1^{(1)} &= \frac{\eta}{2} \partial_\lambda \Gamma_{\kappa\{\mu\nu\}} \int_0^\beta d\tau \left\{ g^{\mu\nu} g^{\kappa\lambda} \Delta(\tau, \tau) \Delta(\tau, \tau) + 2g^{\mu\kappa} g^{\nu\lambda} \Delta^2(\tau, \tau) - \delta(0) g^{\mu\nu} g^{\kappa\lambda} \Delta(\tau, \tau) \right\} \\ &\quad - \frac{\eta}{2} g^{\lambda\kappa} (\Gamma_{\lambda\nu}{}^\mu \Gamma_{\mu\kappa}{}^\nu + g^{\tau\mu} \Gamma_{\tau\kappa}{}^\nu \Gamma_{\mu\lambda\nu}) \delta(0) \int_0^\beta d\tau \Delta(\tau, \tau). \end{aligned} \quad (10.539)$$

Replacing $\Delta(\tau, \tau)$ by $\delta(0) - 1/\beta$ according to (10.394), and using the integrals (10.436), the $\delta(0)$ -terms in the first integral cancel and we obtain

$$\beta f_1^{(1)} = -\beta \frac{\eta}{4} \left[\frac{g^{\mu\nu} g^{\kappa\lambda}}{6} (\partial_\lambda \Gamma_{\mu\kappa\nu} - \partial_\mu \Gamma_{\kappa\lambda\nu}) - \frac{g^{\lambda\kappa}}{3} (\Gamma_{\lambda\nu}{}^\mu \Gamma_{\mu\kappa}{}^\nu + g^{\tau\mu} \Gamma_{\tau\kappa}{}^\nu \Gamma_{\mu\lambda\nu}) \delta(0) \right]. \quad (10.540)$$

In addition, there are contributions of order η from the second cumulant

$$-\frac{\eta}{2!} \int_0^\beta d\tau \int_0^\beta d\tau' \left\langle [\Gamma_{\kappa\mu\nu} q^\kappa(\tau) \dot{q}^\mu(\tau) \dot{q}^\nu(\tau) + \delta(0) \Gamma_{\mu\kappa}{}^\mu q^\kappa(\tau)] \right. \\ \left. \times [\Gamma_{\kappa\mu\nu} q^\kappa(\tau') \dot{q}^\mu(\tau') \dot{q}^\nu(\tau') + \delta(0) \Gamma_{\mu\kappa}{}^\mu q^\kappa(\tau')] \right\rangle_c, \quad (10.541)$$

These add to the free energy

$$\beta f_1^{(2)} = -\frac{\eta}{2} g^{\lambda\kappa} \Gamma_{\lambda\mu}{}^\mu \Gamma_{\kappa\nu}{}^\nu \left[\text{---} \circ \text{---} \circ \text{---} - 2\delta(0) \text{---} \circ \text{---} + \delta^2(0) \text{---} \circ \text{---} \right], \\ \beta f_1^{(3)} = -\eta \Gamma_{\lambda\mu}{}^\mu (g^{\lambda\kappa} \Gamma_{\kappa\nu}{}^\nu + g^{\nu\kappa} \Gamma_{\nu\kappa}{}^\lambda) \left[\text{---} \circ \text{---} \circ \text{---} - \delta(0) \text{---} \circ \text{---} \right], \\ \beta f_1^{(4)} = -\frac{\eta}{2} (g^{\mu\lambda} g^{\kappa\tau} \Gamma_{\mu\lambda}{}^\nu \Gamma_{\kappa\tau\nu} + g^{\mu\nu} \Gamma_{\mu\kappa}{}^\kappa \Gamma_{\nu\lambda}{}^\lambda + 2g^{\mu\nu} \Gamma_{\mu\nu}{}^\kappa \Gamma_{\kappa\lambda}{}^\lambda) \text{---} \circ \text{---} \circ \text{---}, \\ \beta f_1^{(5)} = -\frac{\eta}{2} (g^{\mu\kappa} g^{\nu\lambda} \Gamma_{\mu\lambda}{}^\tau \Gamma_{\kappa\beta}{}^\tau + 3g^{\mu\kappa} \Gamma_{\mu\lambda}{}^\tau \Gamma_{\tau\kappa}{}^\lambda) \text{---} \circ \text{---}, \\ \beta f_1^{(6)} = -\frac{\eta}{2} g^{\lambda\kappa} (\Gamma_{\lambda\nu}{}^\mu \Gamma_{\mu\kappa}{}^\nu + g^{\mu\tau} \Gamma_{\tau\kappa}{}^\nu \Gamma_{\mu\lambda\nu}) \text{---} \circ \text{---}. \quad (10.542)$$

The Feynman integrals associated with the diagrams in the first and second lines are

$$I_{11} = \int \int d\tau d\tau' \{ \dot{\Delta}(\tau, \tau) \Delta(\tau, \tau') \dot{\Delta}(\tau', \tau') - 2\delta(0) \dot{\Delta}(\tau, \tau) \Delta(\tau, \tau') + \delta^2(0) \Delta(\tau, \tau') \} \quad (10.543)$$

and

$$I_{12} = \int \int d\tau d\tau' \{ \dot{\Delta}(\tau, \tau) \dot{\Delta}(\tau, \tau') \dot{\Delta}(\tau', \tau') - \delta(0) \dot{\Delta}(\tau, \tau) \dot{\Delta}(\tau, \tau') \}, \quad (10.544)$$

respectively. Replacing in Eqs. (10.543) and (10.544) $\dot{\Delta}(\tau, \tau)$ and $\dot{\Delta}(\tau', \tau')$ by $\delta(0) - 1/\beta$ leads to cancellation of the infinite factors $\delta(0)$ and $\delta^2(0)$ from the measure, such that we are left with

$$I_{11} = \frac{1}{\beta^2} \int_0^\beta d\tau \int_0^\beta d\tau' \Delta(\tau, \tau') = \frac{\beta}{12} \quad (10.545)$$

and

$$I_{12} = -\frac{1}{\beta} \int_0^\beta d\tau \int_0^\beta d\tau' \dot{\Delta}(\tau, \tau) \dot{\Delta}(\tau, \tau') = -\frac{\beta}{12}. \quad (10.546)$$

The Feynman integral of the diagram in the third line of Eq. (10.542) has d -dimensional extension

$$I_{13} = \int \int d\tau d\tau' \dot{\Delta}(\tau, \tau) \dot{\Delta}(\tau', \tau') \dot{\Delta}(\tau, \tau') \\ \rightarrow \int \int d^d x d^d x' {}_\mu \Delta(x, x) {}_\nu \Delta(x', x') {}_\mu \Delta_\nu(x, x'). \quad (10.547)$$

Integrating this partially yields

$$I_{13} = \frac{1}{\beta} \int \int d\tau d\tau' \dot{\Delta}(\tau, \tau') \dot{\Delta}(\tau', \tau') = \frac{1}{\beta} \int_0^\beta d\tau \int_0^\beta d\tau' \dot{\Delta}(\tau, \tau) \dot{\Delta}(\tau, \tau') = \frac{\beta}{12}, \quad (10.548)$$

where we have interchanged the order of integration $\tau \leftrightarrow \tau'$ in the second line of Eq. (10.548) and used $d[\Delta(\tau, \tau)]/d\tau = -1/\beta$. Multiplying the integrals (10.545), (10.546), and (10.548) by corresponding vertices in Eq. (10.542) and adding them together, we obtain

$$\beta f_1^{(2)} + \beta f_1^{(3)} + \beta f_1^{(4)} = -\frac{\eta\beta}{24} g^{\mu\nu} g^{\kappa\lambda} \Gamma_{\mu\nu}{}^\tau \Gamma_{\kappa\lambda\tau}. \tag{10.549}$$

The contributions of the last three diagrams in $\beta f_1^{(5)}$ and $\beta f_1^{(6)}$ of (10.542) are determined by the initially ambiguous integrals (10.515) and (10.516) to be equal to $I_{14} = -\beta/24$ and $I_{15} = -\beta/8 + \delta(0)\beta^2/6$, respectively. Moreover, the $\delta(0)$ -part in the latter, when inserted into the last line of Eq. (10.542) for $f_1^{(6)}$, is canceled by the contribution of the local diagram with the factor $\delta(0)$ in $f_1^{(1)}$ of (10.540). We see here an example that with general coordinates, the divergences containing powers of $\delta(0)$ no longer cancel order by order in \hbar , but do so at the end.

Thus only the finite part $I_{15}^R = -\beta/24$ remains and we find

$$\begin{aligned} \beta f_1^{(5)} + \beta f_1^{(6)R} &= -\frac{\eta}{2} \left\{ g^{\mu\kappa} g^{\nu\lambda} \Gamma_{\mu\lambda}{}^\tau \Gamma_{\kappa\nu\tau} (I_{14} + I_{15}^R) + g^{\lambda\kappa} \Gamma_{\lambda\nu}{}^\mu \Gamma_{\mu\kappa}{}^\nu (3I_{14} + I_{15}^R) \right\} \\ &= \frac{\eta\beta}{24} g^{\mu\nu} g^{\kappa\lambda} \Gamma_{\mu\kappa}{}^\sigma \Gamma_{\nu\lambda\sigma}. \end{aligned} \tag{10.550}$$

By adding this to (10.549), we find the sum of all diagrams in (10.542) as follows

$$\sum_{i=2}^6 \beta f_1^{(i)} = -\frac{\eta\beta}{24} g^{\mu\nu} g^{\kappa\lambda} (\Gamma_{\mu\nu}{}^\sigma \Gamma_{\kappa\lambda\sigma} - \Gamma_{\mu\kappa}{}^\sigma \Gamma_{\lambda\nu}{}^\sigma). \tag{10.551}$$

Together with the regular part of (10.540) in the first line, this yields the sum of all first-order diagrams

$$\sum_{i=1}^6 \beta f_1^{(i)} = -\frac{\eta\beta}{24} g^{\mu\nu} g^{\kappa\lambda} R_{\lambda\mu\kappa\nu} = \frac{\eta\beta}{24} \bar{R}. \tag{10.552}$$

The result is covariant and agrees, of course, with Eq. (10.492) derived with normal coordinate. Note that to obtain this covariant result, the initially ambiguous integrals (10.515) and (10.516) over distributions appearing in Eq. (10.550) must satisfy

$$\begin{aligned} I_{14} + I_{15}^R &= -\frac{\beta}{12}, \\ 3I_{14} + I_{15}^R &= 0, \end{aligned} \tag{10.553}$$

which leaves only the values (10.517).

10.12 Effective Classical Potential in Curved Space

In Chapter 5 we have seen that the partition function of a quantum statistical system in flat space can always be written as an integral over a classical Boltzmann factor $\exp[-\beta V^{\text{eff cl}}(\mathbf{x}_0)]$, where $B(\mathbf{x}_0) = V^{\text{eff cl}}(\mathbf{x}_0)$ is the so-called *effective classical potential* containing the effects of all quantum fluctuations. The variable of integration is the temporal path average $\mathbf{x}_0 \equiv \beta^{-1} \int_0^\beta d\tau \mathbf{x}(\tau)$. In this section we generalize this concept to curved space, and show how to calculate perturbatively the high-temperature expansion of $V^{\text{eff cl}}(q_0)$. The requirement of independence under coordinate transformations $q^\mu(\tau) \rightarrow q'^\mu(\tau)$ introduces subtleties into the definition

and treatment of the path average q_0^μ , and covariance is achieved only with the help of a procedure invented by Faddeev and Popov [49] to deal with gauge freedoms in quantum field theory.

In the literature, attempts to introduce an effective classical potential in curved space around a fixed temporal average $q_0 \equiv \bar{q}(\tau) \equiv \beta^{-1} \int_0^\beta d\tau q(\tau)$ have so far failed and produced a two-loop perturbative result for $V^{\text{eff cl}}(q_0)$ which turned out to deviate from the covariant one by a noncovariant total derivative [34], in contrast to the covariant result (10.494) obtained with Dirichlet boundary conditions. For this reason, perturbatively defined path integrals with periodic boundary conditions in curved space have been of limited use in the presently popular first-quantized worldline approach to quantum field theory (also called the string-inspired approach reviewed in Ref. [50]). In particular, it has so far been impossible to calculate with periodic boundary conditions interesting quantities such as curved-space effective actions, gravitational anomalies, and index densities, all results having been reproduced with Dirichlet boundary conditions [46, 52].

The development in this chapter cures the problems by exhibiting a manifestly covariant integration procedure for periodic paths [51]. It is an adaption of similar procedures used before in the effective action formalism of two-dimensional sigma-models [46]. Covariance is achieved by expanding the fluctuations in the neighborhood of any given point in powers of geodesic coordinates, and by a covariant definition of a path average different from the naive temporal average. As a result, we shall find the same locally covariant perturbation expansion of the effective classical potential as in Eq. (10.494) calculated with Dirichlet boundary conditions.

All problems encountered in the literature occur in the first correction terms linear in β in the time evolution amplitude. It will therefore be sufficient to consider only to lowest-order perturbation expansion. For this reason we shall from now on drop the parameter of smallness η used before.

10.12.1 Covariant Fluctuation Expansion

We want to calculate the partition function from the functional integral over all periodic paths

$$Z = \oint \mathcal{D}^D q \sqrt{g(q)} e^{-\mathcal{A}[q]}, \quad (10.554)$$

where the symbol \oint indicates the periodicity of the paths. By analogy with (2.443), we split the paths into a time-independent and a time-dependent part:

$$q^\mu = q_0^\mu + \eta^\mu(\tau), \quad (10.555)$$

with the goal to express the partition function as in Eq. (3.811) by an ordinary integral over an effective classical partition function

$$Z = \int \frac{d^D q_0}{\sqrt{2\pi\beta^D}} \sqrt{g(q_0)} e^{-\beta V^{\text{eff cl}}(q_0)}, \quad (10.556)$$

where $V^{\text{eff cl}}(q_0)$ is the curved-space version of the effective classical partition function. For a covariant treatment, we parametrize the small fluctuations $\eta^\mu(\tau)$ in terms of the prepoint normal coordinates $\Delta\xi^\mu(\tau)$ of the point q_0^μ introduced in Eq. (10.98), which are here geodesic due to the absence of torsion. Omitting the smallness symbols Δ , there will be some *nonlinear* decomposition

$$q^\mu(\tau) = q_0^\mu + \eta^\mu(q_0, \xi), \quad (10.557)$$

where $\eta^\mu(q_0, \xi) = 0$ for $\xi^\mu = 0$. Inverting the relation (10.98) we obtain

$$\eta^\mu(q_0, \xi) = \xi^\mu - \frac{1}{2}\bar{\Gamma}_{\sigma\tau}{}^\mu(q_0)\xi^\sigma\xi^\tau - \frac{1}{6}\bar{\Gamma}_{\sigma\tau\kappa}{}^\mu(q_0)\xi^\sigma\xi^\tau\xi^\kappa - \dots, \quad (10.558)$$

where the coefficients $\bar{\Gamma}_{\sigma\tau\dots\kappa}{}^\mu(q_0)$ with more than two subscripts are defined similarly to covariant derivatives with respect to lower indices (they are not covariant quantities):

$$\bar{\Gamma}_{\sigma\tau\kappa}{}^\mu(q_0) = \nabla_\kappa\bar{\Gamma}_{\sigma\tau}{}^\mu = \partial_\kappa\bar{\Gamma}_{\sigma\tau}{}^\mu - 2\bar{\Gamma}_{\kappa\sigma}{}^\nu\bar{\Gamma}_{\nu\tau}{}^\mu, \dots \quad (10.559)$$

If the initial coordinates q^μ are themselves geodesic at q_0^μ , all coefficients $\bar{\Gamma}_{\sigma\tau\dots\kappa}{}^\mu(q_0)$ in Eq. (10.558) are zero, so that $\eta^\mu(\tau) = \xi^\mu(\tau)$, and the decomposition (10.557) is linear. In arbitrary coordinates, however, $\eta^\mu(\tau)$ does not transform like a vector under coordinate transformations, and we must use the nonlinear decomposition (10.557).

We now transform the path integral (10.554) to the new coordinates $\xi^\mu(\tau)$ using Eqs. (10.557)–(10.559). The perturbation expansion for the transformed path integral over $\xi^\mu(\tau)$ is constructed for any chosen q_0^μ by expanding the total action (10.408) including the measure factor (10.406) in powers of small linear fluctuations $\xi^\mu(\tau)$. Being interested only in the lowest-order contributions we shall from now on drop the parameter of smallness η counting the orders in the earlier perturbation expansions. This is also useful since the similar symbol $\eta^\mu(\tau)$ is used here to describe the path fluctuations. The action relevant for the terms to be calculated here consists of a free action, which we write after a partial integration as

$$\mathcal{A}^{(0)}[q_0, \xi] = g_{\mu\nu}(q_0) \int_0^\beta d\tau \frac{1}{2} \xi^\mu(\tau) (-\partial_\tau^2) \xi^\nu(\tau), \quad (10.560)$$

and an interaction which contains only the leading terms in (10.479):

$$\mathcal{A}_{\text{tot}}^{\text{int}}[q_0; \xi] = \int_0^\beta d\tau \left[\frac{1}{6} \bar{R}_{\mu\lambda\nu\kappa} \xi^\lambda \xi^\kappa \dot{\xi}^\mu \dot{\xi}^\nu + \frac{1}{6} \delta(0) \bar{R}_{\mu\nu} \xi^\mu \xi^\nu \right]. \quad (10.561)$$

The partition function (10.554) in terms of the coordinates $\xi^\mu(\tau)$ is obtained from the perturbation expansion

$$Z = \oint \mathcal{D}^D \xi(\tau) \sqrt{g(q_0)} e^{-\mathcal{A}^{(0)}[q_0, \xi] - \mathcal{A}_{\text{tot}}^{\text{int}}[q_0, \xi]}. \quad (10.562)$$

The path integral (10.562) cannot immediately be calculated perturbatively in the standard way, since the quadratic form of the free action (10.560) is degenerate. The spectrum of the operator $-\partial_\tau^2$ in the space of periodic functions $\xi^\mu(\tau)$ has a zero mode. The zero mode is associated with the fluctuations of the temporal average of $\xi^\mu(\tau)$:

$$\xi_0^\mu = \bar{\xi}^\mu \equiv \beta^{-1} \int_0^\beta d\tau \xi^\mu(\tau). \quad (10.563)$$

Small fluctuations of ξ_0^μ have the effect of moving the path as a whole infinitesimally through the manifold. The same movement can be achieved by changing q_0^μ infinitesimally. Thus we can replace the integral over the path average ξ_0^μ by an integral over q_0^μ , provided that we properly account for the change of measure arising from such a variable transformation.

Anticipating such a change, the path average (10.563) can be set equal to zero eliminating the zero mode in the fluctuation spectrum. The basic free correlation function $\langle \xi^\mu(\tau) \xi^\nu(\tau') \rangle$ can then easily be found from its spectral representation as shown in Eq. (3.254). The result is

$$\langle \xi^\mu(\tau) \xi^\nu(\tau') \rangle^{q_0} = g^{\mu\nu}(q_0) (-\partial_\tau^2)^{-1} \delta(\tau - \tau') = g^{\mu\nu}(q_0) \bar{\Delta}(\tau, \tau'), \quad (10.564)$$

where $\bar{\Delta}(\tau, \tau')$ is a short notation for the translationally invariant periodic Green function $G_{0,e}^{\mu\nu}(\tau)$ of the operator $-\partial_\tau^2$ without the zero mode in Eq. (3.254) (for a plot see Fig. 3.4):

$$\bar{\Delta}(\tau, \tau') = \bar{\Delta}(\tau - \tau') \equiv \frac{(\tau - \tau')^2}{2\beta} - \frac{|\tau - \tau'|}{2} + \frac{\beta}{12}, \quad \tau, \tau' \in [0, \hbar\beta]. \quad (10.565)$$

This notation is useful since we shall have to calculate Feynman integrals of precisely the same form as previously with the Dirichlet-type correlation function Eq. (10.392). In contrast to (10.393) and (10.394) for $\Delta(\tau, \tau')$, the translational invariance of the periodic correlation function implies that $\bar{\Delta}(\tau, \tau') = \bar{\Delta}(\tau - \tau')$, so that the first time derivatives of $\bar{\Delta}(\tau, \tau')$ have opposite signs:

$$\dot{\bar{\Delta}}(\tau, \tau') = -\dot{\bar{\Delta}}(\tau, \tau') \equiv \frac{\tau - \tau'}{\beta} - \frac{\epsilon(\tau - \tau')}{2}, \quad \tau, \tau' \in [0, \hbar\beta], \quad (10.566)$$

and the three possible double time derivatives are equal, up to a sign:

$$-\ddot{\bar{\Delta}}(\tau, \tau') = -\ddot{\bar{\Delta}}(\tau, \tau') = \ddot{\bar{\Delta}}(\tau, \tau') = \delta(\tau - \tau') - 1/\beta. \quad (10.567)$$

The right-hand side contains an extra term on the right-hand side due to the missing zero eigenmode in the spectral representation of the δ -function:

$$\frac{1}{\beta} \sum_{m \neq 0} e^{-i\omega_m(\tau - \tau')} = \delta(\tau - \tau') - \frac{1}{\beta}. \quad (10.568)$$

The third equation in (10.567) happens to coincide with the differential equation (10.394) in the Dirichlet case. All three equations have the same right-hand side due to the translational invariance of $\bar{\Delta}(\tau, \tau')$.

10.12.2 Arbitrariness of q_0^μ

We now take advantage of an important property of the perturbation expansion of the partition function (10.562) around $q^\mu(\tau) = q_0^\mu$: the *independence* of the choice of q_0^μ . The separation (10.557) into a constant q_0^μ and a time-dependent $\xi^\mu(\tau)$ paths must lead to the same result for any nearby constant $q_0'^\mu$ on the manifold. The result must therefore be invariant under an arbitrary infinitesimal displacement

$$q_0^\mu \rightarrow q_{0\varepsilon}^\mu = q_0^\mu + \varepsilon^\mu, \quad |\varepsilon| \ll 1. \quad (10.569)$$

In the path integral, this will be compensated by some translation of fluctuation coordinates $\xi^\mu(\tau)$, which will have the general nonlinear form

$$\xi^\mu \rightarrow \xi_\varepsilon^\mu = \xi^\mu - \varepsilon^\nu Q_\nu^\mu(q_0, \xi). \quad (10.570)$$

The transformation matrix $Q_\nu^\mu(q_0, \xi)$ satisfies the obvious initial condition $Q_\nu^\mu(q_0, 0) = \delta_\nu^\mu$. The path $q^\mu(\tau) = q^\mu(q_0, \xi(\tau))$ must remain invariant under simultaneous transformations (10.569) and (10.570), which implies that

$$\delta q^\mu \equiv q_\varepsilon^\mu - q^\mu = \varepsilon^\nu D_\nu q^\mu(q_0, \xi) = 0, \quad (10.571)$$

where D_μ is the infinitesimal transition operator

$$D_\mu = \frac{\partial}{\partial q_0^\mu} - Q_\mu^\nu(q_0, \xi) \frac{\partial}{\partial \xi^\nu}. \quad (10.572)$$

Geometrically, the matrix $Q_\nu^\mu(q_0, \xi)$ plays the role of a locally flat nonlinear connection [46]. It can be calculated as follows. We express the vector $q^\mu(q_0, \xi)$ in terms of the geodesic coordinates ξ^μ using Eqs. (10.557), (10.558), and (10.559), and substitute this into Eq. (10.571). The coefficients of ε^ν yield the equations

$$\delta_\nu^\mu + \frac{\partial \eta^\mu(q_0, \xi)}{\partial q_0^\nu} - Q_\nu^\kappa(q_0, \xi) \frac{\partial \eta^\mu(q_0, \xi)}{\partial \xi^\kappa} = 0, \quad (10.573)$$

where by Eq. (10.558):

$$\frac{\partial \eta^\mu(q_0, \xi)}{\partial q_0^\nu} = -\frac{1}{2} \partial_\nu \bar{\Gamma}_{(\sigma\tau)}^\mu(q_0) \xi^\sigma \xi^\tau - \dots, \quad (10.574)$$

and

$$\begin{aligned} \frac{\partial \eta^\mu(q_0, \xi)}{\partial \xi^\nu} &= \delta_\nu^\mu - \bar{\Gamma}_{(\nu\sigma)}^\mu(q_0) \xi^\sigma - \frac{1}{2} \bar{\Gamma}_{(\nu\sigma\tau)}^\mu(q_0) \xi^\sigma \xi^\tau - \dots \\ &= \delta_\nu^\mu - \bar{\Gamma}_{\nu\sigma}^\mu \xi^\sigma - \frac{1}{3} \left(\partial_\sigma \bar{\Gamma}_{\nu\tau}^\mu + \frac{1}{2} \partial_\nu \bar{\Gamma}_{\sigma\tau}^\mu - 2 \bar{\Gamma}_{\tau\nu}^\kappa \bar{\Gamma}_{\kappa\sigma}^\mu - \bar{\Gamma}_{\tau\sigma}^\kappa \bar{\Gamma}_{\kappa\nu}^\mu \right) \xi^\sigma \xi^\tau - \dots \end{aligned} \quad (10.575)$$

To find $Q_\nu^\mu(q_0, \xi)$, we invert the expansion (10.575) to

$$\begin{aligned} \left[\left(\frac{\partial \eta(q_0, \xi)}{\partial \xi} \right)^{-1} \right]_\nu^\mu &= \delta_\nu^\mu + \bar{\Gamma}_{\nu\sigma}^\mu \xi^\sigma + \frac{1}{3} \left(\partial_\sigma \bar{\Gamma}_{\nu\tau}^\mu + \frac{1}{2} \partial_\nu \bar{\Gamma}_{\sigma\tau}^\mu + \bar{\Gamma}_{\tau\nu}^\kappa \bar{\Gamma}_{\kappa\sigma}^\mu - \bar{\Gamma}_{\tau\sigma}^\kappa \bar{\Gamma}_{\kappa\nu}^\mu \right) \xi^\sigma \xi^\tau + \dots \quad (10.576) \\ &= \left(\frac{\partial \xi^\mu(q_0, \eta)}{\partial \eta^\nu} \right)_{\eta=\eta(q_0, \xi)}, \end{aligned}$$

the last equality indicating that the result (10.576) can also be obtained from the original expansion (10.98) in the present notation [compare (10.558)]:

$$\xi^\mu(q_0, \eta) = \eta^\mu + \frac{1}{2} \tilde{\Gamma}_{\sigma\tau}{}^\mu(q_0) \eta^\sigma \eta^\tau + \frac{1}{6} \tilde{\Gamma}_{\sigma\tau\kappa}{}^\mu(q_0) \eta^\sigma \eta^\tau \eta^\kappa + \dots, \quad (10.577)$$

with coefficients

$$\begin{aligned} \tilde{\Gamma}_{\sigma\tau}{}^\mu(q_0) &= \bar{\Gamma}_{\sigma\tau}{}^\mu, \\ \tilde{\Gamma}_{\sigma\tau\kappa}{}^\mu(q_0) &= \bar{\Gamma}_{\sigma\tau\kappa}{}^\mu + 3\bar{\Gamma}_{\kappa\sigma}{}^\nu \bar{\Gamma}_{\nu\tau}{}^\mu = \partial_\kappa \bar{\Gamma}_{\sigma\tau}{}^\mu + \bar{\Gamma}_{\kappa\sigma}{}^\nu \bar{\Gamma}_{\nu\tau}{}^\mu, \\ &\vdots \quad . \end{aligned} \quad (10.578)$$

Indeed, differentiating (10.577) with respect to η^ν , and re-expressing the result in terms of ξ^μ via Eq. (10.558), we find once more (10.576).

Multiplying both sides of Eq. (10.573) by (10.576), we express the nonlinear connection $Q_\nu^\mu(q_0, \xi)$ by means of geodesic coordinates $\xi^\mu(\tau)$ as

$$Q_\nu^\mu(q_0, \xi) = \delta_\nu^\mu + \bar{\Gamma}_{\nu\sigma}{}^\mu(q_0) \xi^\sigma + \frac{1}{3} \bar{R}_{\sigma\nu\tau}{}^\mu(q_0) \xi^\sigma \xi^\tau + \dots \quad (10.579)$$

The effect of simultaneous transformations (10.569), (10.570) upon the fluctuation function $\eta^\mu = \eta^\mu(q_0, \xi)$ in Eq. (10.558) is

$$\eta^\mu \rightarrow \eta'^\mu = \eta^\mu - \varepsilon^\nu \bar{Q}_\nu^\mu(q_0, \eta), \quad \bar{Q}_\nu^\mu(q_0, 0) = \delta_\nu^\mu, \quad (10.580)$$

where the matrix $\bar{Q}_\nu^\mu(q_0, \eta)$ is related to $Q_\nu^\mu(q_0, \xi)$ as follows

$$\bar{Q}_\nu^\mu(q_0, \eta) = \left[Q_\nu^\kappa(q_0, \xi) \frac{\partial \eta^\mu(q_0, \xi)}{\partial \xi^\kappa} - \frac{\partial \eta^\mu(q_0, \xi)}{\partial q_0^\nu} \right]_{\xi=\xi(q_0, \eta)}. \quad (10.581)$$

Applying Eq. (10.573) to the right-hand side of Eq. (10.581) yields $\bar{Q}_\nu^\mu(q_0, \eta) = \delta_\nu^\mu$, as it should to compensate the translation (10.569).

The above independence of q_0^μ will be essential for constructing the correct perturbation expansion for the path integral (10.562). For some special cases of the Riemannian manifold, such as a surface of sphere in $D + 1$ dimensions which forms a homogeneous space $O(D)/O(D - 1)$, all points are equivalent, and the local independence becomes global. This will be discussed further in Section 10.12.6.

10.12.3 Zero-Mode Properties

We are now prepared to eliminate the zero mode by the condition of vanishing average $\bar{\xi}^\mu = 0$. As mentioned before, the vanishing fluctuation $\xi^\mu(\tau) = 0$ is obviously a classical saddle-point for the path integral (10.562). In addition, because of the symmetry (10.570) there exist other equivalent extrema $\xi_\varepsilon^\mu(\tau) = -\varepsilon^\mu = \text{const}$. The D components of ε^μ correspond to D zero modes which we shall eliminate in favor of

a change of q_0^μ . The proper way of doing this is provided by the Faddeev-Popov procedure. We insert into the path integral (10.562) the trivial unit integral, rewritten with the help of (10.569):

$$1 = \int d^D q_0 \delta^{(D)}(q_{0\varepsilon} - q_0) = \int d^D q_0 \delta^{(D)}(\varepsilon), \quad (10.582)$$

and decompose the measure of path integration over all periodic paths $\xi^\mu(\tau)$ into a product of an ordinary integral over the temporal average $\xi_0^\mu = \bar{\xi}^\mu$, and a remainder containing only nonzero Fourier components [recall (2.448)]

$$\oint \mathcal{D}^D \xi = \int \frac{d^D \xi_0}{\sqrt{2\pi\beta^D}} \oint \mathcal{D}'^D \xi. \quad (10.583)$$

According to Eq. (10.570), the path average $\bar{\xi}^\mu$ is translated under ε^μ as follows

$$\bar{\xi}^\mu \rightarrow \bar{\xi}_\varepsilon^\mu = \bar{\xi}^\mu - \varepsilon^\nu \frac{1}{\beta} \int_0^\beta d\tau Q_\nu^\mu(q_0, \xi(\tau)). \quad (10.584)$$

Thus we can replace

$$\int \frac{d^D \xi_0}{\sqrt{2\pi\beta^D}} \rightarrow \int \frac{d^D \varepsilon}{\sqrt{2\pi\beta^D}} \det \left[\frac{1}{\beta} \int_0^\beta d\tau Q_\nu^\mu(q_0, \xi(\tau)) \right]. \quad (10.585)$$

Performing this replacement in (10.583) and performing the integral over ε^μ in the inserted unity (10.582), we obtain the measure of path integration in terms of q_0^μ and geodesic coordinates of zero temporal average

$$\begin{aligned} \oint \mathcal{D}^D \xi &= \int d^D q_0 \oint \frac{d^D \xi_0}{\sqrt{2\pi\beta^D}} \delta^{(D)}(\varepsilon) \oint \mathcal{D}'^D \xi \\ &= \int \frac{d^D q_0}{\sqrt{2\pi\beta^D}} \oint \mathcal{D}'^D \xi \det \left[\frac{1}{\beta} \int_0^\beta d\tau Q_\nu^\mu(q_0, \xi(\tau)) \right]. \end{aligned} \quad (10.586)$$

The factor on the right-hand side is the Faddeev-Popov determinant $\Delta[q_0, \xi]$ for the change from ξ_0^μ to q_0^μ . We shall write it as an exponential:

$$\Delta[q_0, \xi] = \det \left[\frac{1}{\beta} \int_0^\beta d\tau Q_\nu^\mu(q_0, \xi) \right] = e^{-\mathcal{A}^{\text{FP}}[q_0, \xi]}, \quad (10.587)$$

where $\mathcal{A}^{\text{FP}}[q_0, \xi]$ is an auxiliary action accounting for the Faddeev-Popov determinant

$$\mathcal{A}^{\text{FP}}[q_0, \xi] \equiv -\text{tr} \log \left[\frac{1}{\beta} \int_0^\beta d\tau Q_\nu^\mu(q_0, \xi) \right], \quad (10.588)$$

which must be included into the interaction (10.561). Inserting (10.579) into Eq. (10.588), we find explicitly

$$\begin{aligned} \mathcal{A}^{\text{FP}}[q_0, \xi] &= -\text{tr} \log \left[\delta_\nu^\mu + (3\beta)^{-1} \int_0^\beta d\tau \bar{R}_{\sigma\nu\tau}{}^\mu(q_0) \xi^\sigma(\tau) \xi^\tau(\tau) + \dots \right] \\ &= \frac{1}{3\beta} \int_0^\beta d\tau \bar{R}_{\mu\nu}(q_0) \xi^\mu \xi^\nu + \dots \end{aligned} \quad (10.589)$$

The contribution of this action will be crucial for obtaining the correct perturbation expansion of the path integral (10.562).

With the new interaction

$$\mathcal{A}_{\text{tot,FP}}^{\text{int}}[q_0, \xi] = \mathcal{A}_{\text{tot}}^{\text{int}}[q_0, \xi] + \mathcal{A}^{\text{FP}}[q_0, \xi] \quad (10.590)$$

the partition function (10.562) can be written as a classical partition function

$$Z = \int \frac{d^D q_0}{\sqrt{2\pi\beta}^D} \sqrt{g(q_0)} e^{-\beta V^{\text{eff cl}}(q_0)}, \quad (10.591)$$

where $V^{\text{eff cl}}(q_0)$ is the curved-space version of the effective classical partition function of Ref. [53]. The effective classical Boltzmann factor

$$B(q_0) \equiv e^{-\beta V^{\text{eff cl}}(q_0)} \quad (10.592)$$

is given by the path integral

$$B(q_0) = \oint \mathcal{D}^D \xi \sqrt{g(q_0)} e^{-\mathcal{A}^{(0)}[q_0, \xi] - \mathcal{A}_{\text{tot,FP}}^{\text{int}}[q_0, \xi]}. \quad (10.593)$$

Since the zero mode is absent in the fluctuations on the right-hand side, the perturbation expansion is now straightforward. We expand the path integral (10.593) in powers of the interaction (10.590) around the free Boltzmann factor

$$B_0(q_0) = \oint \mathcal{D}^D \xi \sqrt{g(q_0)} e^{-\int_0^\beta d\tau \frac{1}{2} g_{\mu\nu}(q_0) \dot{\xi}^\mu \dot{\xi}^\nu} \quad (10.594)$$

as follows:

$$B(q_0) = B_0(q_0) \left[1 - \langle \mathcal{A}_{\text{tot,FP}}^{\text{int}}[q_0, \xi] \rangle^{q_0} + \frac{1}{2} \langle \mathcal{A}_{\text{tot,FP}}^{\text{int}}[q_0, \xi]^2 \rangle^{q_0} - \dots \right], \quad (10.595)$$

where the q_0 -dependent correlation functions are defined by the Gaussian path integrals

$$\langle \dots \rangle^{q_0} = B^{-1}(q_0) \oint \mathcal{D}^D \xi [\dots]^{q_0} e^{-\mathcal{A}^{(0)}[q_0, \xi]}. \quad (10.596)$$

By taking the logarithm of (10.594), we obtain directly a cumulant expansion for the effective classical potential $V^{\text{eff cl}}(q_0)$.

For a proper normalization of the Gaussian path integral (10.594) we diagonalize the free action in the exponent by going back to the orthonormal components Δx^i in (10.97). Omitting again the smallness symbols Δ , the measure of the path integral becomes simply:

$$\oint \mathcal{D}^D \xi^\mu \sqrt{g(q_0)} = \oint \mathcal{D}^D x^i, \quad (10.597)$$

and we find

$$B_0(q_0) = \oint \mathcal{D}^D x^i e^{-\int_0^\beta d\tau \frac{1}{2} \dot{\xi}^2}. \quad (10.598)$$

If we expand the fluctuations $x^i(\tau)$ into the eigenfunctions $e^{-i\omega_m\tau}$ of the operator $-\partial_\tau^2$ for periodic boundary conditions $x^i(0) = x^i(\beta)$,

$$x^i(\tau) = \sum_m x_m^i u_m(\tau) = x_0^i + \sum_{m \neq 0} x_m^i u_m(\tau), \quad x_{-m}^i = x_m^{i*}, \quad m > 0, \quad (10.599)$$

and substitute this into the path integral (10.598), the exponent becomes

$$-\frac{1}{2} \int_0^\beta d\tau [x^i(\tau)]^2 = -\frac{\beta}{2} \sum_{m \neq 0} \omega_m^2 x_{-m}^i x_m^i = -\beta \sum_{m > 0} \omega_m^2 x_m^{i*} x_m^i. \quad (10.600)$$

Remembering the explicit form of the measure (2.447) the Gaussian integrals in (10.598) yield the free-particle Boltzmann factor

$$B_0(q_0) = 1, \quad (10.601)$$

corresponding to a vanishing effective classical potential in Eq. (10.592).

The perturbation expansion (10.595) becomes therefore simply

$$B(q_0) = 1 - \langle \mathcal{A}_{\text{tot,FP}}^{\text{int}}[q_0, \xi] \rangle^{q_0} + \frac{1}{2} \langle \mathcal{A}_{\text{tot,FP}}^{\text{int}}[q_0, \xi]^2 \rangle^{q_0} - \dots \quad (10.602)$$

The expectation values on the right-hand side are to be calculated with the help of Wick contractions involving the basic correlation function of $\xi^a(\tau)$ associated with the unperturbed action in (10.598):

$$\langle x^i(\tau) x^j(\tau') \rangle^{q_0} = \delta^{ij} \bar{\Delta}(\tau, \tau'), \quad (10.603)$$

which is, of course, consistent with (10.564) via Eq. (10.97).

10.12.4 Covariant Perturbation Expansion

We now perform all possible Wick contractions of the fluctuations $\xi^\mu(\tau)$ in the expectation values (10.602) using the correlation function (10.564). We restrict our attention to the lowest-order terms only, since all problems of previous treatments arise already there. Making use of Eqs. (10.565) and (10.567), we find for the interaction (10.561):

$$\begin{aligned} \langle \mathcal{A}_{\text{tot}}^{\text{int}}[q_0, \xi] \rangle^{q_0} &= \int_0^\beta d\tau \frac{1}{6} [\bar{R}_{\mu\lambda\nu\kappa}(q_0) \langle \xi^\lambda \xi^\kappa \dot{\xi}^\mu \dot{\xi}^\nu \rangle^{q_0} + \delta(0) \bar{R}_{\mu\nu}(q_0) \langle \xi^\mu \xi^\nu \rangle^{q_0}] \\ &= \frac{1}{72} \bar{R}(q_0) \beta, \end{aligned} \quad (10.604)$$

and for (10.589):

$$\langle \mathcal{A}^{\text{FP}}[q_0, \xi] \rangle^{q_0} = \int_0^\beta d\tau \frac{1}{3\beta} \bar{R}_{\mu\nu}(q_0) \langle \xi^\mu \xi^\nu \rangle^{q_0} = \frac{1}{36} \bar{R}(q_0) \beta. \quad (10.605)$$

The sum of the two contributions yields the manifestly covariant high-temperature expansion up to two loops:

$$B(q_0) = 1 - \langle \mathcal{A}_{\text{tot,FP}}^{\text{int}}[q_0, \xi] \rangle^{q_0} + \dots = 1 - \frac{1}{24} \bar{R}(q_0) \beta + \dots \quad (10.606)$$

in agreement with the partition function density (10.494) calculated from Dirichlet boundary conditions. The associated partition function

$$Z^{\text{P}} = \int \frac{d^D q_0}{\sqrt{2\pi\beta}^D} \sqrt{g(q_0)} B(q_0) \quad (10.607)$$

coincides with the partition function obtained by integrating over the partition function density (10.494). Note the crucial role of the action (10.589) coming from the Faddeev-Popov determinant in obtaining the correct two-loop coefficient in Eq. (10.606) and the normalization in Eq. (10.607).

The intermediate transformation to the geodesic coordinates $\xi^\mu(\tau)$ has made our calculations rather lengthy if the action is given in arbitrary coordinates, but it guarantees complete independence of the coordinates in the result (10.606). The entire derivation simplifies, of course, drastically if we choose from the outset geodesic coordinates to parametrize the curved space.

10.12.5 Covariant Result from Noncovariant Expansion

Having found the proper way of calculating the Boltzmann factor $B(q_0)$ we can easily set up a procedure for calculating the same covariant result without the use of the geodesic fluctuations $\xi^\mu(\tau)$. Thus we would like to evaluate the path integral (10.594) by a direct expansion of the action in powers of the noncovariant fluctuations $\eta^\mu(\tau)$ in Eq. (10.557). In order to make q_0^μ equal to the path average, $\bar{q}(\tau)$, we now require $\eta^\mu(\tau)$ to have a vanishing temporal average $\eta_0^\mu = \bar{\eta}^\mu = 0$.

Instead of (10.560), the free action reads now

$$\mathcal{A}^{(0)}[q_0, \eta] = g_{\mu\nu}(q_0) \int_0^\beta d\tau \frac{1}{2} \eta^\mu(\tau) (-\partial_\tau^2) \eta^\nu(\tau), \quad (10.608)$$

and the small- β behavior of the path integral (10.607) is governed by the interaction $\mathcal{A}_{\text{tot}}^{\text{int}}[q]$ of Eq. (10.536) with unit smallness parameter η . In a notation as in (10.561), the interaction (10.536) reads

$$\begin{aligned} \mathcal{A}_{\text{tot}}^{\text{int}}[q_0; \eta] = \int_0^\beta d\tau \left\{ \left[\Gamma_{\kappa\mu\nu} \eta^\kappa + \frac{1}{2} \partial_\lambda \Gamma_{\kappa\mu\nu} \eta^\lambda \eta^\kappa \right] \dot{\eta}^\mu \dot{\eta}^\nu \right. \\ \left. - \delta(0) \left[\Gamma_{\mu\kappa}{}^\mu \eta^\kappa + \frac{1}{2} \partial_\lambda \Gamma_{\tau\mu}{}^\mu \eta^\lambda \eta^\tau \right] \right\}. \end{aligned} \quad (10.609)$$

We must deduce the measure of functional integration over η -fluctuations without zero mode $\eta_0^\mu = \bar{\eta}^\mu$ from the proper measure in (10.586) of ξ -fluctuations without zero mode:

$$\oint \mathcal{D}^D \xi J(q_0, \xi) \Delta^{\text{FP}}[q_0, \xi] \equiv \oint \mathcal{D}^D \xi(\tau) J(q_0, \xi) \delta^{(D)}(\xi_0) \Delta^{\text{FP}}[q_0, \xi]. \quad (10.610)$$

This is transformed to coordinates $\eta^\mu(\tau)$ via Eqs. (10.577) and (10.578) yielding

$$\oint \mathcal{D}^D \xi J(q_0, \xi) \Delta^{\text{FP}}[q_0, \xi] = \oint \mathcal{D}^D \eta \bar{\Delta}^{\text{FP}}[q_0, \eta], \quad (10.611)$$

where $\bar{\Delta}^{\text{FP}}[q_0, \eta]$ is obtained from the Faddeev-Popov determinant $\Delta^{\text{FP}}[q_0, \xi]$ of (10.587) by expressed the coordinates $\eta^\mu(\tau)$ in terms of $\xi^\mu(\tau)$, and multiplying the result by a Jacobian accounting for the change of the δ -function of ξ_0 to a δ -function of η_0 via the transformation Eq. (10.577):

$$\bar{\Delta}^{\text{FP}}[q_0, \eta] = \Delta^{\text{FP}}[q_0, \xi(q_0, \eta)] \times \det \left(\frac{\partial \bar{\eta}^\mu(q_0, \xi)}{\partial \xi^\nu} \right)_{\xi=\xi(q_0, \eta)}. \quad (10.612)$$

The last determinant has the exponential form

$$\det \left(\frac{\partial \bar{\eta}^\mu(q_0, \xi)}{\partial \xi^\nu} \right)_{\xi=\xi(q_0, \eta)} = \exp \left\{ \text{tr} \log \left[\frac{1}{\beta} \int_0^\beta d\tau \left(\frac{\partial \eta^\mu(q_0, \xi)}{\partial \xi^\nu} \right)_{\xi=\xi(q_0, \eta)} \right] \right\}, \quad (10.613)$$

where the matrix in the exponent has small- η expansion

$$\begin{aligned} \left(\frac{\partial \eta^\mu(q_0, \xi)}{\partial \xi^\nu} \right)_{\xi=\xi(q_0, \eta)} &= \delta_\nu^\mu - \bar{\Gamma}_{\nu\sigma}{}^\mu \eta^\sigma \\ &\quad - \frac{1}{3} \left(\partial_\sigma \bar{\Gamma}_{\nu\tau}{}^\mu + \frac{1}{2} \partial_\nu \bar{\Gamma}_{\sigma\tau}{}^\mu - 2 \bar{\Gamma}_{\tau\nu}{}^\kappa \bar{\Gamma}_{\kappa\sigma}{}^\mu + \frac{1}{2} \bar{\Gamma}_{\tau\sigma}{}^\kappa \bar{\Gamma}_{\kappa\nu}{}^\mu \right) \eta^\sigma \eta^\tau + \dots \end{aligned} \quad (10.614)$$

The factor (10.612) in (10.611) leads to a new contribution to the interaction (10.608), if we rewrite it as

$$\bar{\Delta}^{\text{FP}}[q_0, \eta] = e^{-\bar{\mathcal{A}}^{\text{FP}}[q_0, \eta]}. \quad (10.615)$$

Combining Eqs. (10.587) and (10.613), we find a new Faddeev-Popov type action for η^μ -fluctuations at vanishing η_0^μ :

$$\begin{aligned} \bar{\mathcal{A}}^{\text{FP}}[q_0, \eta] &= \mathcal{A}^{\text{FP}}[q_0, \xi(q_0, \eta)] - \text{tr} \log \left[\frac{1}{\beta} \int_0^\beta d\tau \left(\frac{\partial \eta^\mu(q_0, \xi)}{\partial \xi^\nu} \right)_{\xi=\xi(q_0, \eta)} \right] \\ &= \frac{1}{2\beta} \int_0^\beta d\tau T_{\sigma\tau}(q_0) \eta^\sigma \eta^\tau + \dots, \end{aligned} \quad (10.616)$$

where

$$T_{\sigma\tau}(q_0) = (\partial_\mu \bar{\Gamma}_{\sigma\tau}{}^\mu - 2 \bar{\Gamma}_{\sigma\kappa}{}^\mu \bar{\Gamma}_{\mu\tau}{}^\kappa + \bar{\Gamma}_{\kappa\mu}{}^\mu \bar{\Gamma}_{\sigma\tau}{}^\kappa). \quad (10.617)$$

The unperturbed correlation functions associated with the action (10.608) are:

$$\langle \eta^\mu(\tau) \eta^\nu(\tau') \rangle^{q_0} = g^{\mu\nu}(q_0) \bar{\Delta}(\tau, \tau') \quad (10.618)$$

and the free Boltzmann factor is the same as in Eq. (10.601). The perturbation expansion of the interacting Boltzmann factor is to be calculated from an expansion like (10.602):

$$B(q_0) = 1 - \langle \mathcal{A}_{\text{tot,FP}}^{\text{int}}[q_0, \eta] \rangle^{q_0} + \frac{1}{2} \langle (\mathcal{A}_{\text{tot,FP}}^{\text{int}}[q_0, \eta])^2 \rangle^{q_0} - \dots, \quad (10.619)$$

where the interaction is now

$$\mathcal{A}_{\text{tot,FP}}^{\text{int}}[q_0, \eta] = \mathcal{A}_{\text{tot}}^{\text{int}}[q_0, \eta] + \bar{\mathcal{A}}^{\text{FP}}[q_0, \eta]. \quad (10.620)$$

As before in the Dirichlet case, the divergences containing powers of $\delta(0)$ no longer cancel order by order, but do so at the end.

The calculations proceed as in the Dirichlet case, except that the correlation functions are now given by (10.565) which depend only on the difference of their arguments.

The first expectation value contributing to (10.619) is given again by $f_1^{(1)}$ of Eq. (10.539), except that the integrals have to be evaluated with the periodic correlation function $\bar{\Delta}(\tau, \tau)$ of Eq. (10.565), which has the properties

$$\bar{\Delta}(\tau, \tau) = \frac{1}{12}, \quad \bar{\Delta}(\tau, \tau) = \bar{\Delta}'(\tau, \tau) = 0. \tag{10.621}$$

Using further the common property $\bar{\Delta}'(\tau, \tau') = \delta(\tau - \tau') - 1/\beta$ of Eq. (10.567), we find directly from (10.539):

$$\begin{aligned} \bar{f}_1^{(1)} = \langle \mathcal{A}_{\text{tot}}^{\text{int}}[q_0, \eta] \rangle^{q_0} &= \frac{\beta}{24} g^{\sigma\tau} (\partial_\sigma \bar{\Gamma}_{\tau\mu}{}^\mu + g^{\mu\nu} \bar{\Gamma}_{\tau\mu\kappa} \bar{\Gamma}_{\sigma\nu}{}^\kappa + \bar{\Gamma}_{\tau\nu}{}^\mu \bar{\Gamma}_{\sigma\mu}{}^\nu) \\ &- \frac{\beta^2}{24} \delta(0) g^{\sigma\tau} (g^{\mu\nu} \bar{\Gamma}_{\tau\mu\kappa} \bar{\Gamma}_{\sigma\nu}{}^\kappa + \bar{\Gamma}_{\tau\mu}{}^\nu \bar{\Gamma}_{\sigma\nu}{}^\mu). \end{aligned} \tag{10.622}$$

To this we must the expectation value of the Faddeev-Popov action:

$$\langle \bar{\mathcal{A}}^{\text{FP}}[q_0, \eta] \rangle^{q_0} = -\frac{\beta}{24} g^{\sigma\tau} (\partial_\mu \bar{\Gamma}_{\sigma\tau}{}^\mu - 2\bar{\Gamma}_{\sigma\nu}{}^\mu \bar{\Gamma}_{\mu\tau}{}^\nu + \bar{\Gamma}_{\mu\kappa}{}^\mu \bar{\Gamma}_{\sigma\tau}{}^\kappa). \tag{10.623}$$

The divergent term with the factor $\delta(0)$ in (10.622) is canceled by the same expression in the second-order contribution to (10.602) which we calculate now, evaluating the second cumulant (10.541) with the periodic correlation function $\bar{\Delta}(\tau, \tau)$ of Eq. (10.565). The diagrams are the same as in (10.543), but their evaluation is much simpler. Due to the absence of the zero modes in $\eta^\mu(\tau)$, all one-particle reducible diagrams vanish, so that the analogs of $f_1^{(2)}$, $f_1^{(3)}$, and $f_1^{(4)}$ in (10.542) are all zero. Only those of $f_1^{(5)}$ and $f_1^{(6)}$ survive, which involve now the Feynman integrals I_{14} and I_{15} evaluated with $\bar{\Delta}(\tau, \tau)$ which are

$$\text{Diagram 1} : \bar{I}_{14} = \int_0^\beta \int_0^\beta d\tau d\tau' \bar{\Delta}(\tau, \tau') \bar{\Delta}'(\tau, \tau') \bar{\Delta}'(\tau, \tau') = -\frac{\beta}{24} + \delta(0) \frac{\beta^2}{12}, \tag{10.624}$$

$$\text{Diagram 2} : \bar{I}_{15} = \int_0^\beta \int_0^\beta d\tau d\tau' \bar{\Delta}(\tau, \tau') \bar{\Delta}'^2(\tau, \tau') = -\frac{\beta}{24}. \tag{10.625}$$

This leads to the second cumulant

$$\begin{aligned} \frac{1}{2} \langle (\mathcal{A}_{\text{tot,FP}}^{\text{int}}[q_0, \eta])^2 \rangle_c^{q_0} &= -\frac{\beta}{24} g^{\sigma\tau} (g^{\mu\nu} \bar{\Gamma}_{\tau\mu\kappa} \bar{\Gamma}_{\sigma\nu}{}^\kappa + 2\bar{\Gamma}_{\tau\nu}{}^\mu \bar{\Gamma}_{\sigma\mu}{}^\nu) \\ &+ \frac{\beta^2}{24} \delta(0) g^{\sigma\tau} (g^{\mu\nu} \bar{\Gamma}_{\tau\mu\kappa} \bar{\Gamma}_{\sigma\nu}{}^\kappa + \bar{\Gamma}_{\tau\mu}{}^\nu \bar{\Gamma}_{\sigma\nu}{}^\mu). \end{aligned} \tag{10.626}$$

The sum of Eqs. (10.623) and (10.626) is finite and yields the same covariant result $\beta\bar{R}/24$ as in Eq. (10.552), so that we re-obtain the same covariant perturbation expansion of the effective classical Boltzmann factor as before in Eq. (10.606). Note the importance of the contribution (10.623) from the Faddeev-Popov determinant in producing the curvature scalar. Neglecting this, as done by other authors in Ref. [34], will produce in the effective classical Boltzmann factor (10.619) an additional noncovariant term $g^{\sigma\tau} T_{\sigma\tau}(q_0)/24$. This may be rewritten as a covariant divergence of a nonvectorial quantity

$$g^{\sigma\tau} T_{\sigma\tau} = \nabla_\mu V^\mu, \quad V^\mu(q_0) = g^{\sigma\tau}(q_0) \bar{\Gamma}_{\sigma\tau}{}^\mu(q_0). \tag{10.627}$$

As such it does not contribute to the integral over q_0^μ in Eq. (10.607), but it is nevertheless a wrong noncovariant result for the Boltzmann factor (10.606).

The appearance of a noncovariant term in a treatment where q_0^μ is the path average of $q^\mu(\tau)$ is not surprising. If the time dependence of a path shows an acceleration, the average of a path is not an invariant concept even for an infinitesimal time. One may covariantly impose the condition of a vanishing temporal average only upon fluctuation coordinates which have no acceleration. This is the case of geodesic coordinates $\xi^a(\tau)$ since their equation of motion at q_0^μ is $\ddot{\xi}^a(\tau) = 0$.

10.12.6 Particle on Unit Sphere

A special treatment exists for particle in homogeneous spaces. As an example, consider a quantum particle moving on a unit sphere in $D + 1$ dimensions. The partition function is defined by Eq. (10.554) with the Euclidean action (10.408) and the invariant measure (10.406), where the metric and its determinant are

$$g_{\mu\nu}(q) = \delta_{\mu\nu} + \frac{q_\mu q_\nu}{1 - q^2}, \quad g(q) = \frac{1}{1 - q^2}. \quad (10.628)$$

It is, of course, possible to calculate the Boltzmann factor $B(q_0)$ with the procedure of Section 10.12.3. Instead of doing this we shall, however, exploit the homogeneity of the sphere. The invariance under reparametrizations of general Riemannian space becomes here an isometry of the metric (10.628). Consequently, the Boltzmann factor $B(q_0)$ in Eq. (10.607) becomes *independent* of the choice of q_0^μ , and the integral over q_0^μ in (10.591) yields simply the total surface of the sphere times the Boltzmann factor $B(q_0)$. The homogeneity of the space allows us to treat paths $q^\mu(\tau)$ themselves as small quantum fluctuations around the origin $q_0^\mu = 0$, which extremizes the path integral (10.554). The possibility of this expansion is due to the fact that $\Gamma_{\sigma\tau}^\mu = q^\mu g_{\sigma\tau}$ vanishes at $q^\mu(\tau) = 0$, so that the movement is at this point free of acceleration, this being similar to the situation in geodesic coordinates. As before we now take account of the fact that there are other equivalent saddle-points due to isometries of the metric (10.628) on the sphere (see, e.g., [54]). The infinitesimal transformations of a small vector q^μ :

$$q_\varepsilon^\mu = q^\mu + \varepsilon^\mu \sqrt{1 - q^2}, \quad \varepsilon^\mu = \text{const}, \quad \mu = 1, \dots, D \quad (10.629)$$

move the origin $q_0^\mu = 0$ by a small amount on the surface of the sphere. Due to the rotational symmetry of the system in the D -dimensional space, these fluctuations have a vanishing action. There are also $D(D - 1)/2$ more isometries consisting of the rotations around the origin $q^\mu(\tau) = 0$ on the surface of the sphere. These are, however, irrelevant in the present context since they leave the origin unchanged.

The transformations (10.629) of the origin may be eliminated from the path integral (10.554) by including a factor $\delta^{(D)}(\bar{q})$ to enforce the vanishing of the temporal path average $\bar{q} = \beta^{-1} \int_0^\beta d\tau q(\tau)$. The associated Faddeev-Popov determinant $\Delta^{\text{FP}}[q]$ is determined by the integral

$$\Delta^{\text{FP}}[q] \int d^D \varepsilon \delta^{(D)}(\bar{q}_\varepsilon) = \Delta^{\text{FP}}[q] \int d^D \varepsilon \delta^{(D)} \left(\varepsilon^\mu \frac{1}{\beta} \int_0^\beta d\tau \sqrt{1 - q^2} \right) = 1. \quad (10.630)$$

The result has the exponential form

$$\Delta^{\text{FP}}[q] = \left(\frac{1}{\beta} \int_0^\beta d\tau \sqrt{1 - q^2} \right)^D = e^{-\mathcal{A}^{\text{FP}}[q]}, \quad (10.631)$$

where $\mathcal{A}^{\text{FP}}[q]$ must be added to the action (10.408):

$$\mathcal{A}^{\text{FP}}[q] = -D \log \left(\frac{1}{\beta} \int_0^\beta d\tau \sqrt{1 - q^2} \right). \quad (10.632)$$

The Boltzmann factor $B(q_0) \equiv B$ is then given by the path integral without zero modes

$$\begin{aligned} B &= \oint \prod_{\mu,\tau} \left[dq^\mu(\tau) \sqrt{g(q(\tau))} \right] \delta^{(D)}(\bar{q}) \Delta^{\text{FP}}[q] e^{-\mathcal{A}[q]} \\ &= \oint \mathcal{D}^{1D} q \sqrt{g(q(\tau))} \Delta^{\text{FP}}[q] e^{-\mathcal{A}[q]}, \end{aligned} \quad (10.633)$$

where the measure $\mathcal{D}^{1D} q$ is defined as in Eq. (2.447). This can also be written as

$$B = \oint \mathcal{D}^{1D} q e^{-\mathcal{A}[q] - \mathcal{A}^J[q] - \mathcal{A}^{\text{FP}}[q]}, \quad (10.634)$$

where $\mathcal{A}^J[q]$ is a contribution to the action (10.408) coming from the product

$$\prod_{\tau} \sqrt{g(q(\tau))} \equiv e^{-\mathcal{A}^J[q]}. \quad (10.635)$$

By inserting (10.628), this becomes

$$\mathcal{A}^J[q] = - \int_0^\beta d\tau \frac{1}{2} \delta(0) \log g(q) = \int_0^\beta d\tau \frac{1}{2} \delta(0) \log(1 - q^2). \quad (10.636)$$

The total partition function is, of course, obtained from B by multiplication with the surface of the unit sphere in $D + 1$ dimensions $2\pi^{(D+1)/2}/\Gamma(D + 1/2)$. To calculate B from (10.634), we now expand $\mathcal{A}[q]$, $\mathcal{A}^J[q]$ and $\mathcal{A}^{\text{FP}}[q]$ in powers of $q^\mu(\tau)$. The metric $g_{\mu\nu}(q)$ and its determinant $g(q)$ in Eq. (10.628) have the expansions

$$g_{\mu\nu}(q) = \delta_{\mu\nu} + q_\mu q_\nu + \dots, \quad g(q) = 1 + q^2 + \dots, \quad (10.637)$$

and the unperturbed action reads

$$\mathcal{A}^{(0)}[q] = \int_0^\beta d\tau \frac{1}{2} \dot{q}^2(\tau). \quad (10.638)$$

In the absence of the zero eigenmodes due to the δ -function over \bar{q} in Eq. (10.633), we find as in Eq. (10.601) the free Boltzmann factor

$$B_0 = 1. \quad (10.639)$$

The free correlation function looks similar to (10.603):

$$\langle q^\mu(\tau) q^\nu(\tau') \rangle = \delta^{\mu\nu} \bar{\Delta}(\tau, \tau'). \quad (10.640)$$

The interactions coming from the higher expansions terms in Eq. (10.637) begin with

$$\mathcal{A}_{\text{tot}}^{\text{int}}[q] = \mathcal{A}^{\text{int}}[q] + \mathcal{A}^J[q] = \int_0^\beta d\tau \frac{1}{2} \left[(q\dot{q})^2 - \delta(0)q^2 \right]. \quad (10.641)$$

To the same order, the Faddeev-Popov interaction (10.632) contributes

$$\mathcal{A}^{\text{FP}}[q] = \frac{D}{2\beta} \int_0^\beta d\tau q^2. \quad (10.642)$$

This has an important effect upon the two-loop perturbation expansion of the Boltzmann factor

$$B(q_0) = 1 - \langle \mathcal{A}_{\text{tot}}^{\text{int}}[q] \rangle^{q_0} - \langle \mathcal{A}^{\text{FP}}[q] \rangle^{q_0} + \dots = B(0) \equiv B. \quad (10.643)$$

Performing the Wick contractions with the correlation function (10.640) with the properties (10.565)–(10.567), we find from Eqs. (10.641), (10.642)

$$\begin{aligned} \langle \mathcal{A}_{\text{tot}}^{\text{int}}[q] \rangle^{q_0} &= \frac{1}{2} \int_0^\beta d\tau \left\{ D \bar{\Delta}(\tau, \tau) \bar{\Delta}(\tau, \tau) + D(D+1) \bar{\Delta}^2(\tau, \tau) - \delta(0) D \bar{\Delta}(\tau, \tau) \right\} \\ &= \frac{1}{2} \int_0^\beta d\tau \left\{ -\frac{D}{\beta} \bar{\Delta}(\tau, \tau) + D(D+1) \bar{\Delta}^2(\tau, \tau) \right\} = -\frac{D}{24} \beta, \end{aligned} \quad (10.644)$$

and

$$\langle \mathcal{A}^{\text{FP}}[q] \rangle^{q_0} = \frac{D}{2\beta} \int_0^\beta d\tau D \bar{\Delta}(\tau, \tau) = \frac{D^2}{24} \beta. \quad (10.645)$$

Their combination in Eq. (10.643) yields the high-temperature expansion

$$B = 1 - \frac{D(D-1)}{24} \beta + \dots \quad (10.646)$$

This is in perfect agreement with Eqs. (10.494) and (10.606), since the scalar curvature for a unit sphere in $D+1$ dimensions is $\bar{R} = D(D-1)$. It is remarkable how the contribution (10.645) of the Faddeev-Popov determinant has made the noncovariant result (10.644) covariant.

10.13 Covariant Effective Action for Quantum Particle with Coordinate-Dependent Mass

The classical behavior of a system is completely determined by the extrema of the classical action. The quantum-mechanical properties can be found from the extrema of the effective action (see Subsection 3.22.5). This important quantity can in general only be calculated perturbatively. This will be done here for a particle with a coordinate-dependent mass. The calculation [44] will make use of the background method of Subsection 3.23.6 combined with the techniques developed earlier in this chapter. From the one-particle-irreducible (1PI) Feynman diagrams with no external lines we obtain an expansion in powers of the Planck constant \hbar . The result will be applicable to a large variety of interesting physical systems, for instance compound nuclei, where the collective Hamiltonian, commonly derived from a microscopic description via time-dependent Hartree-Fock theory [45], contains coordinate-dependent mass parameters.

10.13.1 Formulating the Problem

Consider a particle with coordinate-dependent mass $m(q)$ moving as in the one-dimensional potential $V(q)$. We shall study the Euclidean version of the system where the paths $q(t)$ are continued to an imaginary times $\tau = -it$ and the Lagrangian for $q(\tau)$ has the form

$$L(q, \dot{q}) = \frac{1}{2} m(q) \dot{q}^2 + V(q). \quad (10.647)$$

The dot stands for the derivative with respect to the imaginary time. The q -dependent mass may be written as $mg(q)$ where $g(q)$ plays the role of a one-dimensional dynamical metric. It is the trivial 1×1 Hessian metric of the system [recall the definition (1.12) and Eq. (1.388)]. In D -dimensional configuration space, the kinetic term would read $mg_{\mu\nu}(q)\dot{q}^\mu\dot{q}^\nu/2$, having the same form as in the curved-space action (10.186).

Under an arbitrary single-valued coordinate transformation $q = q(\tilde{q})$, the potential $V(q)$ is assumed to transform like a scalar whereas the metric $m(q)$ is a one-dimensional tensor of rank two:

$$V(q) = V(q(\tilde{q})) \equiv \tilde{V}(\tilde{q}), \quad m(q) = \tilde{m}(\tilde{q}) [d\tilde{q}(q)/dq]^2. \quad (10.648)$$

This coordinate transformation leaves the Lagrangian (10.647) and thus also the classical action

$$\mathcal{A}[q] = \int_{-\infty}^{\infty} d\tau L(q, \dot{q}) \quad (10.649)$$

invariant. Quantum theory has to possess the same invariance, exhibited automatically by Schrödinger theory. It must be manifest in the effective action. This will be achieved by combining the background technique in Subsection 3.23.6 with the techniques of Sections 10.6–10.10. In the background field method [46] we split all paths into $q(\tau) = Q(\tau) + \delta q(\tau)$, where $Q(\tau)$ is the final extremal orbit and δq describes the quantum fluctuations around it. At the one-loop level, the covariant effective action $\Gamma[Q]$ becomes a sum of the classical Lagrangian $L(Q, \dot{Q})$ and a correction term ΔL . It is defined by the path integral [recall (3.776)]

$$e^{-\Gamma[Q]/\hbar} = \int \mathcal{D}\mu(\delta q) e^{-(1/\hbar)\{\mathcal{A}[Q+\delta q] - \int d\tau \delta q \delta\Gamma[Q]/\delta Q\}}, \quad (10.650)$$

where the measure of functional integration $\mathcal{D}\mu(\delta q)$ is obtained from the initial invariant measure $\mathcal{D}\mu(q) = Z^{-1} \prod_{\tau} dq(\tau) \sqrt{m(q)}$ and reads

$$\mathcal{D}\mu(\delta q) = Z^{-1} \prod_{\tau} d\delta q(\tau) \sqrt{m(Q)} e^{(1/2)\delta(0) \int d\tau \log[m(Q+\delta q)/m(Q)]}, \quad (10.651)$$

with Z being some normalization factor. The generating functional (10.650) possesses the same symmetry under reparametrizations of the configuration space as the classical action (10.649).

We now calculate $\Gamma[Q]$ in Eq. (10.650) perturbatively as a power series in \hbar :

$$\Gamma[Q] = \mathcal{A}[Q] + \hbar\Gamma_1[Q] + \hbar^2\Gamma_2[Q] + \dots \quad (10.652)$$

The quantum corrections to the classical action (10.649) are obtained by expanding $\mathcal{A}[Q + \delta q]$ and the measure (10.651) *covariantly* in powers of δq :

$$\begin{aligned} \mathcal{A}[Q + \delta q] &= \mathcal{A}[Q] + \int d\tau \frac{D\mathcal{A}}{\delta Q(\tau)} \delta x(\tau) + \frac{1}{2} \int d\tau \int d\tau' \frac{D^2\mathcal{A}}{\delta Q(\tau)\delta Q(\tau')} \delta x(\tau) \delta x(\tau') \\ &+ \frac{1}{6} \int d\tau \int d\tau' \int d\tau'' \frac{D^3\mathcal{A}}{\delta Q(\tau)\delta Q(\tau')\delta Q(\tau'')} \delta x(\tau) \delta x(\tau') \delta x(\tau'') + \dots \end{aligned} \quad (10.653)$$

The expansion is of the type (10.101), i.e., the expressions δx are *covariant fluctuations* related to the ordinary variations δq in the same way as the normal coordinates Δx^μ are related to the differences Δq^μ in the expansion (10.98). The symbol $D/\delta Q$ denotes the *covariant* functional derivative in one dimension. To first order, this is the ordinary functional derivative

$$\frac{D\mathcal{A}[Q]}{\delta Q(\tau)} = \frac{\delta\mathcal{A}[Q]}{\delta Q(\tau)} = V'(Q) - \frac{1}{2} m'(Q) \dot{Q}^2(\tau) - m(Q) \ddot{Q}(\tau). \quad (10.654)$$

This vanishes for the classical orbit $Q(\tau)$. The second covariant derivative is [compare (10.100)]

$$\frac{D^2\mathcal{A}[Q]}{\delta Q(\tau)\delta Q(\tau')} = \frac{\delta^2\mathcal{A}[Q]}{\delta Q(\tau)\delta Q(\tau')} - \Gamma(Q(\tau)) \frac{\delta\mathcal{A}[Q]}{\delta Q(\tau')}, \quad (10.655)$$

where $\Gamma(Q) = m'(Q)/2m(Q)$ is the one-dimensional version of the Christoffel symbol for the metric $g_{\mu\nu} = \delta_{\mu\nu}m(Q)$. More explicitly, the result is

$$\frac{\delta^2\mathcal{A}[Q]}{\delta Q(\tau)\delta Q(\tau')} = - \left[m(Q)\partial_\tau^2 + m'(Q)\dot{Q}\partial_\tau + m'(Q)\ddot{Q} + \frac{1}{2}m''(Q)\dot{Q}^2 - V''(Q) \right] \delta(\tau - \tau'). \quad (10.656)$$

The validity of the expansion (10.653) follows from the fact that it is equivalent by a coordinates transformation to an ordinary functional expansion in Riemannian coordinates where the Christoffel symbol vanishes for the particular background coordinates.

The inverse of the functional matrix (10.655) supplies us with the free correlation function $G(\tau, \tau')$ of the fluctuations $\delta x(\tau)$. The higher derivatives define the interactions. The expansion terms $\Gamma_n[Q]$ in (10.652) are found from all one-particle-irreducible vacuum diagrams (3.784) formed with the propagator $G(\tau, \tau')$ and the interaction vertices. The one-loop correction to the effective action is given by the simple harmonic path integral

$$e^{-\Gamma_1[Q]} = \int \mathcal{D}\delta x \sqrt{m(Q)} e^{-\mathcal{A}^{(2)}[Q, \delta x]}, \quad (10.657)$$

with the quadratic part of the expansion (10.653):

$$\mathcal{A}^{(2)}[Q, \delta x] = \frac{1}{2} \int_{-\infty}^{\infty} d\tau d\tau' \delta x(\tau) \frac{D^2 \mathcal{A}[Q]}{\delta Q(\tau) \delta Q(\tau')} \delta x(\tau'). \quad (10.658)$$

The presence of $m(Q)$ in the free part of the covariant kinetic term (10.658) and in the measure in Eq. (10.657) suggests exchanging the fluctuation δx by the new coordinates $\delta \tilde{x} = h(Q) \delta x$, where $h(Q) \equiv \sqrt{m(Q)}$ is the one-dimensional version of the triad (10.12) $e(Q) = \sqrt{m(Q)}$ associated with the metric $m(Q)$. The fluctuations $\delta \tilde{x}$ correspond to the differences Δx^i in (10.97). The covariant derivative of $e(Q)$ vanishes $D_Q e(Q) = \partial_Q e(Q) - \Gamma(Q) e(Q) \equiv 0$ [recall (10.40)]. Then (10.658) becomes

$$\mathcal{A}^{(2)}[Q, \delta x] = \frac{1}{2} \int_{-\infty}^{\infty} d\tau d\tau' \delta \tilde{x}(\tau) \frac{D^2 \mathcal{A}[Q]}{\delta \tilde{Q}(\tau) \delta \tilde{Q}(\tau')} \delta \tilde{x}(\tau'), \quad (10.659)$$

where

$$\frac{D^2 \mathcal{A}[Q]}{\delta \tilde{Q}(\tau) \delta \tilde{Q}(\tau')} = e^{-1}(Q) \frac{D^2 \mathcal{A}[Q]}{\delta Q(\tau) \delta Q(\tau')} e^{-1}(Q) = \left[-\frac{d^2}{d\tau^2} + \omega^2(Q(\tau)) \right] \delta(\tau - \tau'), \quad (10.660)$$

and

$$\begin{aligned} \omega^2(Q) &= e^{-1}(Q) D^2 V(Q) e^{-1}(Q) = e^{-1}(Q) D V'(Q) e^{-1}(Q) \\ &= \frac{1}{m(Q)} [V''(Q) - \Gamma(Q) V'(Q)]. \end{aligned} \quad (10.661)$$

Note that this is the one-dimensional version of the Laplace-Beltrami operator (1.381) applied to $V(Q)$:

$$\omega^2(Q) = \Delta V(Q) = \frac{1}{\sqrt{m(Q)}} \frac{d}{dQ} \left[\sqrt{m(Q)} \left(\frac{V'(Q)}{m(Q)} \right) \right]. \quad (10.662)$$

Indeed, $e^{-2} D^2$ is the one-dimensional version of $g^{\mu\nu} D_\mu D_\nu$ [recall (10.38)] Since $V(Q)$ is a scalar, so is $\Delta V(Q)$.

Equation (10.660) shows that the fluctuations $\delta \tilde{x}$ behave like those of a harmonic oscillator with the time-dependent frequency $\omega^2(Q)$. The functional measure of integration in Eq. (10.657) simplifies in terms of $\delta \tilde{x}$:

$$\prod_{\tau} d\delta x(\tau) \sqrt{m(Q)} = \prod_{\tau} d\delta \tilde{x}(\tau). \quad (10.663)$$

This allows us to integrate the Gaussian path integral (10.657) trivially to obtain the one-loop quantum correction to the effective action

$$\Gamma_1[Q] = \frac{1}{2} \text{Tr} \log \left[-\partial_\tau^2 + \omega^2(Q(\tau)) \right]. \quad (10.664)$$

Due to the τ -dependence of ω^2 , this cannot be evaluated explicitly. For sufficiently slow motion of $Q(\tau)$, however, we can resort to a gradient expansion which yields asymptotically a local expression for the effective action.

10.13.2 Gradient Expansion

The gradient expansion of the one-loop effective action (10.664) has the general form

$$\Gamma_1[Q] = \int_{-\infty}^{\infty} d\tau \left[V_1(Q) + \frac{1}{2} Z_1(Q) \dot{Q}^2 + \dots \right]. \quad (10.665)$$

It is found explicitly by recalling the gradient expansion of the trace of the logarithm derived in Eq. (4.314):

$$\text{Tr} \log \left[-\partial_\tau^2 + \omega^2(\tau) \right] \equiv \int_{-\infty}^{\infty} d\tau \left\{ \omega(\tau) + \frac{[\partial_\tau \omega^2(\tau)]^2}{32\omega^5(\tau)} + \dots \right\}. \quad (10.666)$$

Inserting $\Omega(\tau) = \omega(Q(\tau))$, we identify

$$V_1(Q) = \hbar\omega(Q)/2, \quad Z_1(Q) = \frac{(D\omega^2)^2(Q)}{32\omega^5(Q)}, \quad (10.667)$$

and obtain the effective action to order \hbar for slow motion

$$\Gamma^{\text{eff}}[Q] = \int_{-\infty}^{\infty} d\tau \left[\frac{1}{2} m^{\text{eff}}(Q) \dot{Q}^2 + V^{\text{eff}}(Q) \right], \quad (10.668)$$

where the bare metric $m^{\text{eff}}(Q)$ and the potential $V^{\text{eff}}(Q)$ are related to the initial classical expressions by

$$m^{\text{eff}}(Q) = m(Q) + \hbar \frac{(D\omega^2)^2(Q)}{32\omega^5(Q)}, \quad (10.669)$$

$$V^{\text{eff}}(Q) = V(Q) + \hbar \frac{\omega(Q)}{2}. \quad (10.670)$$

For systems in which only the mass is Q -independent, the result has also been obtained by Ref. [48].

The range of validity of the expansion is determined by the characteristic time scale $1/\omega$. Within this time, the particle has to move only little.

Appendix 10A Nonholonomic Gauge Transformations in Electromagnetism

To introduce the subject, let us first recall the standard treatment of magnetism. Since there are no magnetic monopoles, a magnetic field $\mathbf{B}(\mathbf{x})$ satisfies the identity $\nabla \cdot \mathbf{B}(\mathbf{x}) = 0$, implying that only two of the three field components of $\mathbf{B}(\mathbf{x})$ are independent. To account for this, one usually expresses a magnetic field $\mathbf{B}(\mathbf{x})$ in terms of a vector potential $\mathbf{A}(\mathbf{x})$, setting $\mathbf{B}(\mathbf{x}) = \nabla \times \mathbf{A}(\mathbf{x})$. Then Ampère's law, which relates the magnetic field to the electric current density $\mathbf{j}(\mathbf{x})$ by $\nabla \times \mathbf{B} = 4\pi\mathbf{j}(\mathbf{x})$, becomes a second-order differential equation for the vector potential $\mathbf{A}(\mathbf{x})$ in terms of an electric current

$$\nabla \times [\nabla \times \mathbf{A}(\mathbf{x})] = \mathbf{j}(\mathbf{x}). \quad (10A.1)$$

The vector potential $\mathbf{A}(\mathbf{x})$ is a *gauge field*. Given $\mathbf{A}(\mathbf{x})$, any locally gauge-transformed field

$$\mathbf{A}(\mathbf{x}) \rightarrow \mathbf{A}'(\mathbf{x}) = \mathbf{A}(\mathbf{x}) + \nabla\Lambda(\mathbf{x}) \quad (10A.2)$$

yields the same magnetic field $\mathbf{B}(\mathbf{x})$. This reduces the number of physical degrees of freedom in the gauge field $\mathbf{A}(\mathbf{x})$ to two, just as those in $\mathbf{B}(\mathbf{x})$. In order for this to hold, the transformation function must be single-valued, i.e., it must have commuting derivatives

$$(\partial_i \partial_j - \partial_j \partial_i) \Lambda(\mathbf{x}) = 0. \quad (10A.3)$$

The equation for absence of magnetic monopoles $\nabla \cdot \mathbf{B} = 0$ is ensured if the vector potential has commuting derivatives

$$(\partial_i \partial_j - \partial_j \partial_i) \mathbf{A}(\mathbf{x}) = 0. \quad (10A.4)$$

This integrability property makes $\nabla \cdot \mathbf{B} = 0$ the *Bianchi identity* in this gauge field representation of the magnetic field.

In order to solve (10A.1), we remove the gauge ambiguity by choosing a particular gauge, for instance the *transverse gauge* $\nabla \cdot \mathbf{A}(\mathbf{x}) = 0$ in which $\nabla \times [\nabla \times \mathbf{A}(\mathbf{x})] = -\nabla^2 \mathbf{A}(\mathbf{x})$, and obtain

$$\mathbf{A}(\mathbf{x}) = \int d^3 x' \frac{\mathbf{j}(\mathbf{x}')}{|\mathbf{x} - \mathbf{x}'|}. \quad (10A.5)$$

The associated magnetic field is

$$\mathbf{B}(\mathbf{x}) = \int d^3 x' \frac{\mathbf{j}(\mathbf{x}') \times \mathbf{R}'}{R'^3}, \quad \mathbf{R}' \equiv \mathbf{x}' - \mathbf{x}. \quad (10A.6)$$

This standard representation of magnetic fields is not the only possible one. There exists another one in terms of a scalar potential $\Lambda(\mathbf{x})$, which must, however, be multivalued to account for the two physical degrees of freedom in the magnetic field.

10A.1 Gradient Representation of Magnetic Field of Current Loops

Consider an infinitesimally thin closed wire carrying an electric current I along the line L . It corresponds to a current density

$$\mathbf{j}(\mathbf{x}) = I \delta(\mathbf{x}; L), \quad (10A.7)$$

where $\delta(\mathbf{x}; L)$ is the δ -function on the line L :

$$\delta(\mathbf{x}; L) = \int_L dx' \delta^{(3)}(\mathbf{x} - \mathbf{x}'). \quad (10A.8)$$

For a closed line L , this function has zero divergence:

$$\nabla \cdot \delta(\mathbf{x}; L) = 0. \quad (10A.9)$$

This follows from the property of the δ -function on an arbitrary line L connecting the points \mathbf{x}_1 and \mathbf{x}_2 :

$$\nabla \cdot \delta(\mathbf{x}; L) = \delta(\mathbf{x}_2) - \delta(\mathbf{x}_1). \quad (10A.10)$$

For closed loops, the right-hand side vanishes.

From Eq. (10A.5) we obtain the associated vector potential

$$\mathbf{A}(\mathbf{x}) = I \int_L dx' \frac{1}{|\mathbf{x} - \mathbf{x}'|}, \quad (10A.11)$$

yielding the magnetic field

$$\mathbf{B}(\mathbf{x}) = -I \int_L \frac{d\mathbf{x}' \times \mathbf{R}'}{R'^3}, \quad \mathbf{R}' \equiv \mathbf{x}' - \mathbf{x}. \quad (10A.12)$$

Figure 10.5 Infinitesimally thin closed current loop L . The magnetic field $\mathbf{B}(\mathbf{x})$ at the point \mathbf{x} is proportional to the solid angle $\Omega(\mathbf{x})$ under which the loop is seen from \mathbf{x} . In any single-valued definition of $\Omega(\mathbf{x})$, there is some surface S across which $\Omega(\mathbf{x})$ jumps by 4π . In the multivalued definition, this surface is absent.

Let us now derive the same result from a scalar field. Let $\Omega(\mathbf{x}; S)$ be the solid angle under which the current loop L is seen from the point \mathbf{x} (see Fig. 10.5). If S denotes an arbitrary smooth surface enclosed by the loop L , and $d\mathbf{S}'$ a surface element, then $\Omega(\mathbf{x}; S)$ can be calculated from the surface integral

$$\Omega(\mathbf{x}; S) = \int_S \frac{d\mathbf{S}' \cdot \mathbf{R}'}{R'^3}. \quad (10A.13)$$

The argument S in $\Omega(\mathbf{x}; S)$ emphasizes that the definition depends on the choice of the surface S . The range of $\Omega(\mathbf{x}; S)$ is from -2π to 2π , as can be most easily be seen if L lies in the xy -plane and S is chosen to lie in the same plane. Then we find for $\Omega(\mathbf{x}; S)$ the value 2π for \mathbf{x} just below S , and -2π just above. Let us calculate from (10A.13) the vector field

$$\mathbf{B}(\mathbf{x}; S) = I \nabla \Omega(\mathbf{x}; S). \quad (10A.14)$$

For this we rewrite

$$\nabla \Omega(\mathbf{x}; S) = \int_S dS'_k \nabla \frac{R'_k}{R'^3} = - \int_S dS'_k \nabla' \frac{R'_k}{R'^3}, \quad (10A.15)$$

which can be rearranged to

$$\nabla \Omega(\mathbf{x}; S) = - \left[\int_S \left(dS'_k \partial'_i \frac{R'_k}{R'^3} - dS'_i \partial'_k \frac{R'_k}{R'^3} \right) + \int_S dS'_i \partial'_k \frac{R'_k}{R'^3} \right]. \quad (10A.16)$$

With the help of Stokes' theorem

$$\int_S (dS'_k \partial'_i - dS'_i \partial'_k) f(\mathbf{x}) = \epsilon_{kil} \int_L dx_l f(\mathbf{x}), \quad (10A.17)$$

and the relation $\partial'_k (R'_k / R'^3) = 4\pi \delta^{(3)}(\mathbf{x} - \mathbf{x}')$, we obtain

$$\nabla \Omega(\mathbf{x}; S) = - \left[\int_L \frac{d\mathbf{x}' \times \mathbf{R}'}{R'^3} + 4\pi \int_S d\mathbf{S}' \delta^{(3)}(\mathbf{x} - \mathbf{x}') \right]. \quad (10A.18)$$

Multiplying the first term by I , we reobtain the magnetic field (10A.12) of the current I . The second term yields the singular magnetic field of an infinitely thin magnetic dipole layer lying on the arbitrarily chosen surface S enclosed by L .

The second term is a consequence of the fact that the solid angle $\Omega(\mathbf{x}; S)$ was defined by the surface integral (10A.13). If \mathbf{x} crosses the surface S , the solid angle jumps by 4π .

It is useful to re-express Eq. (10A.15) in a slightly different way. By analogy with (10A.8) we define a δ -function on a surface as

$$\delta(\mathbf{x}; S) = \int_S d\mathbf{S}' \delta^{(3)}(\mathbf{x} - \mathbf{x}'), \quad (10A.19)$$

and observe that Stokes' theorem (10A.17) can be written as an identity for δ -functions:

$$\nabla \times \delta(\mathbf{x}; S) = \delta(\mathbf{x}; L), \quad (10A.20)$$

where L is the boundary of the surface S . This equation proves once more the zero divergence (10A.9).

Using the δ -function (10A.19) on the surface S , Eq. (10A.15) can be rewritten as

$$\nabla \Omega(\mathbf{x}; S) = - \int d^3 x' \delta_k(\mathbf{x}'; S) \nabla' \frac{R'_k}{R'^3}, \quad (10A.21)$$

and if we used also Eq. (10A.20), we find from (10A.18) a magnetic field

$$\mathbf{B}_i(\mathbf{x}; S) = -I \left[\int d^3 x' [\nabla \times \delta(\mathbf{x}; S)] \times \frac{\mathbf{R}'}{R'^3} + 4\pi \delta(\mathbf{x}'; S) \right]. \quad (10A.22)$$

Stokes theorem written in the form (10A.20) displays an important property. If we move the surface S to S' with the same boundary, the δ -function $\delta(\mathbf{x}; S)$ changes by

$$\delta(\mathbf{x}; S) \rightarrow \delta(\mathbf{x}; S') = \delta(\mathbf{x}; S) + \nabla \delta(\mathbf{x}; V), \quad (10A.23)$$

where

$$\delta(\mathbf{x}; V) \equiv \int d^3 x' \delta^{(3)}(\mathbf{x} - \mathbf{x}'), \quad (10A.24)$$

and V is the volume over which the surface has swept. Under this transformation, the curl on the left-hand side of (10A.20) is invariant. Comparing (10A.23) with (10A.2) we identify (10A.23) as a novel type of gauge transformation.⁹ The magnetic field in the first term of (10A.22) is invariant under this, the second is not. It is then obvious how to find a gauge-invariant magnetic field: we simply subtract the singular S -dependent term and form

$$\mathbf{B}(\mathbf{x}) = I [\nabla \Omega(\mathbf{x}; S) + 4\pi \delta(\mathbf{x}; S)]. \quad (10A.25)$$

This field is independent of the choice of S and coincides with the magnetic field (10A.12) derived in the usual gauge theory. Hence the description of the magnetic field as a gradient of field $\Omega(\mathbf{x}; S)$ is completely equivalent to the usual gauge field description in terms of the vector potential $\mathbf{A}(\mathbf{x})$. Both are gauge theories, but of a completely different type.

The gauge freedom (10A.23) can be used to move the surface S into a standard configuration. One possibility is the make *gauge fixing*. choose S so that the third component of $\delta(\mathbf{x}; S)$ vanishes. This is called the *axial gauge*. If $\delta(\mathbf{x}; S)$ does not have this property, we can always shift S by a volume V determined by the equation

$$\delta(V) = - \int_{-\infty}^z \delta_z(\mathbf{x}; S), \quad (10A.26)$$

⁹For a discussion of this gauge freedom, which is independent of the electromagnetic one, see Ref. [56].

and the transformation (10A.23) will produce a $\delta(\mathbf{x}; S)$ in the axial gauge, to be denoted by $\delta^{\text{ax}}(\mathbf{x}; S)$

Equation (10A.25) suggests defining a solid angle $\Omega(\mathbf{x})$ which is independent of S and depends only on the boundary L of S :

$$\nabla\Omega(\mathbf{x}; L) \equiv \nabla\Omega(\mathbf{x}; S) + 4\pi\delta(\mathbf{x}; S). \quad (10A.27)$$

This is the analytic continuation of $\Omega(\mathbf{x}; S)$ through the surface S which removes the jump and produces a *multivalued function* $\Omega(\mathbf{x}; L)$ ranging from $-\infty$ to ∞ . At each point in space, there are infinitely many Riemann sheets starting from a singularity at L . The values of $\Omega(\mathbf{x}; L)$ on the sheets differ by integer multiples of 4π . From this multivalued function, the magnetic field (10A.12) can be obtained as a simple gradient:

$$\mathbf{B}(\mathbf{x}) = I \nabla\Omega(\mathbf{x}; L). \quad (10A.28)$$

Ampère's law (10A.1) implies that the multivalued solid angle $\Omega(\mathbf{x}; L)$ satisfies the equation

$$(\partial_i\partial_j - \partial_j\partial_i)\Omega(\mathbf{x}; L) = 4\pi\epsilon_{ijk}\delta_k(\mathbf{x}; L). \quad (10A.29)$$

Thus, as a consequence of its multivaluedness, $\Omega(\mathbf{x}; L)$ violates the Schwarz integrability condition as the coordinate transformations do in Eq. (10.19). This makes it an unusual mathematical object to deal with. It is, however, perfectly suited to describe the physics.

To see explicitly how Eq. (10A.29) is fulfilled by $\Omega(\mathbf{x}; L)$, let us go to two dimensions where the loop corresponds to two points (in which the loop intersects a plane). For simplicity, we move one of them to infinity, and place the other at the coordinate origin. The role of the solid angle $\Omega(\mathbf{x}; L)$ is now played by the azimuthal angle $\varphi(\mathbf{x})$ of the point \mathbf{x} :

$$\varphi(\mathbf{x}) = \arctan \frac{x^2}{x^1}. \quad (10A.30)$$

The function $\arctan(x^2/x^1)$ is usually made unique by cutting the \mathbf{x} -plane from the origin along some line C to infinity, preferably along a straight line to $\mathbf{x} = (-\infty, 0)$, and assuming $\varphi(\mathbf{x})$ to jump from π to $-\pi$ when crossing the cut. The cut corresponds to the magnetic dipole surface S in the integral (10A.13). In contrast to this, we shall take $\varphi(\mathbf{x})$ to be the *multivalued* analytic continuation of this function. Then the derivative ∂_i yields

$$\partial_i\varphi(\mathbf{x}) = -\epsilon_{ij} \frac{x_j}{(x^1)^2 + (x^2)^2}. \quad (10A.31)$$

With the single-valued definition of $\partial_i\varphi(\mathbf{x})$, there would have been a δ -function $\epsilon_{ij}\delta_j(C; \mathbf{x})$ across the cut C , corresponding to the second term in (10A.18). When integrating the curl of (10A.31) across the surface s of a small circle c around the origin, we obtain by Stokes' theorem

$$\int_s d^2x (\partial_i\partial_j - \partial_j\partial_i)\varphi(\mathbf{x}) = \int_c dx_i \partial_i\varphi(\mathbf{x}), \quad (10A.32)$$

which is equal to 2π in the multivalued definition of $\varphi(\mathbf{x})$. This result implies the violation of the integrability condition as in (10A.41):

$$(\partial_1\partial_2 - \partial_2\partial_1)\varphi(\mathbf{x}) = 2\pi\delta^{(2)}(\mathbf{x}), \quad (10A.33)$$

whose three-dimensional generalization is (10A.29). In the single-valued definition with the jump by 2π across the cut, the right-hand side of (10A.32) would vanish, making $\varphi(\mathbf{x})$ satisfy the integrability condition (10A.29).

On the basis of Eq. (10A.33) we may construct a Green function for solving the corresponding differential equation with an arbitrary source, which is a superposition of infinitesimally thin line-like currents piercing the two-dimensional space at the points \mathbf{x}_n :

$$j(\mathbf{x}) = \sum_n I_n \delta^{(2)}(\mathbf{x} - \mathbf{x}_n), \quad (10A.34)$$

where I_n are currents. We may then easily solve the differential equation

$$(\partial_1\partial_2 - \partial_2\partial_1)f(\mathbf{x}) = j(\mathbf{x}), \quad (10A.35)$$

with the help of the Green function

$$G(\mathbf{x}, \mathbf{x}') = \frac{1}{2\pi}\varphi(\mathbf{x} - \mathbf{x}') \quad (10A.36)$$

which satisfies

$$(\partial_1\partial_2 - \partial_2\partial_1)G(\mathbf{x} - \mathbf{x}') = \delta^{(2)}(\mathbf{x} - \mathbf{x}'). \quad (10A.37)$$

The solution of (10A.35) is obviously

$$f(\mathbf{x}) = \int d^2\mathbf{x}' G(\mathbf{x}, \mathbf{x}')j(\mathbf{x}'). \quad (10A.38)$$

The gradient of $f(\mathbf{x})$ yields the magnetic field of an arbitrary set of line-like currents vertical to the plane under consideration.

It is interesting to realize that the Green function (10A.36) is the imaginary part of the complex function $(1/2\pi)\log(z - z')$ with $z = x^1 + ix^2$, whose real part $(1/2\pi)\log|z - z'|$ is the Green function $G_\Delta(\mathbf{x} - \mathbf{x}')$ of the two dimensional Poisson equation:

$$(\partial_1^2 + \partial_2^2)G_\Delta(\mathbf{x} - \mathbf{x}') = \delta^{(2)}(\mathbf{x} - \mathbf{x}'). \quad (10A.39)$$

It is important to point out that the superposition of line-like currents cannot be smeared out into a continuous distribution. The integral (10A.38) yields the superposition of multivalued functions

$$f(\mathbf{x}) = \frac{1}{2\pi} \sum_n I_n \arctan \frac{x^2 - x_n^2}{x^1 - x_n^1}, \quad (10A.40)$$

which is properly defined only if one can clearly continue it analytically into the all parts of the Riemann sheets defined by the endpoints of the cut at the origin. If we were to replace the sum by an integral, this possibility would be lost. Thus it is, strictly speaking, impossible to represent arbitrary continuous magnetic fields as gradients of superpositions of scalar potentials $\Omega(\mathbf{x}; L)$. This, however, is not a severe disadvantage of this representation since any current can be approximated by a superposition of line-like currents with any desired accuracy, and the same will be true for the associated magnetic fields.

The arbitrariness of the shape of the jumping surface is the origin of a further interesting gauge structure which has interesting physical consequences discussed in Subsection 10A.5.

10A.2 Generating Magnetic Fields by Multivalued Gauge Transformations

After this first exercise in multivalued functions, we now turn to another example in magnetism which will lead directly to our intended geometric application. We observed before that the local gauge transformation (10A.2) produces the same magnetic field $\mathbf{B}(\mathbf{x}) = \nabla \times \mathbf{A}(\mathbf{x})$ only, as long as the function $\Lambda(\mathbf{x})$ satisfies the Schwarz integrability criterion (10A.29)

$$(\partial_i\partial_j - \partial_j\partial_i)\Lambda(\mathbf{x}) = 0. \quad (10A.41)$$

Any function $\Lambda(\mathbf{x})$ violating this condition would change the magnetic field by

$$\Delta B_k(\mathbf{x}) = \epsilon_{kij}(\partial_i\partial_j - \partial_j\partial_i)\Lambda(\mathbf{x}), \quad (10A.42)$$

thus being no proper gauge function. The gradient of $\Lambda(\mathbf{x})$

$$\mathbf{A}(\mathbf{x}) = \nabla\Lambda(\mathbf{x}) \quad (10A.43)$$

would be a *nontrivial* vector potential.

By analogy with the multivalued coordinate transformations violating the integrability conditions of Schwarz as in (10A.29), the function $\Lambda(\mathbf{x})$ will be called *nonholonomic gauge function*.

Having just learned how to deal with multivalued functions we may change our attitude towards gauge transformations and decide to generate *all* magnetic fields approximately in a field-free space by such improper gauge transformations $\Lambda(\mathbf{x})$. By choosing for instance

$$\Lambda(\mathbf{x}) = \Phi\Omega(\mathbf{x}; L), \quad (10A.44)$$

we find from (10A.29) that this generates a field

$$B_k(\mathbf{x}) = \epsilon_{kij}(\partial_i\partial_j - \partial_j\partial_i)\Lambda(\mathbf{x}) = \Phi\delta_k(\mathbf{x}; L). \quad (10A.45)$$

This is a magnetic field of total flux Φ inside an infinitesimal tube. By a superposition of such infinitesimally thin flux tubes analogous to (10A.38) we can obviously generate a discrete approximation to any desired magnetic field in a field-free space.

10A.3 Magnetic Monopoles

Multivalued fields have also been used to describe magnetic monopoles [10, 13, 14]. A monopole charge density $\rho_m(\mathbf{x})$ is the source of a magnetic field $\mathbf{B}(\mathbf{x})$ as defined by the equation

$$\nabla \cdot \mathbf{B}(\mathbf{x}) = 4\pi\rho_m(\mathbf{x}). \quad (10A.46)$$

If $\mathbf{B}(\mathbf{x})$ is expressed in terms of a vector potential $\mathbf{A}(\mathbf{x})$ as $\mathbf{B}(\mathbf{x}) = \nabla \times \mathbf{A}(\mathbf{x})$, equation (10A.46) implies the noncommutativity of derivatives in front of the vector potential $\mathbf{A}(\mathbf{x})$:

$$\frac{1}{2}\epsilon_{ijk}(\partial_i\partial_j - \partial_j\partial_i)A_k(\mathbf{x}) = 4\pi\rho_m(\mathbf{x}). \quad (10A.47)$$

Thus $\mathbf{A}(\mathbf{x})$ must be multivalued. Dirac in his famous theory of monopoles [16] made the field single-valued by attaching to the world line of the particle a jumping world surface, whose intersection with a coordinate plane at a fixed time forms the *Dirac string*, along which the magnetic field of the monopole is imported from infinity. This world surface can be made physically irrelevant by quantizing it appropriately with respect to the charge. Its shape in space is just as irrelevant as that of the jumping surface S in Fig. 10.5. The invariance under shape deformations constitute once more a second gauge structure of the type mentioned earlier and discussed in Refs. [2, 6, 7, 10, 12].

Once we allow ourselves to work with multivalued fields, we may easily go one step further and express also $\mathbf{A}(\mathbf{x})$ as a gradient of a scalar field as in (10A.43). Then the condition becomes

$$\epsilon_{ijk}\partial_i\partial_j\partial_k\Lambda(\mathbf{x}) = 4\pi\rho_m(\mathbf{x}). \quad (10A.48)$$

Let us construct the field of a magnetic monopole of charge g at a point \mathbf{x}_0 , which satisfies (10A.46) with $\rho_m(\mathbf{x}) = g\delta^{(3)}(\mathbf{x} - \mathbf{x}_0)$. Physically, this can be done only by setting up an infinitely thin solenoid along an arbitrary line L_0^\uparrow whose initial point lies at \mathbf{x}_0 and the final anywhere at infinity. The superscript \uparrow indicates that the line has a starting point \mathbf{x}_0 . Inside this solenoid, the magnetic field is infinite, equal to

$$\mathbf{B}_{\text{inside}}(\mathbf{x}; L) = 4\pi g\delta(\mathbf{x}; L_0^\uparrow), \quad (10A.49)$$

where $\delta(\mathbf{x}; L_0^\uparrow)$ is the open-ended version of (10A.8)

$$\delta(\mathbf{x}; L_0^\uparrow) = \int_{L_0^\uparrow, \mathbf{x}_0} d^3x' \delta^{(3)}(\mathbf{x} - \mathbf{x}'). \quad (10A.50)$$

The divergence of this function is concentrated at the starting point:

$$\nabla \cdot \delta(\mathbf{x}; L_0^\uparrow) = \delta^{(3)}(\mathbf{x} - \mathbf{x}_0). \quad (10A.51)$$

This follows from (10A.10) by moving the end point to infinity. By analogy with the curl relation (10A.20) we observe a further gauge invariance. If we deform the line L , at fixed initial point \mathbf{x} , the δ -function (10A.50) changes as follows:

$$\delta(\mathbf{x}; L_0^\uparrow) \rightarrow \delta(\mathbf{x}; L_0^{\uparrow'}) = \delta(\mathbf{x}; L_0^\uparrow) + \nabla \times \delta(\mathbf{x}; S), \quad (10A.52)$$

where S is the surface over which L^\uparrow has swept on its way to $L^{\uparrow'}$. Under this gauge transformation, the relation (10A.51) is obviously invariant. We shall call this *monopole gauge invariance*. The flux (10A.49) inside the solenoid is therefore a *monopole gauge field*. It is straightforward to construct from it the ordinary gauge field $\mathbf{A}(\mathbf{x})$ of the monopole. First we define the L_0^\uparrow -dependent field

$$\mathbf{A}(\mathbf{x}; L_0^\uparrow) = -g \int d^3 x' \frac{\nabla' \times \delta(\mathbf{x}'; L_0^\uparrow)}{R'} = g \int d^3 x' \delta(\mathbf{x}'; L_0^\uparrow) \times \frac{\mathbf{R}'}{R'^3}. \quad (10A.53)$$

The curl of the first expression is

$$\nabla \times \mathbf{A}(\mathbf{x}; L_0^\uparrow) = -g \int d^3 x' \frac{\nabla' \times [\nabla' \times \delta(\mathbf{x}'; L_0^\uparrow)]}{R'}, \quad (10A.54)$$

and consists of two terms

$$-g \int d^3 x' \frac{\nabla' [\nabla' \cdot \delta(\mathbf{x}'; L_0^\uparrow)]}{R'} + g \int d^3 x' \frac{\nabla'^2 \delta(\mathbf{x}'; L_0^\uparrow)}{R'}. \quad (10A.55)$$

After an integration by parts, and using (10A.51), the first term is L_0^\uparrow -independent and reads

$$g \int d^3 x' \delta^{(3)}(\mathbf{x} - \mathbf{x}_0) \nabla' \frac{1}{R'} = g \frac{\mathbf{x} - \mathbf{x}_0}{|\mathbf{x} - \mathbf{x}_0|^3}. \quad (10A.56)$$

The second term becomes, after two integration by parts,

$$-4\pi g \delta(\mathbf{x}'; L_0^\uparrow). \quad (10A.57)$$

The first term is the desired magnetic field of the monopole. Its divergence is $\delta(\mathbf{x} - \mathbf{x}_0)$, which we wanted to archive. The second term is the monopole gauge field, the magnetic field inside the solenoid. The total divergence of this field is, of course, zero.

By analogy with (10A.25) we now subtract the latter term and find the magnetic field of the monopole

$$\mathbf{B}(\mathbf{x}) = \nabla \times \mathbf{A}(\mathbf{x}; L_0^\uparrow) + 4\pi g \delta(\mathbf{x}; L_0^\uparrow). \quad (10A.58)$$

This field is independent of the string L_0^\uparrow . It depends only on the source point \mathbf{x}_0 and satisfies $\nabla \cdot \mathbf{B}(\mathbf{x}) = 4\pi g \delta^{(3)}(\mathbf{x} - \mathbf{x}_0)$.

Let us calculate the vector potential for some simple choices of \mathbf{x}_0 and L_0^\uparrow , for instance $\mathbf{x}_0 = \mathbf{0}$ and L_0^\uparrow along the positive z -axis, so that $\delta(\mathbf{x}; L_0^\uparrow)$ becomes $\hat{\mathbf{z}} \Theta(z) \delta(x) \delta(y)$, where $\hat{\mathbf{z}}$ is the unit vector in z -direction. Inserting this into the second expression in (10A.53) yields

$$\begin{aligned} \mathbf{A}^{(g)}(\mathbf{x}; L_0^\uparrow) &= -g \int_0^\infty dz' \frac{\hat{\mathbf{z}} \times \mathbf{x}}{\sqrt{x^2 + y^2 + (z' - z)^2}^{3/2}} \\ &= -g \frac{\hat{\mathbf{z}} \times \mathbf{x}}{r(r-z)} = g \frac{(y, -x, 0)}{r(r-z)}. \end{aligned} \quad (10A.59)$$

If L_0^\uparrow runs to $-\infty$, so that $\delta(\mathbf{x}; L_0^\uparrow)$ is equal to $-\hat{\mathbf{z}} \Theta(-z)\delta(x)\delta(y)$, we obtain

$$\begin{aligned} \mathbf{A}^{(g)}(\mathbf{x}; L_0^\uparrow) &= g \int_{-\infty}^0 dz' \frac{\hat{\mathbf{z}} \times \mathbf{x}}{\sqrt{x^2 + y^2 + (z' - z)^2}^{3/2}} \\ &= g \frac{\hat{\mathbf{z}} \times \mathbf{x}}{r(r+z)} = -g \frac{(y, -x, 0)}{r(r+z)}. \end{aligned} \quad (10A.60)$$

The vector potential has only azimuthal components. If we parametrize (x, y, z) in terms of spherical angles θ, φ as $r(\sin \theta \cos \varphi, \sin \theta \sin \varphi, \cos \theta)$, these are

$$A_\varphi^{(g)}(\mathbf{x}; L_0^\uparrow) = \frac{g}{r \sin \theta} (1 - \cos \theta) \quad \text{or} \quad A_\varphi^{(g)}(\mathbf{x}; L_0^\uparrow) = -\frac{g}{r \sin \theta} (1 + \cos \theta), \quad (10A.61)$$

respectively.

The shape of the line L_0^\uparrow can be brought to a standard form, which corresponds to fixing a gauge of the field $\delta(\mathbf{x}; L_0^\uparrow)$. For example, we may always choose L_0^\uparrow to run from \mathbf{x}_0 into the z -direction.

Also here, there exists an equivalent formulation in terms of a multivalued \mathbf{A} -field with infinitely many Riemann sheets around the line L . For a detailed discussion of the physics of multivalued fields see Refs. [2, 6, 7, 10, 12].

An interesting observation is the following: If the gauge function $\Lambda(\mathbf{x})$ is considered as a nonholonomic displacement in some fictitious crystal dimension, then the magnetic field of a current loop which gives rise to noncommuting derivatives $(\partial_i \partial_j - \partial_j \partial_i) \Lambda(\mathbf{x}) \neq 0$ is the analog of a dislocation [compare (10.23)], and thus implies torsion in the crystal. A magnetic monopole, on the other hand, arises from noncommuting derivatives $(\partial_i \partial_j - \partial_j \partial_i) \partial_k \Lambda(\mathbf{x}) \neq 0$ in Eq. (10A.48). It corresponds to a disclination [see (10.57)] and implies curvature. The defects in the multivalued description of magnetism are therefore similar to those in a crystal where dislocations much more abundantly observed than disclinations. They are opposite to those in general relativity which is governed by curvature alone, with no evidence for torsion so far [11].

10A.4 Minimal Magnetic Coupling of Particles from Multivalued Gauge Transformations

Multivalued gauge transformations are the perfect tool to minimally couple electromagnetism to any type of matter. Consider for instance a free nonrelativistic point particle with a Lagrangian

$$L = \frac{M}{2} \dot{\mathbf{x}}^2. \quad (10A.62)$$

The equations of motion are invariant under a gauge transformation

$$L \rightarrow L' = L + \nabla \Lambda(\mathbf{x}) \dot{\mathbf{x}}, \quad (10A.63)$$

since this changes the action $\mathcal{A} = \int_{t_a}^{t_b} dt L$ merely by a surface term:

$$\mathcal{A}' \rightarrow \mathcal{A} = \mathcal{A} + \Lambda(\mathbf{x}_b) - \Lambda(\mathbf{x}_a). \quad (10A.64)$$

The invariance is absent if we take $\Lambda(\mathbf{x})$ to be a multivalued gauge function. In this case, a nontrivial vector potential $\mathbf{A}(\mathbf{x}) = \nabla \Lambda(\mathbf{x})$ (working in natural units with $e = 1$) is created in the field-free space, and the nonholonomically gauge-transformed Lagrangian corresponding to (10A.63),

$$L' = \frac{M}{2} \dot{\mathbf{x}}^2 + \mathbf{A}(\mathbf{x}) \dot{\mathbf{x}}, \quad (10A.65)$$

describes correctly the dynamics of a free particle in an external magnetic field.

The coupling derived by multivalued gauge transformations is automatically invariant under additional ordinary single-valued gauge transformations of the vector potential

$$\mathbf{A}(\mathbf{x}) \rightarrow \mathbf{A}'(\mathbf{x}) = \mathbf{A}(\mathbf{x}) + \nabla\Lambda(\mathbf{x}), \quad (10A.66)$$

since these add to the Lagrangian (10A.65) once more the same pure derivative term which changes the action by an irrelevant surface term as in (10A.64).

The same procedure leads in quantum mechanics to the minimal coupling of the Schrödinger field $\psi(\mathbf{x})$. The action is $\mathcal{A} = \int dt d^3x L$ with a Lagrange density (in natural units with $\hbar = 1$)

$$L = \psi^*(\mathbf{x}) \left(i\partial_t + \frac{1}{2M} \nabla^2 \right) \psi(\mathbf{x}). \quad (10A.67)$$

The physics described by a Schrödinger wave function $\psi(\mathbf{x})$ is invariant under arbitrary local phase changes

$$\psi(\mathbf{x}, t) \rightarrow \psi'(\mathbf{x}) = e^{i\Lambda(\mathbf{x})} \psi(\mathbf{x}, t), \quad (10A.68)$$

called local U(1) transformations. This implies that the Lagrange density (10A.67) may equally well be replaced by the gauge-transformed one

$$L = \psi^*(\mathbf{x}, t) \left(i\partial_t + \frac{1}{2M} \mathbf{D}^2 \right) \psi(\mathbf{x}, t), \quad (10A.69)$$

where $-i\mathbf{D} \equiv -i\nabla - \nabla\Lambda(\mathbf{x})$ is the operator of physical momentum.

We may now go over to nonzero magnetic fields by admitting gauge transformations with multivalued $\Lambda(\mathbf{x})$ whose gradient is a nontrivial vector potential $\mathbf{A}(\mathbf{x})$ as in (10A.43). Then $-i\mathbf{D}$ turns into the covariant momentum operator

$$\hat{\mathbf{P}} = -i\mathbf{D} = -i\nabla - \mathbf{A}(\mathbf{x}), \quad (10A.70)$$

and the Lagrange density (10A.69) describes correctly the magnetic coupling in quantum mechanics.

As in the classical case, the coupling derived by multivalued gauge transformations is automatically invariant under ordinary single-valued gauge transformations under which the vector potential $\mathbf{A}(\mathbf{x})$ changes as in (10A.66), whereas the Schrödinger wave function undergoes a local U(1)-transformation (10A.68). This invariance is a direct consequence of the simple transformation behavior of $\mathbf{D}\psi(\mathbf{x}, t)$ under gauge transformations (10A.66) and (10A.68) which is

$$\mathbf{D}\psi(\mathbf{x}, t) \rightarrow \mathbf{D}\psi'(\mathbf{x}, t) = e^{i\Lambda(\mathbf{x})} \mathbf{D}\psi(\mathbf{x}, t). \quad (10A.71)$$

Thus $\mathbf{D}\psi(\mathbf{x}, t)$ transforms just like $\psi(\mathbf{x}, t)$ itself, and for this reason, \mathbf{D} is called gauge-covariant derivative. The generation of magnetic fields by a multivalued gauge transformation is the simplest example for the power of the nonholonomic mapping principle.

After this discussion it is quite suggestive to introduce the same mathematics into differential geometry, where the role of gauge transformations is played by reparametrizations of the space coordinates. This is precisely what is done in Subsection (10.2.2).

10A.5 Gauge Field Representation of Current Loops and Monopoles

In the previous subsections we have given examples for the use of multivalued fields in describing magnetic phenomena. The nonholonomic gauge transformations by which we created line-like nonzero field configurations were shown to be the natural origin of the minimal couplings to the classical actions as well as to the Schrödinger equation. It is interesting to observe that there exists a fully fledged theory of magnetism (which is easily generalized to electromagnetism) with these

multivalued fields, if we properly handle the freedom in choosing the jumping surfaces S whose boundary represents the physical current loop in Eq. (10A.12).

To understand this we pose ourselves the problem of setting up an action formalism for calculating the magnetic energy of a current loop in the gradient representation of the magnetic field. In this Euclidean field theory, the action is the field energy:

$$\mathcal{E} = \frac{1}{8\pi} \int d^3x \mathbf{B}^2(\mathbf{x}). \quad (10A.72)$$

Inserting the gradient representation (10A.28) of the magnetic field, we can write

$$\mathcal{E} = \frac{I^2}{8\pi} \int d^3x [\nabla\Omega(\mathbf{x})]^2. \quad (10A.73)$$

This holds for the multivalued solid angle $\Omega(\mathbf{x})$ which is independent of S . In order to perform field theoretic calculations, we must go over to the single-valued representation (10A.25), so that

$$\mathcal{E} = \frac{I^2}{8\pi} \int d^3x [\nabla\Omega(\mathbf{x}; S) + 4\pi\delta(\mathbf{x}; S)]^2. \quad (10A.74)$$

The δ -function removes the unphysical field energy on the artificial magnetic dipole layer on S . Let us calculate the magnetic field energy of the current loop from the action (10A.74). For this we rewrite the action (10A.74) in terms of an *auxiliary* vector field $\mathbf{B}(\mathbf{x})$ as

$$\mathcal{E} = \int d^3x \left\{ -\frac{1}{8\pi} \mathbf{B}^2(\mathbf{x}) - \frac{I}{4\pi} \mathbf{B}(\mathbf{x}) \cdot [\nabla\Omega(\mathbf{x}; S) + 4\pi\delta(\mathbf{x}; S)] \right\}. \quad (10A.75)$$

A partial integration brings the second term to

$$\int d^3x \frac{I}{4\pi} \nabla \cdot \mathbf{B}(\mathbf{x}) \Omega(\mathbf{x}; S).$$

Extremizing this in $\Omega(\mathbf{x})$ yields the equation

$$\nabla \cdot \mathbf{B}(\mathbf{x}) = 0, \quad (10A.76)$$

implying that the field lines of $\mathbf{B}(\mathbf{x})$ form closed loops. This equation may be enforced identically (as a Bianchi identity) by expressing $\mathbf{B}(\mathbf{x})$ as a curl of an auxiliary vector potential $\mathbf{A}(\mathbf{x})$, setting

$$\mathbf{B}(\mathbf{x}) \equiv \nabla \times \mathbf{A}(\mathbf{x}). \quad (10A.77)$$

With this ansatz, the equation which brings the action (10A.75) to the form

$$\mathcal{E} = \int d^3x \left\{ -\frac{1}{8\pi} [\nabla \times \mathbf{A}(\mathbf{x})]^2 - I [\nabla \times \mathbf{A}(\mathbf{x})] \cdot \delta(\mathbf{x}; S) \right\}. \quad (10A.78)$$

A further partial integration leads to

$$\mathcal{E} = \int d^3x \left\{ -\frac{1}{8\pi} [\nabla \times \mathbf{A}(\mathbf{x})]^2 - I \mathbf{A}(\mathbf{x}) \cdot [\nabla \times \delta(\mathbf{x}; S)] \right\}, \quad (10A.79)$$

and we identify in the linear term in $\mathbf{A}(\mathbf{x})$ the *auxiliary current*

$$\mathbf{j}(\mathbf{x}) \equiv I \nabla \times \delta(\mathbf{x}; S) = I \delta(\mathbf{x}; L), \quad (10A.80)$$

due to Stoke's law (10A.20). According to Eq. (10A.9), this current is conserved for closed loops L .

By extremizing the action (10A.78), we obtain Ampère's law (10A.1). Thus the auxiliary quantities $\mathbf{B}(\mathbf{x})$, $\mathbf{A}(\mathbf{x})$, and $\mathbf{j}(\mathbf{x})$ coincide with the usual magnetic quantities with the same name. If we insert the explicit solution (10A.5) of Ampère's law into the energy, we obtain the *Biot-Savart* energy for an arbitrary current distribution

$$\mathcal{E} = \frac{1}{2} \int d^3x d^3x' \mathbf{j}(\mathbf{x}) \frac{1}{|\mathbf{x} - \mathbf{x}'|} \mathbf{j}(\mathbf{x}'). \quad (10A.81)$$

Note that the action (10A.78) is invariant under two mutually dual gauge transformations, the usual magnetic one in (10A.2), by which the vector potential receives a gradient of an arbitrary scalar field, and the gauge transformation (10A.23), by which the irrelevant surface S is moved to another configuration S' .

Thus we have proved the complete equivalence of the gradient representation of the magnetic field to the usual gauge field representation. In the gradient representation, there exists a new type of gauge invariance which expresses the physical irrelevance of the jumping surface appearing when using single-valued solid angles.

The action (10A.79) describes magnetism in terms of a *double gauge theory* [8], in which both the gauge of $\mathbf{A}(\mathbf{x})$ and the shape of S can be changed arbitrarily. By setting up a grand-canonical partition function of many fluctuating surfaces it is possible to describe a large family of phase transitions mediated by the proliferation of line-like defects. Examples are vortex lines in the superfluid-normal transition in helium and dislocation and disclination lines in the melting transition of crystals [2, 6, 7, 10, 12].

Let us now go through the analogous calculation for a gas of monopoles at \mathbf{x}_n from the magnetic energy formed with the field (10A.58):

$$\mathcal{E} = \frac{1}{8\pi} \int d^3x \left[\nabla \times \mathbf{A} + 4\pi g \sum_n \delta(\mathbf{x}; L_n^\uparrow) \right]^2. \quad (10A.82)$$

As in (10A.75) we introduce an auxiliary magnetic field and rewrite (10A.82) as

$$\mathcal{E} = \int d^3x \left\{ -\frac{1}{8\pi} \mathbf{B}^2(\mathbf{x}) - \frac{1}{4\pi} \mathbf{B}(\mathbf{x}) \cdot \left[\nabla \times \mathbf{A} + g \sum_n \delta(\mathbf{x}; L_n^\uparrow) \right] \right\}. \quad (10A.83)$$

Extremizing this in \mathbf{A} yields $\nabla \times \mathbf{B} = 0$, so that we may set $\mathbf{B} = \nabla \Lambda$, and obtain

$$\mathcal{E} = \int d^3x \left\{ -\frac{1}{8\pi} [\nabla \Lambda(\mathbf{x})]^2 + g \Lambda(\mathbf{x}) \sum_n \nabla \cdot \delta(\mathbf{x}; L_n^\uparrow) \right\}. \quad (10A.84)$$

Recalling (10A.51), the extremal Λ field is

$$\Lambda(\mathbf{x}) = -\frac{4\pi g}{\nabla^2} \sum_n \delta(\mathbf{x} - \mathbf{x}_n) = g \sum_n \frac{1}{|\mathbf{x} - \mathbf{x}_n|}, \quad (10A.85)$$

which leads, after reinsertion into (10A.84), to the Coulomb interaction energy

$$\mathcal{E} = \frac{g^2}{2} \sum_{n,n'} \frac{1}{|\mathbf{x}_n - \mathbf{x}_{n'}|}. \quad (10A.86)$$

Appendix 10B Comparison of Multivalued Basis Tetrads and Vierbein Fields

The standard *tetrads* or vierbein fields were introduced a long time ago in gravitational theories of spinning particles both in purely Riemann [16] as well as in Riemann-Cartan spacetimes [17, 18,

19, 20, 2]. Their mathematics is described in detail in the literature [21]. Their purpose was to define at every point a local Lorentz frame by means of another set of coordinate differentials

$$dx^\alpha = h^\alpha_\lambda(q) dq^\lambda, \quad \alpha = 0, 1, 2, 3, \quad (10B.1)$$

which can be contracted with Dirac matrices γ^α to form locally Lorentz invariant quantities. Local Lorentz frames are reached by requiring the induced metric in these coordinates to be Minkowskian:

$$g_{\alpha\beta} = h_\alpha^\mu(q) h_\beta^\nu(q) g_{\mu\nu}(q) = \eta_{\alpha\beta}, \quad (10B.2)$$

where $\eta_{\alpha\beta}$ is the flat Minkowski metric (10.30). Just like $e^i_\mu(q)$ in (10.12), these vierbeins possess reciprocals

$$h_\alpha^\mu(q) \equiv \eta_{\alpha\beta} g^{\mu\nu}(q) h^\beta_\nu(q), \quad (10B.3)$$

and satisfy orthonormality and completeness relations as in (10.13):

$$h_\alpha^\mu h^\beta_\mu = \delta_\alpha^\beta, \quad h^\alpha_\mu h^\nu_\alpha = \delta_\mu^\nu. \quad (10B.4)$$

They also can be multiplied with each other as in (10.14) to yield the metric

$$g_{\mu\nu}(q) = h^\alpha_\mu(q) h^\beta_\nu(q) \eta_{\alpha\beta}. \quad (10B.5)$$

Thus they constitute another “square root” of the metric. The relation between these square roots is some linear transformation

$$e^a_\mu(q) = e^a_\alpha(q) h^\alpha_\mu(q), \quad (10B.6)$$

which must necessarily be a local Lorentz transformation

$$\Lambda^a_\alpha(q) = e^a_\alpha(q), \quad (10B.7)$$

since this matrix connects the two Minkowski metrics (10.30) and (10B.2) with each other:

$$\eta_{ab} \Lambda^a_\alpha(q) \Lambda^b_\beta(q) = \eta_{\alpha\beta}. \quad (10B.8)$$

The different local Lorentz transformations allow us to choose different local Lorentz frames which distinguish fields with definite spin by the irreducible representations of these transformations. The physical consequences of the theory must be independent of this local choice, and this is the reason why the presence of spinning fields requires the existence of an additional gauge freedom under local Lorentz transformations, in addition to Einstein’s invariance under general coordinate transformations. Since the latter may be viewed as local translations, the theory with spinning particles are locally Poincaré invariant.

The vierbein fields $h^\alpha_\mu(q)$ have in common with ours that both violate the integrability condition as in (10.22), thus describing nonholonomic coordinates dx^α for which there exists only a differential relation (10B.1) to the physical coordinates q^μ . However, they differ from our multivalued tetrads $e^a_\mu(q)$ by being *single-valued* fields satisfying the integrability condition

$$(\partial_\mu \partial_\nu - \partial_\nu \partial_\mu) h^\alpha_\lambda(q) = 0, \quad (10B.9)$$

in contrast to our multivalued tetrads $e^i_\lambda(q)$ in Eq. (10.23).

In the local coordinate system dx^α , curvature arises from a violation of the integrability condition of the local Lorentz transformations (10B.7).

The simple equation (10.24) for the torsion tensor in terms of the multivalued tetrads $e^i_\lambda(q)$ must be contrasted with a similar-looking, but geometrically quite different, quantity formed from the vierbein fields $h^\alpha_\lambda(q)$ and their reciprocals, the *objects of anholonomy* [21]:

$$\Omega_{\alpha\beta}^\gamma(q) = \frac{1}{2} h_\alpha^\mu(q) h_\beta^\nu(q) [\partial_\mu h^\gamma_\nu(q) - \partial_\nu h^\gamma_\mu(q)]. \quad (10B.10)$$

$dx^a = e^a{}_\mu dq^\mu$	$\Gamma_{ab}{}^c = 0$
$dx^\alpha = h^\alpha{}_\mu dq^\mu$	$\Gamma_{\alpha\beta}{}^\gamma = h^\gamma{}_\lambda h^\alpha{}_\mu h^\beta{}_\nu K_{\mu\nu}{}^\lambda - \overset{h}{K}_{\alpha\beta}{}^\gamma$
dq^μ	$\Gamma_{\mu\nu}{}^\lambda = e_a{}^\lambda \partial_\mu e^a{}_\nu$

Figure 10.6 Coordinate system q^μ and the two sets of local nonholonomic coordinates dx^α and dx^a . The intermediate coordinates dx^α have a Minkowski metric only at the point q , the coordinates dx^a in an entire small neighborhood (at the cost of a closure failure).

A combination of these similar to (10.28),

$$\overset{h}{K}_{\alpha\beta}{}^\gamma(q) = \Omega_{\alpha\beta}{}^\gamma(q) - \Omega_{\alpha\beta}{}^\gamma(q) + \Omega_{\alpha\beta}{}^\gamma(q), \quad (10B.11)$$

appears in the so-called *spin connection*

$$\Gamma_{\alpha\beta}{}^\gamma = h^\gamma{}_\lambda h^\alpha{}_\mu h^\beta{}_\nu (K_{\mu\nu}{}^\lambda - \overset{h}{K}_{\mu\nu}{}^\lambda), \quad (10B.12)$$

which is needed to form a covariant derivative of local vectors

$$v_\alpha(q) = v_\mu(q) h^\alpha{}^\mu(q), \quad v^\alpha(q) = v^\mu(q) h^\alpha{}_\mu(q). \quad (10B.13)$$

These have the form

$$D_\alpha v_\beta(q) = \partial_\alpha v_\beta(q) - \Gamma_{\alpha\beta}{}^\gamma(q) v_\gamma(q), \quad D_\alpha v^\beta(q) = \partial_\alpha v^\beta(q) + \Gamma_{\alpha\gamma}{}^\beta(q) v^\gamma(q). \quad (10B.14)$$

For details see Ref. [2, 6]. In spite of the similarity between the defining equations (10.24) and (10B.10), the tensor $\Omega_{\alpha\beta}{}^\gamma(q)$ bears no relation to torsion, and $\overset{h}{K}_{\alpha\beta}{}^\gamma(q)$ is independent of the contortion $K_{\alpha\beta}{}^\gamma$. In fact, the objects of anholonomy $\Omega_{\alpha\beta}{}^\gamma(q)$ are in general nonzero in the absence of torsion [22], and may even be nonzero in flat spacetime, where the matrices $h^\alpha{}_\mu(q)$ degenerate to local Lorentz transformations. The quantities $\overset{h}{K}_{\alpha\beta}{}^\gamma(q)$, and thus the spin connection (10B.12), characterize the orientation of the local Lorentz frames.

The nonholonomic coordinates dx^α transform the metric $g_{\mu\nu}(q)$ to a Minkowskian form η_{ab} at any given point q^μ . They correspond to a small “falling elevator” of Einstein in which the gravitational forces vanish precisely at the center of mass, the neighborhood still being subject to tidal forces. In contrast, the nonholonomic coordinates dx^a flatten the spacetime *in an entire neighborhood* of the point. This is at the expense of producing defects in spacetime (like those produced when flattening an orange peel by stepping on it), as will be explained in Section IV. The affine connection $\Gamma_{ab}{}^c(q)$ in the latter coordinates dx^a vanishes identically.

The difference between our multivalued tetrads and the usual vierbeins is illustrated in the diagram of Fig. 10.6.

Appendix 10C Cancellation of Powers of $\delta(0)$

There is a simple way of proving the cancellation of all UV-divergences $\delta(0)$. Consider a free particle whose mass depends on the time with an action

$$\mathcal{A}_{\text{tot}}[q] = \int_0^\beta d\tau \left[\frac{1}{2} Z(\tau) \dot{q}^2(\tau) - \frac{1}{2} \delta(0) \log Z(\tau) \right], \quad (10C.1)$$

where $Z(\tau)$ is some function of τ but independent now of the path $q(\tau)$. The last term is the simplest nontrivial form of the Jacobian action in (10.408). Since it is independent of q , it is conveniently taken out of the path integral as a factor

$$J = e^{(1/2)\delta(0) \int_0^\beta d\tau \log Z(\tau)}. \tag{10C.2}$$

We split the action into a sum of a free and an interacting part

$$\mathcal{A}^{(0)} = \int_0^\beta d\tau \frac{1}{2} \dot{q}^2(\tau), \quad \mathcal{A}^{\text{int}} = \int_0^\beta d\tau \frac{1}{2} [Z(\tau) - 1] \dot{q}^2(\tau), \tag{10C.3}$$

and calculate the transition amplitude (10.411) as a sum of all connected diagrams in the cumulant expansion

$$\begin{aligned} (0|\beta|0) &= J \int \mathcal{D}q(\tau) e^{-\mathcal{A}^{(0)}[q] - \mathcal{A}^{\text{int}}[q]} = J \int \mathcal{D}q(\tau) e^{-\mathcal{A}^{(0)}[q]} \left(1 - \mathcal{A}^{\text{int}} + \frac{1}{2} \mathcal{A}^{\text{int}2} - \dots \right) \\ &= (2\pi\beta)^{-1/2} J \left[1 - \langle \mathcal{A}^{\text{int}} \rangle + \frac{1}{2} \langle \mathcal{A}^{\text{int}2} \rangle - \dots \right] \\ &= (2\pi\beta)^{-1/2} J e^{-\langle \mathcal{A}^{\text{int}} \rangle_c + \frac{1}{2} \langle \mathcal{A}^{\text{int}2} \rangle_c - \dots}. \end{aligned} \tag{10C.4}$$

We now show that the infinite series of $\delta(0)$ -powers appearing in a Taylor expansion of the exponential (10C.2) is precisely compensated by the sum of all terms in the perturbation expansion (10C.4). Being interested only in these singular terms, we may extend the τ -interval to the entire time axis. Then Eq. (10.394) yields the propagator $\Delta(\tau, \tau') = \delta(\tau - \tau')$, and we find the first-order expansion term

$$\langle \mathcal{A}^{\text{int}} \rangle_c = \int d\tau \frac{1}{2} [Z(\tau) - 1] \Delta(\tau, \tau) = -\frac{1}{2} \delta(0) \int d\tau [1 - Z(\tau)]. \tag{10C.5}$$

To second order, divergent integrals appear involving products of distributions, thus requiring an intermediate extension to d dimensions as follows

$$\begin{aligned} \langle \mathcal{A}^{\text{int}2} \rangle_c &= \int \int d\tau_1 d\tau_2 \frac{1}{2} (Z - 1)_1 \frac{1}{2} (Z - 1)_2 2 \Delta(\tau_1, \tau_2) \Delta(\tau_2, \tau_1) \\ &\rightarrow \int \int d^d x_1 d^d x_2 \frac{1}{2} (Z - 1)_1 \frac{1}{2} (Z - 1)_2 2 \Delta_\mu \Delta_\nu(x_1, x_2) \nu \Delta_\mu(x_2, x_1) \\ &= \int \int d^d x_1 d^d x_2 \frac{1}{2} (Z - 1)_1 \frac{1}{2} (Z - 1)_2 2 \Delta_{\mu\mu}(x_2, x_1) \Delta_{\nu\nu}(x_1, x_2), \end{aligned} \tag{10C.6}$$

the last line following from partial integrations. For brevity, we have abbreviated $[Z(\tau_i) - 1]$ by $(Z - 1)_i$. Using the field equation (10.418) and going back to one dimension yields, with the further abbreviation $(Z - 1)_i \rightarrow z_i$:

$$\langle \mathcal{A}^{\text{int}2} \rangle_c = \frac{1}{2} \int \int d\tau_1 d\tau_2 z_1 z_2 \delta^2(\tau_1, \tau_2). \tag{10C.7}$$

To third order we calculate

$$\begin{aligned} \langle \mathcal{A}^{\text{int}3} \rangle_c &= \int \int \int d\tau_1 d\tau_2 d\tau_3 \frac{1}{2} z_1 \frac{1}{2} z_2 \frac{1}{2} z_3 8 \Delta(\tau_1, \tau_2) \Delta(\tau_2, \tau_3) \Delta(\tau_3, \tau_1) \\ &\rightarrow \int \int \int d^d x_1 d^d x_2 d^d x_3 \frac{1}{2} z_1 \frac{1}{2} z_2 \frac{1}{2} z_3 8 \Delta_\mu \Delta_\nu(x_1, x_2) \nu \Delta_\sigma(x_2, x_3) \sigma \Delta_\mu(x_3, x_1) \\ &= - \int \int \int d^d x_1 d^d x_2 d^d x_3 \frac{1}{2} z_1 \frac{1}{2} z_2 \frac{1}{2} z_3 8 \Delta_{\mu\mu}(x_3, x_1) \Delta_{\nu\nu}(x_1, x_2) \Delta_{\sigma\sigma}(x_2, x_3). \end{aligned} \tag{10C.8}$$

Applying again the field equation (10.418) and going back to one dimension, this reduces to

$$\langle \mathcal{A}_{\text{int}}^3 \rangle_c = \int \int \int d\tau_1 d\tau_2 d\tau_3 z_1 z_2 z_3 \delta(\tau_1, \tau_2) \delta(\tau_2, \tau_3) \delta(\tau_3, \tau_1). \quad (10C.9)$$

Continuing to n -order and substituting Eqs. (10C.5), (10C.7), (10C.9), etc. into (10C.4), we obtain in the exponent of Eq. (10C.4) a sum

$$-\langle \mathcal{A}_{\text{int}} \rangle_c + \frac{1}{2} \langle \mathcal{A}_{\text{int}}^2 \rangle_c - \frac{1}{3!} \langle \mathcal{A}_{\text{int}}^3 \rangle_c + \dots = \frac{1}{2} \sum_1^{\infty} (-1)^n \frac{c_n}{n}, \quad (10C.10)$$

with

$$c_n = \int d\tau_1 \dots d\tau_n C(\tau_1, \tau_2) C(\tau_2, \tau_3) \dots C(\tau_n, \tau_1) \quad (10C.11)$$

where

$$C(\tau, \tau') = [Z(\tau) - 1] \delta(\tau, \tau'). \quad (10C.12)$$

Substituting this into Eq. (10C.11) and using the rule (10.369) yields

$$c_n = \int \int d\tau_1 d\tau_n [Z(\tau_1) - 1]^n \delta^2(\tau_1 - \tau_n) = \delta(0) \int d\tau [Z(\tau) - 1]^n. \quad (10C.13)$$

Inserting these numbers into the expansion (10C.10), we obtain

$$\begin{aligned} -\langle \mathcal{A}_{\text{int}} \rangle_c + \frac{1}{2} \langle \mathcal{A}_{\text{int}}^2 \rangle_c - \frac{1}{3!} \langle \mathcal{A}_{\text{int}}^3 \rangle_c + \dots &= \frac{1}{2} \delta(0) \int d\tau \sum_1^{\infty} (-1)^n \frac{[Z(\tau) - 1]^n}{n} \\ &= -\frac{1}{2} \delta(0) \int d\tau \log Z(\tau), \end{aligned} \quad (10C.14)$$

which compensates precisely the Jacobian factor J in (10C.4).

Notes and References

Path integrals in spaces with curvature but no torsion have been discussed by B.S. DeWitt, *Rev. Mod. Phys.* **29**, 377 (1957).

We do not agree with the measure of path integration in this standard work since it produces a physically incorrect $\hbar^2 \bar{R}/12M$ -term in the energy. This has to be subtracted from the Lagrangian before summing over all paths to obtain the correct energy spectrum on surfaces of spheres and on group spaces. Thus, DeWitt's action in the short-time amplitude of the path integral is non-classical, in contrast to the very idea of path integration. A similar criticism holds for

K.S. Cheng, *J. Math. Phys.* **13**, 1723 (1972),
who has an extra $\hbar^2 \bar{R}/6M$ -term.

Schrödinger Equation in General Metric-Affine Spaces

We now use the path integral representation of the last chapter to find out which Schrödinger equation is obeyed by the time evolution amplitude in a space with curvature and torsion. If there is only curvature, the result establishes the connection with the operator quantum mechanics described in Chapter 1. In particular, it will properly reproduce the energy spectra of the systems in Sections 1.14 and 1.15 — a particle on the surface of a sphere and a spinning top — which were quantized there via group commutation rules. If the space carries torsion also, the Schrödinger operator emerging from our formulation will be a *prediction*. Its correctness will be verified in Chapter 13 by an application to the path integral of the Coulomb system which can be transformed into a harmonic oscillator by a nonholonomic mapping involving curvature and torsion.

11.1 Integral Equation for Time Evolution Amplitude

Consider the time-sliced path integral Eq. (10.146)

$$\langle q | e^{-i(t-t')\hat{H}/\hbar} | q' \rangle = \frac{1}{\sqrt{2\pi i \hbar \epsilon / M}^D} \prod_{n=2}^{N+1} \left[\int d^D \Delta q_n \frac{\sqrt{g(q_n)}}{\sqrt{2\pi i \hbar \epsilon / M}^D} \right] e^{i \sum_{n=1}^{N+1} (\mathcal{A}^\epsilon + \mathcal{A}_J^\epsilon) / \hbar}, \quad (11.1)$$

with the integrals over Δq_n to be performed successively from $n = N$ down to $n = 1$.

Let us study the effect of the last Δq_n -integration upon the remaining product of integrals. We denote the entire product briefly by $\psi(q_{N+1}, t_{N+1}) \equiv \psi(q, t)$ and the product without the last factor by

$$\psi(q_N, t_N) = \psi(q_{N+1} - \Delta q_{N+1}, t_{N+1} - \epsilon) \equiv \psi(q - \Delta q, t - \epsilon).$$

Since the initial coordinate q_0 and time t_0 of the amplitude are kept fixed in the sequel, they are not shown in the arguments. We assume N to be so large that the

amplitude has had time to develop from the initial state localized at q' to a smooth function of $\psi(q - \Delta q, t - \epsilon)$, smooth compared to the width of the last short-time amplitude, which is of the order $\sqrt{\hbar\epsilon \operatorname{tr}(g_{\mu\nu})/M}$.

From Eq. (11.1) we deduce the recursion relation

$$\psi(q, t) = \sqrt{g(q)} \int \frac{d^D \Delta q}{\sqrt{2\pi i \epsilon \hbar / M}^D} \exp \left[\frac{i}{\hbar} (\mathcal{A}^\epsilon + \mathcal{A}_J^\epsilon) \right] \psi(q - \Delta q, t - \epsilon). \quad (11.2)$$

This is an integral equation

$$\psi(q, t) = \int d^D \Delta q K^\epsilon(q, \Delta q) \psi(q - \Delta q, t - \epsilon), \quad (11.3)$$

with an integral kernel

$$K^\epsilon(q, \Delta q) = \frac{\sqrt{g(q)}}{\sqrt{2\pi i \epsilon \hbar / M}^D} \exp \left[\frac{i}{\hbar} (\mathcal{A}^\epsilon + \mathcal{A}_J^\epsilon) \right]. \quad (11.4)$$

The integral equation (11.3) will now be turned into a Schrödinger equation. This will be done in two ways, a short way which gives direct insight into the relevance of the different terms in the mapping (10.96), and a historic more tedious way, which is useful for comparing our path integral with previous alternative proposals in the literature (cited at the end).

11.1.1 From Recursion Relation to Schrödinger Equation

The evaluation of (11.3) is much easier if we take advantage of the simplicity of the integral kernel $K^\epsilon(q, \Delta q)$ and the measure when expressed in terms of the variables Δx^i . Thus we introduce into (11.3) the integration variables $\Delta \xi^\mu \equiv \Delta x^i e_i^\mu$, with e_i^μ evaluated at the postpoint q . The explicit relation between $\Delta \xi^\mu$ and Δq^μ follows directly from (10.96). In terms of $\Delta \xi^\mu$, we rewrite (11.3) as

$$\psi(q, t) = \int d^D \Delta \xi K_0^\epsilon(q, \Delta \xi) \psi(q - \Delta q(\Delta \xi), t - \epsilon),$$

with the zeroth-order kernel

$$K_0^\epsilon(q, \Delta \xi) = \frac{\sqrt{g(q)}}{\sqrt{2\pi i \epsilon \hbar / M}^D} \exp \left[\frac{i}{\hbar} \frac{M}{2\epsilon} g_{\mu\nu}(q) \Delta \xi^\mu \Delta \xi^\nu \right] \quad (11.5)$$

of unit normalization

$$\int d^D \Delta \xi K_0^\epsilon(q, \Delta \xi) = 1. \quad (11.6)$$

To perform the integrals in (11.2), we expand the wave function as

$$\psi(q - \Delta q, t - \epsilon) = \left(1 - \Delta q^\mu \partial_\mu + \frac{1}{2} \Delta q^\mu \Delta q^\nu \partial_\mu \partial_\nu + \dots \right) \psi(q, t - \epsilon), \quad (11.7)$$

and the coordinate differences Δq^μ in powers of $\Delta\xi$ by inverting Eq. (10.96):

$$\Delta q^\lambda = \left[\Delta\xi^\lambda + \frac{1}{2!} \Gamma_{\mu\nu}{}^\lambda \Delta\xi^\mu \Delta\xi^\nu - \frac{1}{3!} (\partial_\sigma \Gamma_{\mu\nu}{}^\lambda - \Gamma_{\mu\nu}{}^\tau \Gamma_{\{\sigma\tau\}^\lambda}) \Delta\xi^\mu \Delta\xi^\nu \Delta\xi^\sigma + \dots \right]. \quad (11.8)$$

All affine connections are evaluated at the postpoint q . Including in (11.2) only the relevant expansion terms, we find the integral equation

$$\begin{aligned} \psi(q, t) &= \int d^D \Delta\xi K_0^\epsilon(q, \Delta\xi) \\ &\times \left[1 - \left(\Delta\xi^\mu + \frac{1}{2!} \Gamma_{\nu\lambda}{}^\mu \Delta\xi^\nu \Delta\xi^\lambda \right) \partial_\mu + \frac{1}{2} \Delta\xi^\mu \Delta\xi^\nu \partial_\mu \partial_\nu + \dots \right] \psi(q, t - \epsilon). \end{aligned} \quad (11.9)$$

The evaluation requires only the normalization integral (11.6) and the two-point correlation function

$$\langle \Delta\xi^\mu \Delta\xi^\nu \rangle = \int d^D \Delta\xi K_0^\epsilon(q, \Delta\xi) \Delta\xi^\mu \Delta\xi^\nu = \frac{i\hbar\epsilon}{M} g^{\mu\nu}(q). \quad (11.10)$$

The result is

$$\psi(q, t) = \left[1 + i\epsilon \frac{\hbar^2}{2M} (g^{\mu\nu} \partial_\mu \partial_\nu - \Gamma_{\nu}{}^{\nu\mu} \partial_\mu) + \dots \right] \psi(q, t - \epsilon). \quad (11.11)$$

The differential operator in parentheses is proportional to the covariant Laplacian of the field $\psi(q, t - \epsilon)$:

$$D_\mu D^\mu \psi \equiv g^{\mu\nu} D_\mu D_\nu \psi = g^{\mu\nu} D_\mu \partial_\nu \psi = (g^{\mu\nu} \partial_\mu \partial_\nu - \Gamma_{\nu}{}^{\nu\mu} \partial_\mu) \psi. \quad (11.12)$$

In a space with no torsion, this is equal to the Laplace-Beltrami operator applied to the field ψ :

$$\Delta \psi = \frac{1}{\sqrt{g}} \partial_\mu \sqrt{g} g^{\mu\nu} \partial_\nu \psi. \quad (11.13)$$

In a more general space, the relation between the two operators is obtained by working out the derivatives

$$\Delta = g^{\mu\nu} \partial_\mu \partial_\nu + \left(\frac{1}{\sqrt{g}} \partial_\mu \sqrt{g} \right) g^{\mu\nu} \partial_\nu + (\partial_\mu g^{\mu\nu}) \partial_\nu. \quad (11.14)$$

Using

$$\begin{aligned} \left(\frac{1}{\sqrt{g}} \partial_\mu \sqrt{g} \right) &= \frac{1}{2} g^{\sigma\tau} \partial_\mu g_{\sigma\tau} = \bar{\Gamma}_{\mu\nu}{}^\nu, \\ \partial_\mu g^{\sigma\nu} &= -g^{\sigma\lambda} g^{\nu\kappa} \partial_\mu g_{\lambda\kappa}, \\ \partial_\mu g^{\mu\nu} &= -\bar{\Gamma}_\mu{}^{\mu\nu} - \bar{\Gamma}^\nu{}_\mu{}^\mu, \end{aligned} \quad (11.15)$$

we see that

$$\frac{1}{\sqrt{g}}(\partial_\mu g^{\mu\nu} \sqrt{g}) = -\bar{\Gamma}_\mu{}^{\mu\nu}, \quad (11.16)$$

and hence

$$\Delta\psi = (g^{\mu\nu} \partial_\mu \partial_\nu - \bar{\Gamma}_\mu{}^{\mu\nu} \partial_\nu)\psi = \bar{D}_\mu \bar{D}^\mu \psi. \quad (11.17)$$

Thus, the relation between the Laplacian and the Laplace-Beltrami operator is given by

$$D_\mu D^\mu \psi = (\bar{D}_\mu \bar{D}^\mu - K_\mu{}^{\mu\nu} \partial_\nu)\psi = (\bar{D}_\mu \bar{D}^\mu - 2S^\nu \partial_\nu)\psi, \quad (11.18)$$

where \bar{D}_μ denotes the covariant derivative formed with the Riemannian affine connection, the Christoffel symbol $\bar{\Gamma}_{\mu\nu}{}^\lambda$, and S_μ is the contracted torsion

$$S_\mu \equiv S_{\mu\nu}{}^\nu. \quad (11.19)$$

As a result, the amplitude $\psi(q, t)$ in (11.2) satisfies the equation

$$\psi(q, t) = \left(1 + \frac{i\epsilon\hbar}{2M} D_\mu D^\mu\right) \psi(q, t - \epsilon) + \mathcal{O}(\epsilon^2). \quad (11.20)$$

In the limit $\epsilon \rightarrow 0$, this leads to the Schrödinger equation

$$i\hbar \partial_t \psi(q, t) = \hat{H}_0 \psi(q, t), \quad (11.21)$$

where \hat{H}_0 is the free-particle Schrödinger operator

$$\hat{H}_0 = -\frac{\hbar^2}{2M} D_\mu D^\mu. \quad (11.22)$$

It is the naively expected generalization of the flat-space operator

$$\hat{H}_0 = -\frac{\hbar^2}{2M} \partial_i^2, \quad (11.23)$$

from which (11.22) arises by transforming the derivatives with respect to Cartesian coordinates ∂_i to the general coordinate derivatives ∂_μ via the nonholonomic transformation

$$\partial_i = e_i{}^\mu \partial_\mu. \quad (11.24)$$

The result is

$$\partial_i^2 = e_i{}^\mu \partial_\mu e^{i\nu} \partial_\nu = g^{\mu\nu} \partial_\mu \partial_\nu - \Gamma_\mu{}^{\mu\nu} \partial_\nu, \quad (11.25)$$

which coincides with the Laplacian $D_\mu D^\mu$ when applied to a scalar field. Note that the operator (11.22) contains no extra term proportional to the scalar curvature R allowed by other theories.

11.1.2 Alternative Evaluation

For completeness, we also present an alternative evaluation of the q -integrals in Eq. (11.3) which is more tedious but facilitates comparison with previous work. First, the postpoint action \mathcal{A}^ϵ is conveniently split into the leading term

$$\mathcal{A}_0^\epsilon = \frac{M}{2\epsilon} g_{\mu\nu}(q) \Delta q^\mu \Delta q^\nu \quad (11.26)$$

and a remainder

$$\Delta \mathcal{A}^\epsilon \equiv \mathcal{A}^\epsilon - \mathcal{A}_0^\epsilon. \quad (11.27)$$

Correspondingly, we introduce as in (11.5) the zeroth-order kernel

$$K_0^\epsilon(q, \Delta q) = \frac{\sqrt{g(q)}}{\sqrt{2\pi i \epsilon \hbar / M}^D} \exp\left(\frac{i}{\hbar} \mathcal{A}_0^\epsilon\right), \quad (11.28)$$

with the unit normalization

$$\int d^D \Delta q K_0^\epsilon(q, \Delta q) = 1, \quad (11.29)$$

and expand $K^\epsilon(q, \Delta q)$ around $K_0^\epsilon(q, \Delta q)$ with a series of correction terms of higher order in Δq :

$$K^\epsilon(q, \Delta q) = K_0^\epsilon(q, \Delta q) [1 + C(\Delta q)] \equiv K_0^\epsilon(q, \Delta q) \left[1 + \sum_{n=1}^{\infty} c_n(\Delta q)^n\right]. \quad (11.30)$$

Under the smoothness assumptions above, the wave function $\psi(q - \Delta q, t - \epsilon)$ can be expanded into a Taylor series around the endpoint q , so that the integral equation (11.2) reads

$$\begin{aligned} \psi(q, t) &= \int d^D \Delta q K_0^\epsilon(q, \Delta q) \left[1 + \sum_{n=1}^{\infty} c_n(\Delta q)^n\right] \\ &\quad \times \left(1 - \Delta q^\mu \partial_\mu + \frac{1}{2} \Delta q^\mu \Delta q^\nu \partial_\mu \partial_\nu + \dots\right) \psi(q, t - \epsilon). \end{aligned} \quad (11.31)$$

Due to the normalization property (11.6), the leading term simply reproduces $\psi(q, t - \epsilon)$. To calculate the correction terms $c_n(\Delta q)$, we expand

$$C(\Delta q) = \exp\left[\frac{i}{\hbar} (\Delta \mathcal{A}^\epsilon + \mathcal{A}_J^\epsilon)\right] - 1 \quad (11.32)$$

in powers of Δq^μ . After inserting here $\Delta \mathcal{A}^\epsilon$ from (11.27) with \mathcal{A}_0^ϵ from (11.26), we expand \mathcal{A}^ϵ as in (10.107) [recalling (10.121)]. By separating the expansion for C into even and odd powers of Δq ,

$$C = C^e + C^o, \quad (11.33)$$

we find for the odd terms

$$C^o = -\Gamma_{\{\mu\nu\}}{}^\nu \Delta q^\mu - \frac{i}{\hbar} \frac{M}{2\epsilon} \Gamma_{\mu\nu\lambda} \Delta q^\mu \Delta q^\nu \Delta q^\lambda + \dots, \quad (11.34)$$

and the even terms

$$C^e = \sum_{a=1}^4 C_a^e + \dots, \quad (11.35)$$

with

$$\begin{aligned} C_1^e &= \frac{1}{2} [\partial_{\{\mu} \Gamma_{\nu\lambda\}}{}^\lambda + \Gamma_{\{\nu\kappa}{}^\sigma \Gamma_{\{\sigma|\mu\}}{}^\kappa + \Gamma_{\{\mu\sigma\}}{}^\sigma \Gamma_{\{\nu\lambda\}}{}^\lambda - \Gamma_{\{\nu\kappa\}}{}^\sigma \Gamma_{\{\mu\sigma\}}{}^\kappa] \Delta q^\mu \Delta q^\nu, \\ C_2^e &= \frac{iM}{2\hbar\epsilon} \Gamma_{\{\mu\nu\}}{}^\nu \Gamma_{\sigma\lambda\kappa} \Delta q^\mu \Delta q^\sigma \Delta q^\lambda \Delta q^\kappa, \\ C_3^e &= \frac{iM}{2\hbar\epsilon} \left[\frac{1}{3} g_{\kappa\tau} (\partial_\lambda \Gamma_{\mu\nu}{}^\tau + \Gamma_{\mu\nu}{}^\sigma \Gamma_{\{\lambda\sigma\}}{}^\tau) + \frac{1}{4} \Gamma_{\mu\nu}{}^\sigma \Gamma_{\lambda\kappa\sigma} \right] \Delta q^\mu \Delta q^\nu \Delta q^\lambda \Delta q^\kappa, \\ C_4^e &= -\frac{1}{2} \frac{M^2}{4\hbar^2 \epsilon^2} \Gamma_{\mu\nu\lambda} \Gamma_{\sigma\tau\kappa} \Delta q^\mu \Delta q^\nu \Delta q^\lambda \Delta q^\sigma \Delta q^\tau \Delta q^\kappa. \end{aligned} \quad (11.36)$$

The dots denote terms of higher order in Δq^μ which do not contribute to the limit $\epsilon \rightarrow 0$.

The evaluation now proceeds perturbatively and requires the harmonic expectation values

$$\langle \mathcal{O}(\Delta q) \rangle_0 \equiv \int d^D \Delta q K_0^\epsilon(q, \Delta q) \mathcal{O}(\Delta q). \quad (11.37)$$

The relevant correlation functions are

$$\langle \Delta q^\mu \Delta q^\nu \rangle_0 = \frac{i\hbar\epsilon}{M} g^{\mu\nu}, \quad (11.38)$$

$$\langle \Delta q^\mu \Delta q^\nu \Delta q^\lambda \Delta q^\kappa \rangle_0 = \left(\frac{i\hbar\epsilon}{M} \right)^2 g^{\mu\nu\lambda\kappa}, \quad (11.39)$$

$$\langle \Delta q^\mu \Delta q^\nu \Delta q^\lambda \Delta q^\kappa \Delta q^\sigma \Delta q^\tau \rangle_0 = \left(\frac{i\hbar\epsilon}{M} \right)^3 g^{\mu\nu\lambda\kappa\sigma\tau}. \quad (11.40)$$

The tensor $g^{\mu\nu\lambda\kappa}$ in the second expectation (11.39) collects three Wick contractions [recall (3.305)] and reads

$$g^{\mu\nu\lambda\kappa} \equiv g^{\mu\nu} g^{\lambda\kappa} + g^{\mu\lambda} g^{\nu\kappa} + g^{\mu\kappa} g^{\nu\lambda}. \quad (11.41)$$

The tensor $g^{\mu\nu\lambda\kappa\sigma\tau}$ in the third expectation (11.40) collecting 15 Wick contractions is obtained recursively following the rule (3.306) by expanding

$$g^{\mu\nu\lambda\kappa\sigma\tau} = g^{\mu\nu} g^{\lambda\kappa\sigma\tau} + g^{\mu\lambda} g^{\nu\kappa\sigma\tau} + g^{\mu\kappa} g^{\nu\lambda\sigma\tau} + g^{\mu\sigma} g^{\nu\lambda\kappa\tau} + g^{\mu\tau} g^{\nu\lambda\kappa\sigma}. \quad (11.42)$$

A product of $2n$ factors Δq results in $(2n - 1)!!$ pair contractions.

Let us collect all contributions in (11.31) relevant to order ϵ . Obviously, the highest derivative term of $\psi(q, t - \epsilon)$ is $\frac{1}{2}\Delta q^\mu \Delta q^\nu \partial_\mu \partial_\nu \psi(q, t - \epsilon)$. It receives only a leading contribution from $K_0^\epsilon(q, \Delta q)$,

$$i\epsilon \frac{\hbar^2}{2M} g^{\mu\nu}(q) \partial_\mu \partial_\nu \psi(q, t - \epsilon), \tag{11.43}$$

with no more corrections from $C(\Delta q)$. The term with one derivative ∂_μ on $\psi(q, t - \epsilon)$ in (11.31) becomes

$$A^\mu \partial_\mu \psi(q, t - \epsilon), \tag{11.44}$$

where A^μ is the expectation involving the odd correction terms

$$A^\mu = -\langle C^\circ \Delta q^\mu \rangle_0. \tag{11.45}$$

Using the rules (11.38) and (11.39), we find

$$\begin{aligned} A^\mu &= \left\langle \left(\Gamma_{\{\lambda\nu\}}{}^\nu \Delta q^\lambda + \frac{iM}{2\hbar\epsilon} \Gamma_{\sigma\tau\lambda} \Delta q^\sigma \Delta q^\tau \Delta q^\lambda \right) \Delta q^\mu + \dots \right\rangle_0 \\ &= i\epsilon \frac{\hbar}{M} \left[\Gamma^{\{\mu\nu\}}{}_\nu - \frac{1}{2} (\Gamma^{\mu\nu}{}_\nu + \Gamma^{\nu\mu}{}_\nu + \Gamma_\nu{}^{\nu\mu}) \right] + \dots \\ &= -i\epsilon \frac{\hbar}{2M} \Gamma_\nu{}^{\nu\mu} + \dots \end{aligned} \tag{11.46}$$

In combination with (11.43), this produces the Laplacian $D_\mu D^\mu$ of the field $\psi(q, t - \epsilon)$ as in Eq. (11.11).

We now turn to the remaining contributions in (11.31) which contain no more derivatives of $\psi(q, t - \epsilon)$. They are all due to the expectation value $\langle C^e \rangle_0$ of the even correction terms. Let us define

$$V_{\text{eff}} \equiv \frac{i\hbar}{\epsilon} \langle C \rangle_0 = \frac{i\hbar}{\epsilon} \langle C^e \rangle_0, \tag{11.47}$$

to be called the effective potential caused by the correction terms $\langle C \rangle_0$ of (11.32). Using the expectation values (11.38)–(11.40) we find

$$V_{\text{eff}} = \frac{\hbar^2}{M} v \equiv \frac{\hbar^2}{M} \sum_{A,B} v_A{}^B, \tag{11.48}$$

where the sum runs over the six terms

$$\begin{aligned} v_2^1 &= -\frac{1}{2} (\Gamma_{\{\mu\sigma\}}{}^\sigma \Gamma_{\{\nu\lambda\}}{}^\lambda - \Gamma_{\{\nu\kappa\}}{}^\sigma \Gamma_{\{\mu\sigma\}}{}^\kappa) g^{\mu\nu}, \\ v_2^2 &= \frac{1}{8} \Gamma_{\{\mu\nu\}}{}^\tau \Gamma_{\lambda\sigma\tau} g^{\mu\nu\sigma\lambda}, \\ v_2^3 &= \frac{1}{2} \Gamma_{\{\mu\kappa\}}{}^\kappa \Gamma_{\nu\tau\lambda} g^{\mu\nu\tau\lambda}, \\ v_2^4 &= -\frac{1}{8} \Gamma_{\mu\nu\lambda} \Gamma_{\sigma\tau\kappa} g^{\mu\nu\lambda\sigma\tau\kappa}, \\ v_3^1 &= -\frac{1}{2} (\partial_{\{\mu} \Gamma_{\nu\lambda\}}{}^\lambda + \Gamma_{\{\nu\kappa\}}{}^\sigma \Gamma_{\{\sigma|\mu\}}{}^\kappa) g^{\mu\nu}, \\ v_3^2 &= \frac{1}{6} g_{\mu\tau} (\partial_\kappa \Gamma_{\lambda\nu}{}^\tau + \Gamma_{\lambda\nu}{}^\sigma \Gamma_{\{\kappa\sigma\}}{}^\tau) g^{\mu\nu\lambda\kappa}. \end{aligned} \tag{11.49}$$

The subscripts 2 and 3 distinguish contributions coming from the quadratic and the cubic terms in the expansion (10.96) of Δx^i . By inserting on the right-hand sides the explicit expansions (11.42) and (11.41), we find after some algebra that the sum of all v_A^B -terms is zero. In fact, the v_2^B - and v_3^B -terms disappear separately. A simple structural reason for this is given in Appendix 11A.

Explicitly, the cancellation is rather obvious for v_3^B after inserting (11.41). For v_2^B , the proof requires more work which is relegated to Appendix 11A.

Note that in a space without curvature and torsion, the above manipulations are equivalent to a direct transformation of the flat-space integral equation

$$\begin{aligned} \psi(\mathbf{x}, t) &= \int \frac{d^D \Delta x}{\sqrt{2\pi i \epsilon \hbar / M}^D} \exp \left[i \epsilon \frac{M}{2} (\Delta x^i)^2 \right] \\ &\times (1 - \Delta x^i \partial_{x^i} + \frac{1}{2} \Delta x^i \Delta x^j \partial_{x^i} \partial_{x^j} + \dots) \psi(\mathbf{x}, t - \epsilon) \\ &= \left[1 + \frac{i \epsilon \hbar}{2M} \partial_i^2 + \mathcal{O}(\epsilon^2) \right] \psi(\mathbf{x}, t - \epsilon), \end{aligned} \quad (11.50)$$

to the variable Δq by a coordinate transformation. In a general metric-affine space, the wave function $\psi(q, t)$ has no counter image in x -space so that (11.50) cannot be used as a starting point for a nonholonomic transformation.

11.2 Equivalent Path Integral Representations

From the derivation of the Schrödinger equation in Subsection 11.1.1 we learn an important lesson. When deriving the transformation law (10.96) between the finite coordinate differences Δx^i and Δq^μ by evaluating the integral equation (10.60) along the autoparallel, the cubic terms in Δq , which make the action and measure lengthy, can be dropped altogether. A completely equivalent path integral representation of the time evolution amplitude is obtained by transforming the flat-space path integral (10.89) into the general metric-affine one (10.146) with the help of the shortened transformation

$$\Delta x^i = e^i{}_\lambda \left(\Delta q^\lambda - \frac{1}{2!} \Gamma_{\mu\nu}{}^\lambda \Delta q^\mu \Delta q^\nu \right). \quad (11.51)$$

This has the simple Jacobian

$$J = \frac{\partial(\Delta x)}{\partial(\Delta q)} = \det(e^i{}_\kappa) \det(\delta^\kappa{}_\mu - e_i{}^\kappa e^i{}_{\{\mu,\nu\}} \Delta q^\nu), \quad (11.52)$$

whose effective action reads

$$\frac{i}{\hbar} \mathcal{A}_J^\epsilon = -e_i{}^\kappa e^i{}_{\kappa,\nu} \Delta q^\nu - \frac{1}{2} e_i{}^\mu e^i{}_{\{\kappa,\nu\}} e_j{}^\kappa e^j{}_{\{\mu,\lambda\}} \Delta q^\nu \Delta q^\lambda + \dots \quad (11.53)$$

With the help of (10.16), this is expressed in terms of the connection yielding

$$\frac{i}{\hbar} \mathcal{A}_J^\epsilon = -\Gamma_{\{\nu\mu\}}{}^\mu \Delta q^\nu - \frac{1}{2} \Gamma_{\{\nu\kappa\}}{}^\sigma \Gamma_{\{\mu,\sigma\}}{}^\kappa \Delta q^\nu \Delta q^\mu + \dots \quad (11.54)$$

The mapping (11.51) has, however, an unattractive feature: The short-time action following from (11.51)

$$\mathcal{A}^\epsilon = \frac{M}{2\epsilon}(\Delta x^i)^2 = \frac{M}{2\epsilon} \left(g_{\mu\nu} \Delta q^\mu \Delta q^\nu - \Gamma_{\mu\nu\lambda} \Delta q^\mu \Delta q^\nu \Delta q^\lambda + \frac{1}{4} \Gamma_{\lambda\kappa}{}^\sigma \Gamma_{\mu\nu\sigma} \Delta q^\mu \Delta q^\nu \Delta q^\lambda \Delta q^\kappa + \dots \right) \tag{11.55}$$

is no longer equal to the classical action (10.107) [recall the convention (10.121)] evaluated along the autoparallel.

This was also a feature of another mapping which is the most convenient for calculations. Instead of deriving the relation between Δx^i and Δq^μ by evaluating (10.60) along the autoparallel, one may assume, for the moment, the absence of curvature and torsion and expand $\Delta x^i = x^i(q) - x^i(q - \Delta q)$ in powers of Δq :

$$\Delta x^i = e^i{}_\mu \Delta q^\mu - \frac{1}{2} e^i{}_{\mu,\nu} \Delta q^\mu \Delta q^\nu + \frac{1}{3!} e^i{}_{\mu,\nu\lambda} \Delta q^\mu \Delta q^\nu \Delta q^\lambda + \dots \tag{11.56}$$

After this, curvature and torsion are introduced by allowing the functions $x(q)$ and $\partial_\mu x(q)$ to be nonintegrable in the sense of the Schwartz criterion, i.e., the second derivatives of $x(q)$ and $e^i{}_\mu(q)$ need not commute with each other [implying that the right-hand side of (11.56) can no longer be written as $x^i(q) - x^i(q - \Delta q)$]. The expansion (11.56) is then a *definition* of the transformation from Δx^i to Δq^μ . Using the identities (10.16), (10.131), and (10.132), the transformation (11.56) turns into

$$\Delta x^i = e^i{}_\lambda \left[\Delta q^\lambda - \frac{1}{2!} \Gamma_{\mu\nu}{}^\lambda \Delta q^\mu \Delta q^\nu + \frac{1}{3!} (\partial_\sigma \Gamma_{\mu\nu}{}^\lambda + \Gamma_{\mu\nu}{}^\tau \Gamma_{\sigma\tau}{}^\lambda) \Delta q^\mu \Delta q^\nu \Delta q^\sigma + \dots \right]. \tag{11.57}$$

This differs from the correct one (10.96) by the third-order term

$$\Delta' x^i = \frac{1}{3!} e^i{}_{[\tau,\sigma]} e_k{}^\tau e^k{}_{\nu,\mu} \Delta q^\mu \Delta q^\nu \Delta q^\sigma = \frac{1}{3!} e^i{}_\lambda S_{\sigma\tau}{}^\lambda \Gamma_{\mu\nu}{}^\tau \Delta q^\mu \Delta q^\nu \Delta q^\sigma, \tag{11.58}$$

which vanishes if the q -space has no torsion. The Jacobian associated with (11.56) is

$$J = \frac{\partial(\Delta x)}{\partial(\Delta q)} = \det(e^i{}_\kappa) \det \left(\delta^\kappa{}_\mu - e_i{}^\kappa e^i{}_{\{\mu,\nu\}} \Delta q^\nu + \frac{1}{2} e_i{}^\kappa e^i{}_{\{\mu,\nu\lambda\}} \Delta q^\nu \Delta q^\lambda + \dots \right), \tag{11.59}$$

and corresponds to the effective action

$$\frac{i}{\hbar} \mathcal{A}_J^\epsilon = - e_i{}^\kappa e^i{}_{\kappa,\nu} \Delta q^\nu + \frac{1}{2} [e_i{}^\mu e^i{}_{\{\mu,\nu\lambda\}} - e_i{}^\mu e^i{}_{\{\kappa,\nu\}} e_j{}^\kappa e^j{}_{\{\mu,\lambda\}}] \Delta q^\nu \Delta q^\lambda + \dots \tag{11.60}$$

With (10.16), (10.131), and (10.132), this becomes

$$\frac{i}{\hbar} \mathcal{A}_J^\epsilon = - \Gamma_{\{\nu\mu\}}{}^\mu \Delta q^\nu + \frac{1}{2} (\partial_{\{\mu\}} \Gamma_{\nu,\kappa}{}^\kappa + \Gamma_{\{\nu,\kappa}{}^\sigma \Gamma_{\mu\},\sigma}{}^\kappa - \Gamma_{\{\nu\kappa\}}{}^\sigma \Gamma_{\{\mu,\sigma\}}{}^\kappa) \Delta q^\nu \Delta q^\mu + \dots, \tag{11.61}$$

which differs from the proper Jacobian action (10.145) only by one index symmetrization.

To find the short-time action following from the mapping (11.56), we form

$$\begin{aligned} \mathcal{A}^\epsilon = \frac{M}{2\epsilon} (\Delta x^i)^2 = \frac{M}{2\epsilon} & \left[g_{\mu\nu} \Delta q^\mu \Delta q^\nu - e^i{}_\mu e^i{}_{\nu,\lambda} \Delta q^\mu \Delta q^\nu \Delta q^\lambda \right. \\ & \left. + \left(\frac{1}{3} e^i{}_\mu e^i{}_{\nu,\lambda\kappa} + \frac{1}{4} e^i{}_{\mu,\nu} e^i{}_{\lambda,\kappa} \right) \Delta q^\mu \Delta q^\nu \Delta q^\lambda \Delta q^\kappa + \dots \right], \end{aligned} \quad (11.62)$$

and use the identities (10.16), (10.131), and (10.132) to obtain

$$\begin{aligned} \mathcal{A}^\epsilon = \frac{M}{2\epsilon} & \left\{ g_{\mu\nu} \Delta q^\mu \Delta q^\nu - \Gamma_{\mu\nu\lambda} \Delta q^\mu \Delta q^\nu \Delta q^\lambda \right. \\ & \left. + \left[\frac{1}{3} g_{\mu\tau} (\partial_\kappa \Gamma_{\lambda\nu}{}^\tau + \Gamma_{\lambda\nu}{}^\delta \Gamma_{\kappa\delta}{}^\tau) + \frac{1}{4} \Gamma_{\lambda\kappa}{}^\sigma \Gamma_{\mu\nu\sigma} \right] \Delta q^\mu \Delta q^\nu \Delta q^\lambda \Delta q^\kappa + \dots \right\}. \end{aligned} \quad (11.63)$$

This differs from the proper short-time action (10.107) [recall the convention (10.107)] only by the absence of the symmetrization in the indices κ and δ in the fourth term, the difference vanishing if the q -space has no torsion.

The equivalent path integral representation in which (11.2) contains the short-time action (11.63) and the Jacobian action (11.61) will be useful in Chapter 13 when solving the path integral of the Coulomb system.

The equivalence of different time-sliced path integral representations manifests itself in certain moment properties of the integral kernel (11.4). The derivations of the Schrödinger equation in Subsections. 11.1.1 and 11.1.2 have made use only of the following three moment properties of the kernel:

$$\int d^D \Delta q K^\epsilon(q, \Delta q) = 1 + \dots, \quad (11.64)$$

$$\int d^D \Delta q K^\epsilon(q, \Delta q) \Delta q^\nu = -i\epsilon \frac{\hbar}{2M} \Gamma_\mu{}^{\mu\nu} + \dots, \quad (11.65)$$

$$\int d^D \Delta q K^\epsilon(q, \Delta q) \Delta q^\mu \Delta q^\nu = i\epsilon \frac{\hbar}{M} g^{\mu\nu} + \dots, \quad (11.66)$$

evaluated at fixed postpoint q . The omitted terms indicated by the dots and all higher moments contribute to higher orders in ϵ which are irrelevant for the derivation of the differential equation obeyed by the amplitude. Any kernel $K^\epsilon(q, \Delta q)$ with these properties leads to the same Schrödinger equation. If a kernel is written as

$$K^\epsilon(q, \Delta q) = K_0^\epsilon(q, \Delta q) [1 + C(\Delta q)], \quad (11.67)$$

where $K_0^\epsilon(q, \Delta q)$ is the free-particle postpoint kernel

$$K_0^\epsilon(q, \Delta q) = \frac{\sqrt{g(q)}}{\sqrt{2\pi i\epsilon\hbar/M}^D} \exp \left[\frac{i}{\hbar} g_{\mu\nu}(q) \Delta q^\mu \Delta q^\nu \right], \quad (11.68)$$

the moment properties (11.64)–(11.66) are equivalent to

$$\langle C \rangle_0 = 0 + \dots, \tag{11.69}$$

$$\langle C \Delta q^\mu \rangle_0 = i\epsilon \frac{\hbar}{2M} \Gamma_{\mu}^{\mu\nu} + \dots, \tag{11.70}$$

where the expectation values are taken with respect to the kernel $K_0^\epsilon(q, \Delta q)$, the dots on the right-hand side indicating terms of the order ϵ^2 . Note that the third of the three moment properties is trivially true since it receives only a contribution from the leading part of the kernel $K^\epsilon(q, \Delta q)$, i.e., from $K_0^\epsilon(q, \Delta q)$. The verification of the other two requires some work, in particular the first, which is the normalization condition.

Two kernels $K_1^\epsilon, K_2^\epsilon$ are equivalent if their correction terms C_1, C_2 have expectations which are small of the order ϵ^2 :

$$\langle C_1 \rangle_0 = \langle C_2 \rangle_0 = \mathcal{O}(\epsilon^2), \tag{11.71}$$

$$\langle (C_1 - C_2) \Delta q^\mu \rangle_0 = \mathcal{O}(\epsilon^2). \tag{11.72}$$

These are necessary and sufficient conditions for the equivalence. Many possible correction terms C lead to the same moment integrals. All of them are physically equivalent, being associated with the same Schrödinger equation. The simplest possibilities are

$$K^\epsilon(q, \Delta q) = K_0^\epsilon(q, \Delta q) \left[1 + \frac{1}{2} \Gamma_{\mu}^{\mu\nu} \Delta q^\nu \right], \tag{11.73}$$

or

$$K^\epsilon(q, \Delta q) = K_0^\epsilon(q, \Delta q) \left[1 - \frac{i}{D + 2} \frac{M}{2\hbar\epsilon} \Gamma_{\mu}^{\mu\nu} \Delta q^\nu g_{\lambda\kappa} \Delta q^\lambda \Delta q^\kappa \right], \tag{11.74}$$

where D is the space dimension. The zero-order kernel satisfies automatically the first and third moment condition, (11.64) and (11.66), while the additional term enforces precisely the second condition, (11.65), without changing the others. The equivalent kernels can also be considered as the result of working with Jacobian actions

$$\frac{i}{\hbar} \mathcal{A}_J^\epsilon = \frac{1}{2} \Gamma_{\mu}^{\mu\nu} \Delta q^\nu - \frac{1}{8} (\Gamma_{\mu}^{\mu\nu} \Delta q^\nu)^2, \tag{11.75}$$

$$\frac{i}{\hbar} \mathcal{A}_J^\epsilon = -\frac{i}{D + 2} \frac{M}{2\hbar\epsilon} \Gamma_{\mu}^{\mu\nu} \Delta q^\nu g_{\lambda\kappa} \Delta q^\lambda \Delta q^\kappa, \tag{11.76}$$

instead of the original one (10.145). Indeed, the second term in (11.75) can further be reduced by perturbation theory to

$$\begin{aligned} -\frac{1}{8} (\Gamma_{\mu}^{\mu\nu} \Delta q^\nu)^2 &\rightarrow -\frac{1}{8} \Gamma_{\mu}^{\mu\nu} \Gamma_{\lambda}^{\lambda\kappa} \langle \Delta q^\nu \Delta q^\kappa \rangle_0 \\ &= -i\epsilon \frac{\hbar}{8M} (\Gamma_{\mu}^{\mu\nu})^2, \end{aligned} \tag{11.77}$$

yielding an alternative and most useful form for the Jacobian action

$$\frac{i}{\hbar} \mathcal{A}_J^\epsilon = \frac{1}{2} \Gamma_{\mu}{}^{\mu}{}_{\nu} \Delta q^\nu - i\epsilon \frac{\hbar}{8M} (\Gamma_{\mu}{}^{\mu}{}_{\nu})^2. \quad (11.78)$$

Remarkably, this expression involves only the connection contracted in the first two indices:

$$\Gamma_{\mu}{}^{\mu\nu} = g^{\mu\lambda} \Gamma_{\mu\lambda}{}^{\nu}. \quad (11.79)$$

11.3 Potentials and Vector Potentials

It is straightforward to find the effect of external potentials and vector potentials upon the Schrödinger equation. For this, we merely observe that the time-sliced potential term

$$\mathcal{A}_{\text{pot}}^\epsilon = \frac{e}{c} A_\mu \Delta q^\mu - \frac{e}{2c} \partial_\nu A_\mu \Delta q^\mu \Delta q^\nu - \epsilon V(q) + \dots \quad (11.80)$$

derived in Eq. (10.182) appears in the kernel $K^\epsilon(q, \Delta q)$ via a factor $e^{i\mathcal{A}_{\text{pot}}^\epsilon/\hbar}$. This factor can be combined with the postpoint expansion of the wave function in the integral equation (11.31), which becomes

$$\begin{aligned} \psi(q, t) &= \int d^D \Delta q K_0^\epsilon(q, \Delta q) [1 + C(\Delta q)] \\ &\quad \times e^{i\mathcal{A}_{\text{pot}}^\epsilon/\hbar} \left(1 - \Delta q^\mu \partial_\mu + \frac{1}{2} \Delta q^\mu \Delta q^\nu \partial_\mu \partial_\nu \right) \psi(q, t - \epsilon) + \dots \\ &= \int d^D \Delta q K_0^\epsilon(q, \Delta q) [1 + C(\Delta q)] \left[1 - \Delta q^\mu \left(\partial_\mu - i \frac{e}{\hbar c} A_\mu \right) \right. \\ &\quad \left. + \frac{1}{2} \Delta q^\mu \Delta q^\nu \left(\partial_\mu - i \frac{e}{\hbar c} A_\mu \right) \left(\partial_\nu - i \frac{e}{\hbar c} A_\nu \right) - i\epsilon V(q) \right] \psi(q, t - \epsilon) + \dots \end{aligned} \quad (11.81)$$

By going through the steps of Subsection 11.1.1 or 11.1.2, we obtain the same Schrödinger equation as in (11.21),

$$i\hbar \partial_t \psi(q, t) = \hat{H} \psi(q, t). \quad (11.82)$$

The Hamiltonian operator \hat{H} differs from the free operator \hat{H}_0 of (11.22),

$$\hat{H}_0 = -\frac{\hbar^2}{2M} D_\mu D^\mu, \quad (11.83)$$

in two ways. First, a potential energy $V(q)$ is added. Second, the covariant derivatives D_μ are replaced by

$$D_\mu^A \equiv D_\mu - i \frac{e}{\hbar c} A_\mu. \quad (11.84)$$

This is the Schrödinger version of the minimal substitution in Eq. (2.644).

The minimal substitution extends the covariance of D_μ with respect to coordinate changes to a covariance with respect to gauge transformations of the vector potential A_μ . The subtraction of iA_μ/\hbar on the right-hand side of (11.84) reflects the fact that $P_\mu = p_\mu - A_\mu$ rather than p^μ is the gauge-invariant physical momentum of a particle in the presence of an electromagnetic field. Only the use of P_μ guarantees the gauge invariance of the electromagnetic interaction, just as in the flat-space action (2.643).

Let us briefly verify that the Schrödinger equation (11.82) with the covariant derivative (11.84) is invariant under gauge transformations. If the amplitude is multiplied by a space-dependent phase

$$\psi(q) \rightarrow e^{-i(e/\hbar c)\Lambda(q)}\psi(q), \quad (11.85)$$

the covariant derivative (11.84) is multiplied by precisely the same phase:

$$D_\mu\psi(q) \rightarrow e^{-i(e/\hbar c)\Lambda(q)}D_\mu\psi(q), \quad (11.86)$$

if the vector potential is gauge transformed as follows:

$$A_\mu \rightarrow A_\mu + \partial_\mu\Lambda(q). \quad (11.87)$$

Under these joint transformations, the Schrödinger equation (11.82) is multiplied by an overall phase factor $e^{-i\Lambda(q)}$, and thus gauge invariant.

Adding a potential $V(q)$, the Hamilton operator in the Schrödinger equation (11.82) is therefore

$$\hat{H} = -\frac{\hbar^2}{2M}D_\mu^A D^{A\mu} + V(q). \quad (11.88)$$

Observe that the mixed terms containing derivative and vector potential appears in the symmetrized form

$$-\frac{\hbar}{2Mc}(\hat{p}_\mu A^\mu + A^\mu \hat{p}_\mu). \quad (11.89)$$

This corresponds to a symmetric time slicing of the interaction term $\dot{q}^\mu A_\mu$ which was derived in Section 10.5 by using the equation of motion in calculation of the short-time action. Here we see that this time slicing guarantees the gauge invariance of the Schrödinger equation.

Note further that there is no extra R -term in the Schrödinger equation (11.88).

11.4 Unitarity Problem

The appearance of the Laplace operator $D_\mu D^\mu$ in the free-particle Schrödinger equation (11.82) is in conflict with the traditional physical scalar product between two wave functions $\psi_1(q)$ and $\psi_2(q)$:

$$\langle\psi_2|\psi_1\rangle \equiv \int d^Dq\sqrt{g(q)}\psi_2^*(q)\psi_1(q). \quad (11.90)$$

In such a scalar product, only the Laplace-Beltrami operator (11.13),

$$\Delta = \frac{1}{\sqrt{g}} \partial_\mu \sqrt{g} g^{\mu\nu} \partial_\nu, \quad (11.91)$$

is a Hermitian operator, not the Laplacian $D_\mu D^\mu$. The bothersome term is the contracted torsion term

$$(D_\mu D^\mu - \Delta)\psi = -2S^\mu \partial_\mu \psi. \quad (11.92)$$

This term ruins the Hermiticity and thus also the unitarity of the time evolution operator of a particle in a space with curvature and torsion.

For presently known physical systems in spaces with curvature and torsion, the unitarity problem is fortunately absent. Consider first field theories of gravity with torsion. There, the torsion field $S_{\mu\nu}{}^\lambda$ is generated by the spin current density of the fundamental matter fields. The requirement of renormalizability restricts these fields to carry spin 1/2. However, the spin current density of spin-1/2 particles happens to be a completely antisymmetric tensor.¹ This property carries over to the torsion tensor. Hence, the torsion field in the universe satisfies $S^\mu = 0$. This implies that for a particle in a universe with curvature and torsion, the Laplacian always degenerates into the Laplace-Beltrami operator, assuring unitarity after all.

In Chapter 13 we shall witness another way of escaping the unitarity problem. The path integral of the three-dimensional Coulomb system is solved by a multi-valued transformation to a four-dimensional space with torsion where the physical scalar product is

$$\langle \psi_2 | \psi_1 \rangle_{\text{phys}} \equiv \int d^D q \sqrt{g} w(q) \psi_2^*(q) \psi_1(q), \quad (11.93)$$

with some scalar weight function $w(q)$. This scalar product is different from the naive scalar product (11.90). It is, however, reparametrization-invariant, and $w(q)$ makes the Laplacian $D_\mu D^\mu$ a Hermitian operator.

The characteristic property of torsion in the transformed Coulomb system is that $S_\mu(q) = S_{\mu\nu}{}^\nu$ can be written as a gradient of a scalar function: $S_\mu(q) = \partial_\mu \sigma(q)$ [see Eq. (13.143)]. Such torsion fields admit a Hermitian Laplace operator of a scalar field in a scalar product (11.93) with the weight

$$w(q) = e^{-2\sigma(q)}. \quad (11.94)$$

Thus, the physical scalar product can be expressed in terms of the naive one as follows:

$$\langle \psi_2 | \psi_1 \rangle_{\text{phys}} \equiv \int d^D q \sqrt{g(q)} e^{-2\sigma(q)} \psi_2^*(q) \psi_1(q). \quad (11.95)$$

To prove the Hermiticity, we observe that within the naive scalar product (11.93), a partial integration changes the covariant derivative $-D_\mu$ into

$$D_\mu^* \equiv (D_\mu + 2S_\mu). \quad (11.96)$$

¹See the standard textbooks on quantum field theory, for example, Ref. [1, 2].

Consider, for example, the scalar product

$$\int d^D q \sqrt{g} U^{\mu\nu_1 \dots \nu_n} D_\mu V_{\nu_1 \dots \nu_n}. \quad (11.97)$$

A partial integration of the derivative term ∂_μ in D_μ gives

$$\begin{aligned} \text{surface term} &= \int d^D q [(\partial_\mu \sqrt{g} U^{\mu\nu_1 \dots \nu_n}) V_{\nu_1 \dots \nu_n} \\ &\quad - \sum_i \sqrt{g} U^{\mu\nu_1 \dots \nu_i \dots \nu_n} \Gamma_{\mu\nu_i}^{\lambda_i} V_{\nu_1 \dots \lambda_i \dots \nu_n}]. \end{aligned} \quad (11.98)$$

Now we use

$$\partial_\mu \sqrt{g} = \sqrt{g} \bar{\Gamma}_{\mu\nu}^\nu = \sqrt{g} (2S_\mu + \Gamma_{\mu\nu}^\nu), \quad (11.99)$$

to rewrite (11.98) as

$$\begin{aligned} \text{surface term} &= \int d^D q \sqrt{g} [(\partial_\mu U^{\mu\nu_1 \dots \nu_n}) V_{\nu_1 \dots \nu_n} \\ &\quad - \sum_i \Gamma_{\mu\nu_i}^{\lambda_i} U^{\mu\nu_1 \dots \nu_i \dots \nu_n} V_{\nu_1 \dots \lambda_i \dots \nu_n} - 2S_\mu U^{\mu\nu_1 \dots \nu_n} V_{\nu_1 \dots \nu_n}], \end{aligned} \quad (11.100)$$

which is equal to

$$\text{surface term} = \int d^D q \sqrt{g} (D_\mu^* U^{\mu\nu_1 \dots \nu_n}) V_{\nu_1 \dots \nu_n}. \quad (11.101)$$

In the physical scalar product (11.95), the corresponding operation is

$$\begin{aligned} \int d^D q \sqrt{g} e^{-2\sigma(q)} U^{\mu\nu_1 \dots \nu_n} D_\mu V_{\nu_1 \dots \nu_n} &= \\ &= \text{surface term} - \int d^D q \sqrt{g} (D_\mu^* e^{-2\sigma(q)} U^{\mu\nu_1 \dots \nu_n}) V_{\nu_1 \dots \nu_n} \\ &= \text{surface term} - \int d^D q \sqrt{g} e^{-2\sigma(q)} (D_\mu \sqrt{g} U^{\mu\nu_1 \dots \nu_n}) V_{\nu_1 \dots \nu_n}. \end{aligned} \quad (11.102)$$

Hence, iD_μ is a Hermitian operator, and so is the Laplacian $D_\mu D^\mu$.

For spaces with an arbitrary torsion, the correct scalar product has yet to be found. Thus the quantum equivalence principle is so far only applicable to spaces with arbitrary curvature and gradient torsion.

11.5 Alternative Attempts

Our procedure has to be contrasted with earlier proposals for constructing path integrals in spaces with curvature, in which torsion was always assumed to be absent. In the notable work of DeWitt,² the measure is taken to be proportional to

$$\prod_{n=1}^N \int dq_n \sqrt{g(q_{n-1})} = \prod_{n=1}^N \int dq_n \sqrt{g(q_n - \Delta q)} \quad (11.103)$$

²See Section 11.5.

so that the expansion in powers Δq gives a Jacobian action $\mathcal{A}_{J_0}^\epsilon$ of Eq. (10.133).

If one uses this action instead of the correct expression \mathcal{A}_J^ϵ of Eq. (10.145), the amplitude obeys a Schrödinger equation

$$i\hbar\partial_t\psi(q,t) = (\hat{H}_0 + V_{\text{eff}})\psi(q,t), \quad (11.104)$$

where

$$\hat{H}_0 = -\frac{\hbar^2}{2M}\Delta \quad (11.105)$$

contains the Laplace-Beltrami operator Δ , and V_{eff} is an additional effective potential

$$V_{\text{eff}} = \frac{\hbar^2}{6M}\bar{R}. \quad (11.106)$$

The Schrödinger equation (11.104) differs from ours in Eq. (11.21) derived by the nonholonomic mapping procedure by the extra R -term. The derivation is reviewed in Appendix 11A. Note that our sign convention for \bar{R} is such that the surface of a sphere of radius R has $\bar{R} = 2/R^2$.

In the amplitude proposed by DeWitt, the short-time amplitude carries an extra semiclassical prefactor, a curved-space version of the Van Vleck-Pauli-Morette determinant in Eq. (4.125). It contributes another term proportional to \bar{R} which reduces (11.106) to $(\hbar^2/12M)\bar{R}$ (see Appendix 11B). Other path integral prescriptions lead even to additional noncovariant terms [3]. All such nonclassical terms proportional to \hbar^2 have to be subtracted from the classical action to arrive at the correct amplitude which satisfies the Schrödinger equation (11.104) without an extra V_{eff} .

There are two compelling arguments in favor of our construction principle: On the one hand, if the space has only curvature and no torsion, our path integral gives the correct time evolution amplitude of a particle on the surface of a sphere in D dimensions and on group spaces, as we have seen in Sections 8.7–8.9 and 10.4. In contrast to other proposals, only the classical action appears in the short-time amplitude. In spaces with constant curvature, just as in flat space, our amplitude agrees with the one obtained from operator quantum mechanics by quantizing the theory via the commutation rules of the generators of the group of motion.

In the presence of torsion the result is new. It will be tested by the integration of the path integral of the Coulomb system in Chapter 13. This requires a multivalued coordinate transformation to an auxiliary space with curvature and torsion, which reduces the system to a harmonic oscillator (see Section 13.5). The multivaleud mapping principle leads to the correct result.

The solution is so far the only indirect evidence for the question first raised by Bryce DeWitt in his fundamental 1957 paper [4], whether the Hamiltonian operator for a particle in curved space contains merely the Laplace-Beltrami operator Δ in the kinetic energy, or whether there exists an additional term proportional

to $\hbar^2 R$. Recall the various older path integral literature on the subject cited in Chapter 10. From the measure generated by the nonholonomic mapping principle in Subsection 10.3.2 it follows that there is no extra $\hbar^2 R$ -term. See the discussion in Section 11.5. It would, of course, be more satisfactory to have a direct experimental evidence, but so far all experimentally accessible systems in curved space have either a very small R caused by gravitation, whose detection is presently impossible, or a constant R which does not change level spacings, an example for the latter being the spinning symmetric and asymmetric top discussed in the context of Eq. (1.471).

11.6 DeWitt-Seeley Expansion of Time Evolution Amplitude

An important tool for comparing the results of path integrals in curved space with operator results of Schrödinger theory is the short-time expansion of the imaginary-time evolution amplitude $(q, \beta | q', 0)$. In Schrödinger theory, the amplitude is given by the matrix elements of the evolution operator $e^{-\beta \hat{H}} = e^{\beta \Delta/2}$, with Δ being the Laplace-Beltrami operator (11.13). This expansion has first been given by DeWitt [6] and by Seeley [7] and reads³

$$(q \beta | q' 0) = (q | e^{\beta \Delta/2} | q') = \frac{1}{\sqrt{2\pi\beta^D}} e^{-g_{\mu\nu}(q)\Delta q^\mu \Delta q^\nu / 2\beta} \sum_{k=0}^{\infty} \beta^k a_k(q, q'), \quad (11.107)$$

The associated *DeWitt-Seeley expansion coefficients* $a_k(q, q')$ are, up to fourth order in Δq^μ ,

$$\begin{aligned} a_0(q, q') &\equiv 1 + \frac{1}{12} \bar{R}_{\mu\nu} \Delta q^\mu \Delta q^\nu + \left(\frac{1}{360} \bar{R}^\mu{}_\kappa{}^\nu{}_\lambda \bar{R}_{\mu\sigma\nu\tau} + \frac{1}{288} \bar{R}_{\kappa\lambda} \bar{R}_{\sigma\tau} \right) \Delta q^\kappa \Delta q^\lambda \Delta q^\sigma \Delta q^\tau, \\ a_1(q, q') &\equiv \frac{1}{12} \bar{R} + \left(\frac{1}{144} \bar{R} \bar{R}_{\mu\nu} + \frac{1}{360} \bar{R}^{\kappa\lambda} \bar{R}_{\kappa\mu\lambda\nu} + \frac{1}{360} \bar{R}^{\kappa\lambda\sigma}{}_\mu \bar{R}_{\kappa\lambda\sigma\nu} - \frac{1}{180} \bar{R}^\kappa{}_\mu \bar{R}_{\kappa\nu} \right) \Delta q^\mu \Delta q^\nu, \\ a_2(q, q') &\equiv \frac{1}{288} \bar{R}^2 + \frac{1}{720} \bar{R}^{\mu\nu\kappa\lambda} \bar{R}_{\mu\nu\kappa\lambda} - \frac{1}{720} \bar{R}^{\mu\nu} \bar{R}_{\mu\nu}, \end{aligned} \quad (11.108)$$

where $\Delta q^\mu \equiv (q - q')^\mu$. The metric at q is assumed to be Minkowskian, and all curvature tensors are evaluated at q . For $\Delta q^\mu = 0$ this simplifies to

$$(q \beta | q 0) = \frac{1}{\sqrt{2\pi\beta^D}} \left\{ 1 + \frac{\beta}{12} \bar{R} + \frac{\beta^2}{2} \left[\frac{1}{144} \bar{R}^2 + \frac{1}{360} \left(\bar{R}^{\mu\nu\kappa\lambda} \bar{R}_{\mu\nu\kappa\lambda} - \bar{R}^{\mu\nu} \bar{R}_{\mu\nu} \right) \right] + \dots \right\}. \quad (11.109)$$

This can also be written in the cumulant form as

$$(q \beta | q 0) = \frac{1}{\sqrt{2\pi\beta^D}} \exp \left[\frac{\beta}{12} \bar{R} + \frac{\beta^2}{720} \left(\bar{R}^{\mu\nu\kappa\lambda} \bar{R}_{\mu\nu\kappa\lambda} - \bar{R}^{\mu\nu} \bar{R}_{\mu\nu} \right) + \dots \right]. \quad (11.110)$$

³In the mathematical nomenclature of Footnote 16 in Chapter 2, this is a so-called *heat kernel expansion* or a *Hadamard expansion* [8], and the DeWitt-Seeley coefficients $a_k(q, q')$ are also called *Hadamard coefficients*.

The derivation goes as follows. In a neighborhood of some arbitrary point q_0^μ we expand the Laplace-Beltrami operator in normal coordinates where the metric and its determinant have the expansions (10.477) and (10.478) as

$$\Delta = \partial^2 - \frac{1}{3}\bar{R}_{ik_1jk_2}(q_0)(q - q_0)^{k_1}(q - q_0)^{k_2}\partial_\mu\partial_\nu - \frac{2}{3}\bar{R}_{\mu\nu}(q_0)(q - q_0)^\mu\partial_\nu. \quad (11.111)$$

The time evolution operator $\hat{H} = -\Delta/2$ in the exponent of Eq. (11.107) is now separated into a free part \hat{H}_0 and an interaction part \hat{H}_{int} as follows

$$\hat{H}_0 = -\frac{1}{2}\partial^2, \quad (11.112)$$

$$\hat{H}_{\text{int}} = \frac{1}{6}\bar{R}_{ik_1jk_2}(q - q_0)^{k_1}(q - q_0)^{k_2}\partial_\mu\partial_\nu + \frac{1}{3}\bar{R}_{\mu\nu}(q - q_0)^\mu\partial_\nu. \quad (11.113)$$

We now recall Eq. (1.294) and see that the transition amplitude (11.107) satisfies the integral equation

$$\begin{aligned} (q\beta | q'0) &= \langle q | e^{-\beta(\hat{H}_0 + \hat{H}_{\text{int}})} | q' \rangle = \langle q | e^{-\beta\hat{H}_0} \left[1 - \int_0^\beta d\sigma e^{\sigma\hat{H}_0} \hat{H}_{\text{int}} e^{-\sigma\hat{H}} \right] | q' \rangle \\ &= (q\beta | q'0)_0 - \int_0^\beta d\sigma \int d^D\bar{q} (q\beta - \sigma | \bar{q}0)_0 \hat{H}_{\text{int}}(\bar{q}) (\bar{q}\sigma | q0), \end{aligned} \quad (11.114)$$

where

$$(q\beta | q'0)_0 = \langle q | e^{-\beta\hat{H}_0} | q' \rangle = \frac{1}{\sqrt{2\pi\beta^n}} e^{-(\Delta q)^2/2\beta}. \quad (11.115)$$

To first order in \hat{H}_{int} we can replace \hat{H} in the last exponential of Eq. (11.114) by \hat{H}_0 and obtain

$$(q\beta | q'0) \approx (q\beta | q'0)_0 - \int_0^\beta d\sigma \int d^D\bar{q} (q\beta - \sigma | \bar{q}0)_0 \hat{H}_{\text{int}}(\bar{q}) (\bar{q}\sigma | q0)_0. \quad (11.116)$$

Inserting (11.113) and choosing $q_0 = q'$, we find

$$\begin{aligned} (q\beta | q'0) &= (q\beta | q'0)_0 \left\{ 1 + \int_0^\beta d\sigma \int \frac{d^D(\Delta\bar{q})}{\sqrt{2\pi a}^D} e^{-[\Delta\bar{q} - (\sigma/\beta)\Delta q]^2/2a} \right. \\ &\quad \times \left. \left[-\frac{1}{6}\bar{R}_{\mu\kappa\nu\lambda}\Delta\bar{q}^\kappa\Delta\bar{q}^\lambda \left(-\frac{\delta^{\mu\nu}}{\sigma} + \frac{\Delta\bar{q}^\mu\Delta\bar{q}^\nu}{\sigma^2} \right) + \frac{1}{3}\bar{R}_{\mu\nu}\frac{\Delta\bar{q}^\mu\Delta\bar{q}^\nu}{\sigma} \right] \right\}, \end{aligned} \quad (11.117)$$

where we have replaced the integrating variable \bar{q} by $\Delta\bar{q} = \bar{q} - q'$ and introduced the variable $a \equiv (\beta - \sigma)\sigma/\beta$. There is initially also a term of fourth order in $\Delta\bar{q}$ which vanishes, however, because of the antisymmetry of $\bar{R}_{\mu\kappa\nu\lambda}$ in $\mu\kappa$ and $\nu\lambda$. The remaining Gaussian integrals are performed after shifting $\Delta\bar{q} \rightarrow \Delta\bar{q} + \sigma\Delta q/\beta$, and we obtain

$$\begin{aligned} (q\beta | q'0) &= (q\beta | q'0)_0 \left\{ 1 + \frac{1}{6} \int_0^\beta d\sigma \left[\frac{\sigma}{\beta^2} \bar{R}_{\mu\nu}(q') \Delta q^\mu \Delta q^\nu + \frac{a}{\sigma} \bar{R}(q') \right] \right\} \\ &= (q\beta | q'0)_0 \left[1 + \frac{1}{12} \bar{R}_{\mu\nu}(q') \Delta q^\mu \Delta q^\nu + \frac{\beta}{12} \bar{R}(q') \right]. \end{aligned} \quad (11.118)$$

Note that all geometrical quantities are evaluated at the initial point q' . They can be re-expressed in power series around the final position q using the fact that in normal coordinates

$$g_{\mu\nu}(q') = g_{\mu\nu}(q) + \frac{1}{3}\bar{R}_{ik_1jk_2}(q)\Delta q^{k_1}\Delta q^{k_2} + \dots, \tag{11.119}$$

$$g_{\mu\nu}(q')\Delta q^\mu\Delta q^\nu = g_{\mu\nu}(q)\Delta q^\mu\Delta q^\nu, \tag{11.120}$$

the latter equation being true to all orders in Δq due to the antisymmetry of the tensors $\bar{R}_{\mu\nu\kappa\lambda}$ in all terms of the expansion (11.119), which is just another form of writing the expansion (10.477) up to the second order in Δq^μ .

Going back to the general coordinates, we obtain all coefficients of the expansion (11.107) linear in the curvature tensor

$$(q\ \beta \mid q' 0) \simeq \frac{1}{\sqrt{2\pi\beta}^D} e^{-g_{\mu\nu}(q)\Delta q^\mu\Delta q^\nu/2\beta} \left[1 + \frac{1}{12}\bar{R}_{\mu\nu}(q)\Delta q^\mu\Delta q^\nu + \frac{\beta}{12}\bar{R}(q) \right]. \tag{11.121}$$

The higher-order terms in the Seeley-DeWitt expansion (10.512) can be derived similarly, although with much more effort [9].

A simple cross check of the expansion (10.512) to high orders is possible if we restrict the space to the surface of a sphere of radius r in D dimensions which has $D - 1$ dimensions. Then

$$\bar{R}_{\mu\nu\kappa\lambda} = \frac{1}{r^2} (g_{\mu\lambda}g_{\nu\kappa} - g_{\mu\kappa}g_{\nu\lambda}), \quad \mu, \nu = 1, 2, \dots, D - 1. \tag{11.122}$$

Contractions yield Ricci tensor and scalar curvature

$$\bar{R}_{\mu\nu} = \bar{R}_{\kappa\mu\nu}{}^\kappa = \frac{D - 2}{r^2} g_{\mu\nu}, \quad \bar{R} = \bar{R}_\mu{}^\mu = \frac{(D - 1)(D - 2)}{r^2} \tag{11.123}$$

and further:

$$\bar{R}_{\mu\nu\kappa\lambda}^2 = \frac{2(D - 1)(D - 2)}{r^4}, \quad \bar{R}_{\mu\nu}^2 = \frac{(D - 1)(D - 2)^2}{r^4}. \tag{11.124}$$

Inserting these into (11.108), we obtain the DeWitt-Seeley short-time expansion of the diagonal amplitude for any q , up to order β^2 :

$$(q\ \beta \mid q 0) = \frac{1}{\sqrt{2\pi\beta}^{D-1}} \left[1 + (D - 1)(D - 2)\frac{\beta}{12r^2} + (D - 1)(D - 2)(5D^2 - 17D + 18)\frac{\beta^2}{1440r^4} + \dots \right]. \tag{11.125}$$

This expansion may easily be reproduced by a simple direct calculation of the partition function for a particle on the surface of a sphere [10]

$$Z(\beta) = \sum_{l=0}^{\infty} d_l \exp[-l(l + D - 2)\beta/2r^2], \tag{11.126}$$

where $-l(l+D-2)$ are the eigenvalues of the Laplace-Beltrami operator on a sphere [recall (10.165)] and $d_l = (2l+D-2)(l+D-3)!/l!(D-2)!$ their degeneracies [recall (8.114)]. Since the space is homogeneous, the amplitude $(q\beta | q0)$ is obtained from this by dividing out the constant surface of a sphere:

$$(q\beta | q0) = \frac{\Gamma(D/2)}{2\pi^{D/2}r^{D-1}}Z(\beta). \quad (11.127)$$

For any given D , the sum in (11.126) easily be expanded in powers of β . As an example, take $D = 3$ where

$$Z(\beta) = \sum_{l=0}^{\infty} (2l+1) \exp[-l(l+1)\beta/2r^2]. \quad (11.128)$$

In the small- β limit, the sum (11.128) is evaluated as follows

$$Z(\beta) = \int_0^{\infty} d[l(l+1)] \exp[-l(l+1)\beta/2r^2] + \sum_{l=0}^{\infty} (2l+1) \left[1 - l(l+1)\beta/2r^2 + \dots \right]. \quad (11.129)$$

The integral is immediately done and yields

$$\int_0^{\infty} dz \exp(-z\beta/2r^2) = \frac{2r^2}{\beta}. \quad (11.130)$$

The sums are divergent but can be evaluated by analytic continuation from negative powers of l to positive ones with the help of Riemann zeta functions $\zeta(z) = \sum_{n=1}^{\infty} n^{-z}$, which vanishes for all even negative arguments. Thus we find

$$\sum_{l=0}^{\infty} (2l+1) = 1 + \sum_{l=1}^{\infty} (2l+1) = 1 + 2\zeta(-1) - \frac{1}{2} = \frac{1}{3}, \quad (11.131)$$

$$-\frac{\beta}{2r^2} \sum_{l=0}^{\infty} (2l+1)l(l+1) = -\frac{\beta}{2r^2} \sum_{l=1}^{\infty} (2l^3+l) = -\frac{\beta}{2r^2} [2\zeta(-3) + \zeta(-1)] = \frac{\beta}{30r^2}. \quad (11.132)$$

Substituting these into (11.129) yields

$$Z(\beta) = \frac{2r^2}{\beta} \left(1 + \frac{\beta}{6r^2} + \frac{\beta^2}{60r^4} + \dots \right). \quad (11.133)$$

Dividing out the constant surface of a sphere $4\pi r^2$ as required by Eq. (11.127), we obtain indeed the expansion (11.125) for the surface of a sphere in three dimensions.

11.7 Recursive Calculation

If one wants to proceed to higher orders, an efficient recursive scheme was devised by DeWitt [6]. He considers the real-time version of the amplitude (10.512)

$$(qt | q'0) = (q | e^{it\Delta/2} | q'), \quad (11.134)$$

which satisfies the Schrödinger equation in curved space

$$i\partial_t(qt | q'0) = -\frac{\Delta}{2}(q\beta | q'0), \quad (11.135)$$

with the initial condition

$$(q0 | q'0) = \delta^{(D)}(q - q'). \quad (11.136)$$

To solve (11.135) he first sets up a semiclassical time evolution amplitude in curved spacetime which is a direct analog the amplitude (4.125). He considers the action (10.2) of a point particle in curved space with a metric

$$\mathcal{A} = \frac{1}{2} \int_0^t dt' g_{\mu\nu}(q(t')) \dot{q}^\mu(t') \dot{q}^\nu(t') \quad (11.137)$$

along the geodetic trajectory (10.9) between the initial and final points q' and q , denoting it by $A(q, q'; t)$, as in Eq. (4.87). Associated with this he defines the *geodetic distance*

$$\sigma(q, q') \equiv tA(q, q'; t) = \sigma(q', q). \quad (11.138)$$

This is a bilocal function called the *geodetic interval*. The classical momentum of the particle along the orbit is given by the derivative [recall Eq. (4.88)]

$$p_\mu = \partial_\mu A(q, q'; t) = \partial_\mu \sigma(q, q')/t. \quad (11.139)$$

The classical path follows the Hamilton-Jacobi equation (1.65), which reads for an action satisfying (11.138):

$$\partial_t \sigma(q, q') = \frac{1}{2} \partial_\mu \sigma(q, q') \partial^\mu \sigma(q, q'). \quad (11.140)$$

The derivative $\partial_\mu \sigma(q, q')$ points in the direction of the tangent vector of the geodetic trajectory. The Hamilton-Jacobi equation states that its square length is equal to twice the geodetic interval.

Then he writes the semiclassical amplitude in curved spacetime as an obvious extension of the flat-space expression (4.125) [11]:

$$(qt | q'0) = (q | e^{it\Delta/2} | q') = \frac{1}{\sqrt{2\pi it}^D} \mathcal{D}^{1/2}(q, q') e^{i\sigma(q, q')/2t}, \quad (11.141)$$

where \mathcal{D} denotes the determinant

$$\mathcal{D} \equiv \det_D[-\partial_\mu \partial'_\nu A(q, q'; t)] = \frac{\det_D[-\partial_\mu \partial'_\nu \sigma(q, q')]}{t^D}. \quad (11.142)$$

The exact amplitude has a short-time expansion

$$(qt | q'0) = (q | e^{it\Delta/2} | q') = \frac{1}{\sqrt{2\pi it}^D} \mathcal{D}^{1/2}(q, q') e^{i\sigma(q, q')/2t} \sum_{n=0}^{\infty} t^n a_n(q, q'; t), \quad (11.143)$$

where for $q = q'$. $a_0(q, q') = 1$, and all other coefficients vanish. Applying the Schrödinger equation (11.135) to (11.143), he derives the recursion relation

$$\partial^\mu \sigma \partial_\mu a_0 = 0, \quad (11.144)$$

$$\partial^\mu \sigma \partial_\mu a_{n+1} + (n+1)a_{n+1} = \tilde{\mathcal{D}}^{-1/2} \bar{D}^\mu \partial_\mu (\tilde{\mathcal{D}}^{1/2} a_n), \quad n = 0, 1, 2, \dots \quad (11.145)$$

where $\tilde{\mathcal{D}}(q, q') \equiv g^{-1/2}(q) \mathcal{D} g^{1/2}(q')$ and \bar{D}^μ is the covariant derivative of the derivative $\partial_\mu \sigma$ defined as in Eq. (10.37). He solves the lowest coefficient by the bilocal function $I(q, q')$ with the properties

$$\partial^\mu \sigma \partial_\mu I(q, q') = 0, \quad \partial^{\mu'} \sigma \partial_{\mu'} I(q, q') = 0, \quad I(q, q) = 1. \quad (11.146)$$

From this he finds the solution of (11.145) as

$$a_{n+1}(q, q') = \frac{1}{t^{n+1}} \int_0^t dt'' t''^n \tilde{\mathcal{D}}^{-1/2} \bar{D}^\mu \partial_\mu [\tilde{\mathcal{D}}^{1/2} a_n(q(\tau''), q')]. \quad (11.147)$$

Appendix 11A Cancellations in Effective Potential

Here we demonstrate the cancellation of the terms v_2^B and v_3^B in formula (11.48) for the effective potential. First we give a simple reason why the cancellation occurs *separately* for the contributions stemming from the second and third terms in the expansion (10.96) of Δx^i . Consider the model integral

$$\int \frac{d\Delta x}{\sqrt{2\pi\epsilon}} \exp\left[-\frac{(\Delta x)^2}{2\epsilon}\right], \quad (11A.1)$$

and assume that Δx has an expansion of the type (10.96):

$$\Delta x = \Delta q [1 + a_2 \Delta q + a_3 (\Delta q)^2 + \dots]. \quad (11A.2)$$

The integral transforms into

$$\int \frac{d\Delta q}{\sqrt{2\pi\epsilon}} [1 + 2a_2 \Delta q + 3a_3 (\Delta q)^2 + \dots] \exp\left\{-\frac{(\Delta q)^2}{2\epsilon} [1 + 2a_2 \Delta q + 2a_3 (\Delta q)^2 + a_2^2 (\Delta q)^2 + \dots]\right\}, \quad (11A.3)$$

and is evaluated perturbatively via the expansion

$$\int \frac{d\Delta q}{\sqrt{2\pi\epsilon}} \exp\left[-\frac{(\Delta q)^2}{2\epsilon}\right] \left[1 - a_2 \frac{(\Delta q)^3}{\epsilon} - a_3 \frac{(\Delta q)^4}{\epsilon} - a_2^2 \frac{(\Delta q)^4}{2\epsilon} + a_2^2 \frac{(\Delta q)^6}{2\epsilon} - 2a_2^2 \frac{(\Delta q)^4}{\epsilon} + 3a_3 (\Delta q)^2 + \dots\right]. \quad (11A.4)$$

If $\langle \mathcal{O} \rangle_0$ denotes the harmonic expectation value

$$\langle \mathcal{O} \rangle_0 \equiv \int \frac{d\Delta q}{\sqrt{2\pi i \epsilon}} \mathcal{O} \exp[-(\Delta q)^2/2\epsilon], \quad (11A.5)$$

one has

$$\langle (\Delta q)^2 \rangle_0 = \epsilon, \quad \langle (\Delta q)^4 \rangle_0 = 3!\epsilon^2, \quad \langle (\Delta q)^6 \rangle_0 = 5!\epsilon^3, \dots \quad (11A.6)$$

Using these values we find that the a_2 - and a_3 -terms cancel separately. Precisely this cancellation mechanism is active in the separate cancellation of the more complicated expressions v_1^B, v_2^B in Eq. (11.49).

To demonstrate the cancellations explicitly, consider first the derivative terms in v_3^B . They are

$$v_3^{\partial\Gamma} = -\frac{1}{2}g^{\mu\nu}\partial_{\{\mu}\Gamma_{\nu\lambda\}}^\lambda + \frac{1}{6}g_{\mu\tau}\partial_\kappa\Gamma_{\lambda\nu}^\tau (g^{\mu\nu}g^{\lambda\kappa} + g^{\mu\lambda}g^{\nu\kappa} + g^{\mu\kappa}g^{\nu\lambda}). \tag{11A.7}$$

Due to the symmetrization of the first term in $\mu\nu\lambda$, this gives zero. The cancellation of the remaining terms in v_3^B which are quadratic in Γ is most easily shown by writing all indices as subscripts, inserting $g_{\mu\nu\lambda\kappa}$ from (11.41), and working out the contractions.

To calculate the v_2^B -terms, it is useful to introduce the notation $\Gamma_{1\mu} \equiv \Gamma_{\mu\nu}^\nu$, $\Gamma_{2\mu} \equiv \Gamma_{\nu\mu}^\nu$, $\Gamma_{3\mu} \equiv \Gamma_{\nu\mu}^\nu$ and similarly the matrices $\tilde{\Gamma}_{1\mu} \hat{=} (\Gamma_\mu)_{\lambda\kappa}$, $\tilde{\Gamma}_{1\mu}^T \hat{=} (\Gamma_\mu)_{\kappa\lambda}$, $\tilde{\Gamma}_{2\mu} \hat{=} \Gamma_{\lambda\mu\kappa}$, $\tilde{\Gamma}_{2\mu}^T \hat{=} \Gamma_{\kappa\mu\lambda}$, $\tilde{\Gamma}_{3\mu} \hat{=} \Gamma_{\lambda\kappa\mu}$, $\tilde{\Gamma}_{3\mu}^T \hat{=} \Gamma_{\kappa\lambda\mu}$. For contractions such as $\Gamma_{1\mu}\Gamma_{1\mu}$ we write $\Gamma_1\Gamma_1$, and for $\Gamma_{\mu\nu\lambda}\Gamma_{\mu\nu\lambda}$ we write $\tilde{\Gamma}_1\tilde{\Gamma}_1 = \tilde{\Gamma}_2\tilde{\Gamma}_2 = \tilde{\Gamma}_3\tilde{\Gamma}_3$, whichever is most convenient. Similarly, $\Gamma_{\mu\nu\lambda}\Gamma_{\lambda\mu\nu} = \tilde{\Gamma}_1\tilde{\Gamma}_2^T = \tilde{\Gamma}_2\tilde{\Gamma}_3^T = \tilde{\Gamma}_3\tilde{\Gamma}_1$. Then we work out

$$\begin{aligned} v_2^1 &= -\frac{1}{8}[(\Gamma_1 + \Gamma_2)^2 - \tilde{\Gamma}_3(\tilde{\Gamma}_1 + \tilde{\Gamma}_1^T + \tilde{\Gamma}_2 + \tilde{\Gamma}_2^T)], \\ v_2^2 &= \frac{1}{8}[\Gamma_3\Gamma_3 + \tilde{\Gamma}_3(\tilde{\Gamma}_3 + \tilde{\Gamma}_3^T)], \\ v_2^3 &= \frac{1}{4}[(\Gamma_1 + \Gamma_2)^2 + \Gamma_3(\Gamma_1 + \Gamma_2)], \\ v_2^4 &= -\frac{1}{8}[\Gamma_1^2 + \Gamma_2^2 + \Gamma_3^2 + 2(\Gamma_1\Gamma_2 + \Gamma_2\Gamma_3 + \Gamma_3\Gamma_1) \\ &\quad + \tilde{\Gamma}_3(\tilde{\Gamma}_1 + \tilde{\Gamma}_1^T + \tilde{\Gamma}_2 + \tilde{\Gamma}_2^T + \Gamma_3 + \tilde{\Gamma}_3^T)]. \end{aligned} \tag{11A.8}$$

It is easy to check that the sum of these v_2^B -terms vanishes.

Incidentally, if the symmetrizations in (11.49) following from our Jacobian action had been absent, we would find the additional terms

$$\Delta v_3^{\partial\Gamma} = \frac{1}{6}\bar{R} - \frac{2}{3}\partial_\mu S^\mu + \frac{1}{6}(\tilde{\Gamma}_3\tilde{\Gamma}_2^T - \Gamma_3\Gamma_2), \tag{11A.9}$$

$$\Delta v_3^{\Gamma^2} = -\frac{1}{2}\tilde{\Gamma}_3\tilde{\Gamma}_2 + \frac{1}{6}(\tilde{\Gamma}_3\tilde{\Gamma}_2 + \tilde{\Gamma}_3\tilde{\Gamma}_2^T + \Gamma_3\Gamma_2), \tag{11A.10}$$

whose sum yields the additional contribution to the v_3^B -terms

$$\Delta v_3 = \frac{1}{6}\bar{R} - \frac{2}{3}\partial_\mu S^\mu + \frac{2}{3}\tilde{\Gamma}_3\tilde{S}_1, \tag{11A.11}$$

after having used the identity

$$\tilde{S}_3\tilde{\Gamma}_2 = -\tilde{\Gamma}_3\tilde{S}_1. \tag{11A.12}$$

The first term in (11A.11) is the R -term derived by K.S. Cheng⁴ as an effective potential in the Schrödinger equation.

For v_2^B , we would find the extra terms

$$\Delta v_2^1 = -\frac{1}{2}(\Gamma_1\Gamma_1 - \tilde{\Gamma}_3\tilde{\Gamma}_2) + \frac{1}{8}[(\Gamma_1 + \Gamma_2)^2 - \tilde{\Gamma}_3(\tilde{\Gamma}_1 + \tilde{\Gamma}_1^T + \tilde{\Gamma}_2 + \tilde{\Gamma}_2^T)], \tag{11A.13}$$

$$\Delta v_2^3 = \frac{1}{4}(\Gamma_1 - \Gamma_2)(\Gamma_1 + \Gamma_2 + \Gamma_3), \tag{11A.14}$$

⁴K.S. Cheng, *J. Math. Phys.* 13, 1723 (1972).

which add up to

$$\Delta v_2 = -\frac{1}{2}S_1 S_1 + \frac{1}{2}\Gamma_3 S_1 - \frac{1}{3}\tilde{\Gamma}_3 \tilde{S}_1 + \frac{1}{2}\tilde{S}_1 \tilde{S}_3, \tag{11A.15}$$

where we have written S_1 for S_μ and used some trivial identities such as

$$\tilde{\Gamma}_3 \tilde{\Gamma}_2^T = \tilde{\Gamma}_3 \tilde{\Gamma}_1. \tag{11A.16}$$

Thus we would obtain an additional effective potential $V_{\text{eff}} = (\hbar^2/M)v$ with

$$v = \frac{1}{6}R - \frac{2}{3}g^{\mu\nu} \partial_\mu S_\nu - \frac{1}{2}(S_1^2 - \Gamma_3 S_1) + \frac{1}{2}\tilde{S}_1 \tilde{S}_3 - \frac{1}{3}\tilde{\Gamma}_3 \tilde{S}_1. \tag{11A.17}$$

The second and the fourth term can be combined to

$$-\frac{2}{3}D_\mu S^\mu - \frac{1}{6}\Gamma_3 S_1. \tag{11A.18}$$

Due to the presence of Γ 's in v , this is a noncovariant expression which cannot possibly be physically correct. In the absence of torsion, however, v happens to be reparametrization-invariant, and this is the reason why the resulting effective potential $V_{\text{eff}} = \hbar^2 \bar{R}/6M$ appeared acceptable in earlier works. A procedure which has no reparametrization-invariant extension to spaces with torsion cannot be correct.

Appendix 11B DeWitt's Amplitude

Bryce DeWitt, in his frequently quoted paper,⁵ attempted to quantize the motion of a particle in a curved space using the naive measure of path integration as in Eq. (10.153), but with the short-time amplitude (11.141) with $q \equiv q_n, q' \equiv q_{n-1}$. However, after taking the Jacobian action $A_{J_0}^\epsilon$ into account, this leads to an integral kernel $K^\epsilon(q, \Delta q)$ which differs from our correct one in Eq. (11.4) by an extra factor

$$\mathcal{D}^{1/2}(q, q') e^{-iA_J^\epsilon/\hbar} / \sqrt{g(q)}. \tag{11B.1}$$

This has the postpoint expansion $1 + \frac{1}{12}\bar{R}_{\mu\nu}(q)\Delta q^\mu \Delta q^\nu + \dots$. When treated perturbatively, the extra term is equivalent to $\epsilon \hbar \bar{R}/12M$. Thus, in order to obtain the correct amplitude without an extra \bar{R} -term, DeWitt had to subtract the nonclassical potential $\hbar^2 \bar{R}/12M$ from the Hamiltonian. Such a correction procedure must be rejected on the grounds that it runs contrary to the very essence of the path integral approach, in which the contribution of each path is controlled entirely by the phase $e^{iA/\hbar}$ with the *classical action* in the exponent.

The short-time kernel proposed fifteen years later by Cheng requires the artificial subtraction of the full effective potential (11.106) to obtain the correct amplitude (11.4).

Notes and References

The first path integral in a curved space was written down by B.S. DeWitt, Rev. Mod. Phys. **29**, 377 (1957), making use of previous work by C. DeWitt-Morette [11]. New Path Integral Formula for Singular Potentials

In Chapter 8 we have seen that for systems with a centrifugal barrier, the Euclidean form of Feynman's original time-sliced path integral formula diverges for certain attractive barriers. This happens even if the quantum statistics of the systems is well defined. The same problem arises for a particle in an attractive Coulomb potential, and thus in any atomic system.

In this chapter we set up a new and more flexible path integral formula which is free of this problem for any singular potential. This has recently turned out to be the key for a simple solution of many other path integrals which were earlier considered intractable.

12.1 Path Collapse in Feynman's formula for the Coulomb System

The attractive Coulomb potential $V(r) = -e^2/r$ has a singularity at the coordinate origin $r = 0$. This singularity is weaker than that of the centrifugal barrier, but strong enough to cause a catastrophe in the Euclidean path integral. Recall that an attractive centrifugal barrier does not even possess a classical partition function. The same thing is true for the attractive Coulomb potential where formula (2.352) reads

$$Z_{\text{cl}} = \int \frac{d^3x}{\sqrt{2\pi\hbar^2\beta/M}^3} \exp\left(\beta\frac{e^2}{r}\right).$$

The integral diverges near the origin. In addition, there is a divergence at large r . The leading part of the latter can be removed by subtracting the free-particle partition function and forming

$$Z'_{\text{cl}} \equiv Z_{\text{cl}} - Z_{\text{cl}}|_{e=0} = \int \frac{d^3x}{\sqrt{2\pi\hbar^2\beta/M}^3} \left[\exp\left(\beta\frac{e^2}{r}\right) - 1 \right], \quad (12.1)$$

leaving only a quadratic divergence. In a realistic many-body system with an equal number of oppositely charged particles, this disappears by screening effects. Thus we shall not worry about it any further and concentrate only on the remaining small- r divergence. In a real atom, this singularity is not present since the nucleus is not a point particle but occupies a finite volume. However, this “physical regularization” of the singularity is not required for quantum-mechanical stability. The Schrödinger equation is perfectly solvable for the singular pure $-e^2/r$ potential. We should therefore be able to recover the existing Schrödinger results from the path integral formalism without any short-distance regularization.

On the basis of Feynman’s original time-sliced formula, this is impossible. If a path consists of a *finite* number of straight pieces, its Euclidean action

$$\mathcal{A} = \int_{\tau_a}^{\tau_b} d\tau \left[\frac{M}{2} \dot{\mathbf{x}}^2(\tau) - \frac{e^2}{r(\tau)} \right] \quad (12.2)$$

can be lowered indefinitely by a path with an almost stretched configuration which corresponds to a slowly moving particle sliding down into the $-e^2/r$ abyss. We call this phenomenon a *path collapse*. In nature, this catastrophe is prevented by quantum fluctuations. In order to understand how this happens, it is useful to reinterpret the paths in the Euclidean path integral as random lines parametrized by $\tau \in (\tau_a, \tau_b)$. Their distribution is governed by the “Boltzmann factor” $e^{-\mathcal{A}/\hbar}$, whose effective “quantum” temperature is $T_{\text{eff}} \equiv \hbar/k_B(\tau_b - \tau_a)$.¹ The logarithm of the Euclidean amplitude $(\mathbf{x}_b\tau_b|\mathbf{x}_a\tau_a)$ multiplied by $-T_{\text{eff}}$ defines a free energy

$$F = E - k_B T S$$

of the random line with fixed endpoints. The quantum fluctuations equip the path with a configurational entropy S . This must be sufficiently singular to produce a regular free energy bounded from below. Obviously, such a mechanism can only work if the exact path integral contains an *infinite* number of infinitesimally small sections. Only these can contain enough configurational entropy near the singularity to halt the collapse.

The variational approach in Section 5.10 has shown an important effect of the configurational entropy of quantum fluctuations. It smoothes the singular Coulomb potential producing an effective classical potential that is finite at the origin. A path collapse was avoided by defining the path integral as an infinite product of integrals over all Fourier coefficients. The infinitely high-frequency components were integrated out and this produced the desired stability. These high-frequency components are absent in a finitely time-sliced path with a finite number of pieces, where frequencies Ω_m are bounded by twice the inverse slice thickness $1/\epsilon$ [recall

ref(2.111) Eqs. (2.111), (2.112)].

lab(2.70) Unfortunately, the path measure used in the variational approach is unsuitable
est(2.80) for exact calculations of nontrivial path integrals. Except for the free particle and
ref(2.112)

lab(2.71) ¹This amounts to viewing the path as a polymer with configurational fluctuations in space, a
est(2.81) possibility which is a major topic in Chapters 15 and 16.

the harmonic oscillator, these are all based on solving a finite number of ordinary integrals in a time-sliced formula. We therefore need a more powerful time-sliced path integral formula which avoids a collapse in singular potentials.

For the Coulomb system, such a formula has been found in 1979 by Duru and Kleinert.² It has become the basis for solving the path integral of many other nontrivial systems. Here we describe the most general extension of this formula which will later be applied to a number of systems. For the attractive Coulomb potential and other singular potentials, such as attractive centrifugal barriers, it will not only halt the collapse, but also be the key to an analytic solution.

The derived stabilization is achieved by introducing a path-independent width of the time slices. If the path approaches an abyss, the widths decrease and the number of slices increases. This enables the configurational entropy of Eq. (12.3) to grow large enough to cancel the singularity in the energy. To see the cancellation mechanism, consider a random line with n links which has, on a simple cubic lattice in D dimensions, $(2D)^n$ configurations with an entropy

$$S = n \log(2D). \quad (12.3)$$

If the number of time slices n increases near the $-e^2/r$ singularity like const/r , then the entropy is proportional to $1/r$. A path section which slides down into the abyss must stretch itself to make the kinetic energy small. But then it gives up a certain entropy S , and this raises the free energy by $k_B T_{\text{eff}} S$ according to (12.3). This compensates for the singularity in the potential and halts the collapse. The purpose of this chapter is to set up a path integral formula in which this stabilizing mechanism is at work.

It should be pointed out that no instability problem would certainly arise if we were to *define* the imaginary-time path integral for the time evolution amplitude in the continuum

$$\langle \mathbf{x}_b \tau_b | \mathbf{x}_a \tau_a \rangle \equiv \int \mathcal{D}^D x(\tau) \int \frac{\mathcal{D}^D p(\tau)}{(2\pi\hbar)^D} \exp \left\{ \frac{1}{\hbar} \int_{\tau_a}^{\tau_b} d\tau [i\mathbf{p}\dot{\mathbf{x}} - H(\mathbf{p}, \mathbf{x})] \right\} \quad (12.4)$$

without any time slicing as the solution of the Schrödinger differential equation

$$(\hbar\partial_\tau + \hat{H})(\mathbf{x} \tau | \mathbf{x}_a \tau_a) = \hbar\delta(\tau - \tau_a)\delta^{(D)}(\mathbf{x} - \mathbf{x}_a) \quad (12.5)$$

[compare Eq. (1.308)]. After solving the Schrödinger equation $\hat{H}\psi_n(\mathbf{x}) = E_n\psi_n(\mathbf{x})$, the spectral representation (1.323) renders directly the amplitude (12.4).

All subtleties described above are due to the finite number of time slices in the path integral. As explained at the end of Section 2.1, the explicit sum over all paths is an essential ingredient of Feynman's global approach to the phenomena of

²I.H. Duru and H. Kleinert, Phys. Lett. B 84, 30 (1979) (<http://www.physik.fu-berlin.de/~kleinert/65>); Fortschr. Phys. 30, 401 (1982) (*ibid.*[http/83](http://83)). See also the historical remarks in the preface.

quantum fluctuations. Within this approach, the finite time slicing is essential for being able to perform this sum in any nontrivial system.

We now present a general solution to the stability problem of time-sliced quantum-statistical path integrals.

12.2 Stable Path Integral with Singular Potentials

Consider the fixed-energy amplitude (9.1) which is the local matrix element

$$(\mathbf{x}_b|\mathbf{x}_a)_E = \langle \mathbf{x}_b | \hat{R} | \mathbf{x}_a \rangle \quad (12.6)$$

of the resolvent operator (1.319):

ref(1.319)
lab(9.8)
est(9.15)

$$\hat{R} = \frac{i\hbar}{E - \hat{H} + i\eta}. \quad (12.7)$$

Recall that the $i\eta$ -prescription ensures the causality of the Fourier transform of (12.6), making it vanish for $t_b < t_a$ [see the discussion after Eq. (1.327)].

The fixed-energy amplitude has poles of the form

$$(\mathbf{x}_b|\mathbf{x}_a)_E = \sum_n \frac{i\hbar}{E - E_n + i\eta} \psi_n(\mathbf{x}_b) \psi_n^*(\mathbf{x}_a) + \dots$$

at the bound-state energies, and a cut along the continuum part of the energy spectrum. The energy integral over the discontinuity across the singularities yields the completeness relation (1.330).

The new path integral formula is based on the following observation. If the system possesses a Feynman path integral for the time evolution amplitude, it does so also for the fixed-energy amplitude. This is seen after rewriting the latter as an integral

$$(\mathbf{x}_b|\mathbf{x}_a)_E = \int_{t_a}^{\infty} dt_b \langle \mathbf{x}_b | \hat{U}_E(t_b - t_a) | \mathbf{x}_a \rangle \quad (12.8)$$

involving the modified time evolution operator

$$\hat{U}_E(t) \equiv e^{-it(\hat{H}-E)/\hbar}, \quad (12.9)$$

that is associated with the modified Hamiltonian

$$\hat{H}_E \equiv \hat{H} - E. \quad (12.10)$$

Obviously, as long as the matrix elements of the ordinary time evolution operator $\hat{U}(t) = e^{-it\hat{H}/\hbar}$ can be represented by a time-sliced Feynman path integral, the same is true for the matrix elements of the modified operator $\hat{U}_E(t) = e^{-it\hat{H}_E/\hbar}$. Its

explicit form is obtained, as in Section 2.1, by slicing the t -variable into $N + 1$ pieces, factorizing $\exp(-it\hat{H}_E/\hbar)$ into the product of $N + 1$ factors,

$$e^{-it\hat{H}_E/\hbar} = e^{-i\epsilon\hat{H}_E/\hbar} \dots e^{-i\epsilon\hat{H}_E/\hbar}, \quad (12.11)$$

and inserting a sequence of N completeness relations

$$\prod_{n=1}^N \int d^D x_n |\mathbf{x}_n\rangle \langle \mathbf{x}_n| = 1 \quad (12.12)$$

(omitting the continuum part of the spectrum). In this way, we have arrived at the path integral for the time-sliced amplitude with $t_b - t_a = \epsilon(N + 1)$

$$\langle \mathbf{x}_b | \hat{U}_E^N(t_b - t_a) | \mathbf{x}_a \rangle = \prod_{n=1}^N \left[\int d^D x_n \right] \prod_{n=1}^{N+1} \left[\int \frac{d^D p_n}{(2\pi\hbar)^D} \right] \exp\left(\frac{i}{\hbar} A_E^N\right), \quad (12.13)$$

where A_E^N is the sliced action

$$A_E^N = \sum_{n=1}^{N+1} \{ \mathbf{p}_n(\mathbf{x}_n - \mathbf{x}_{n-1}) - \epsilon[H(\mathbf{p}_n, \mathbf{x}_n) - E] \}. \quad (12.14)$$

In the limit of large N at fixed $t_b - t_a = \epsilon(N + 1)$, this defines the path integral

$$\langle \mathbf{x}_b | \hat{U}_E(t) | \mathbf{x}_a \rangle = \int \mathcal{D}^D x(t) \int \frac{\mathcal{D}^D p(t')}{(2\pi\hbar)^D} \exp\left\{ \frac{i}{\hbar} \int_0^t dt' [\mathbf{p}\dot{\mathbf{x}}(t') - H_E(\mathbf{p}(t'), \mathbf{x}(t'))] \right\}. \quad (12.15)$$

It is easy to derive a finite- N approximation also for the fixed-energy amplitude $(\mathbf{x}_b | \mathbf{x}_a)_E$ of Eq. (12.8). The additional integral over $t_b > t_a$ can be approximated at the level of a finite N by an integral over the slice thickness ϵ :

$$\int_{t_a}^{\infty} dt_b = (N + 1) \int_0^{\infty} d\epsilon. \quad (12.16)$$

The resulting finite- N approximation to the fixed-energy amplitude,

$$(\mathbf{x}_b | \mathbf{x}_a)_E^N \equiv (N + 1) \int_0^{\infty} d\epsilon \langle \mathbf{x}_b | \hat{U}_E^N(\epsilon(N + 1)) | \mathbf{x}_a \rangle = \int_{t_a}^{\infty} dt_b \langle \mathbf{x}_b | \hat{U}_E^N(t_b - t_a) | \mathbf{x}_a \rangle, \quad (12.17)$$

converges against the correct limit $(\mathbf{x}_b | \mathbf{x}_a)_E$. As an example, take the free-particle case where

$$\begin{aligned} (\mathbf{x}_b | \mathbf{x}_a)_E^N &= (N + 1) \int_0^{\infty} d\epsilon \frac{1}{\sqrt{2\pi i(N + 1)\epsilon\hbar/M}^D} \\ &\times \exp\left[i \frac{M}{2(N + 1)\epsilon} (\mathbf{x}_b - \mathbf{x}_a)^2 + iE(N + 1)\epsilon \right]. \end{aligned} \quad (12.18)$$

After a trivial change of the integration variable, this is the same integral as in (1.343) whose result was given in (1.348) and (1.355), depending on the sign of

the energy E . The N -dependence happens to disappear completely as observed in Section 2.2.5. In the general case of an arbitrary smooth potential, the convergence is still assured by the dominance of the kinetic term in the integral measure.

The time-sliced path integral formula for the fixed-energy amplitude $(\mathbf{x}_b|\mathbf{x}_a)_E$ given by (12.17), (12.13), (12.14) has apparently the same range of validity as the original Feynman path integral for the time evolution amplitude $(\mathbf{x}_b t_b|\mathbf{x}_a t_a)$. Thus, so far nothing has been gained. However, the new formula has an important advantage over Feynman's. Due to the additional time integration it possesses a new *functional* degree of freedom. This can be exploited to find a path-integral formula without collapse at imaginary times. The starting point is the observation that the resolvent operator \hat{R} in Eq. (12.7) may be rewritten in the following three ways:

$$\hat{R} = \frac{i\hbar}{\hat{f}_l(E - \hat{H} + i\eta)} \hat{f}_l, \quad (12.19)$$

or

$$\hat{R} = \hat{f}_r \frac{i\hbar}{(E - \hat{H} + i\eta) \hat{f}_r}, \quad (12.20)$$

or, more generally,

$$\hat{R} = \hat{f}_r \frac{i\hbar}{\hat{f}_l(E - \hat{H} + i\eta) \hat{f}_r} \hat{f}_l, \quad (12.21)$$

where \hat{f}_l, \hat{f}_r are arbitrary operators which may depend on $\hat{\mathbf{p}}$ and $\hat{\mathbf{x}}$. They are called *regulating functions*. In the subsequent discussion, we shall avoid operator-ordering subtleties by assuming \hat{f}_l, \hat{f}_r to depend only on $\hat{\mathbf{x}}$, although the general case can also be treated along similar lines. Moreover, in the specific application to follow in Chapters 13 and 14, the operators \hat{f}_l, \hat{f}_r to be assumed consist of two different powers of one and the same operator \hat{f} , i.e.,

$$\hat{f}_l = \hat{f}^{1-\lambda}, \quad \hat{f}_r = \hat{f}^\lambda, \quad (12.22)$$

whose product is

$$\hat{f}_l \hat{f}_r = \hat{f}. \quad (12.23)$$

Taking the local matrix elements of (12.21) renders the alternative representations for the fixed-energy amplitude

$$\langle \mathbf{x}_b | \hat{R} | \mathbf{x}_a \rangle = (\mathbf{x}_b | \mathbf{x}_a)_E = \int_{s_a}^{\infty} ds_b \langle \mathbf{x}_b | \hat{U}_E(s_b - s_a) | \mathbf{x}_a \rangle, \quad (12.24)$$

where $\hat{U}_E(s)$ is the generalization of the modified time evolution operator (12.9), to be called the *pseudotime evolution operator*,

$$\hat{U}_E(s) \equiv f_r(\mathbf{x}) e^{-isf_l(\mathbf{x})(\hat{H}-E)f_r(\mathbf{x})} f_l(\mathbf{x}). \quad (12.25)$$

The operator in the exponent,

$$\hat{\mathcal{H}}_E \equiv f_l(\mathbf{x})(\hat{H} - E)f_r(\mathbf{x}), \quad (12.26)$$

may be considered as an auxiliary Hamiltonian which drives the state vectors $|\mathbf{x}\rangle$ of the system along a pseudotime s -axis, with the operator $e^{-is\hat{\mathcal{H}}_E/\hbar}$. Note that $\hat{\mathcal{H}}_E$ is in general not Hermitian, in which case $\hat{\mathcal{U}}_E(s)$ is not unitary.

As usual, we convert the expression (12.24) into a path integral by slicing the pseudotime interval $(0, s)$ into $N+1$ pieces, factorizing $\exp(-is\hat{\mathcal{H}}_E/\hbar)$ into a product of $N+1$ factors, and inserting a sequence of N completeness relations. The result is the approximate integral representation for the fixed-energy amplitude,

$$\langle \mathbf{x}_b | \mathbf{x}_a \rangle_E \approx (N+1) \int_0^\infty d\epsilon_s \langle \mathbf{x}_b | \hat{\mathcal{U}}_E^N(\epsilon_s(N+1)) | \mathbf{x}_a \rangle, \quad (12.27)$$

with the path integral for the pseudotime-sliced amplitude

$$\langle \mathbf{x}_b | \hat{\mathcal{U}}_E^N(\epsilon_s(N+1)) | \mathbf{x}_a \rangle = f_r(\mathbf{x}_b) f_l(\mathbf{x}_a) \prod_{n=1}^N \left[\int d^D x_n \right] \prod_{n=1}^{N+1} \left[\int \frac{d^D p_n}{(2\pi\hbar)^D} \right] e^{i\mathcal{A}_E^N/\hbar}, \quad (12.28)$$

whose time-sliced action reads

$$\mathcal{A}_E^N = \sum_{n=1}^{N+1} \{ \mathbf{p}_n(\mathbf{x}_n - \mathbf{x}_{n-1}) - \epsilon_s f_l(\mathbf{x}_n) [H(\mathbf{p}_n, \mathbf{x}_n) - E] f_r(\mathbf{x}_n) \}. \quad (12.29)$$

These equations constitute the desired generalization of the formulas (12.13)–(12.17). In the limit of large N , we can write the fixed-energy amplitude as an integral

$$\langle \mathbf{x}_b | \mathbf{x}_a \rangle_E = \int_0^\infty dS \langle \mathbf{x}_b | \hat{\mathcal{U}}_E(S) | \mathbf{x}_a \rangle \quad (12.30)$$

over the amplitude

$$\langle \mathbf{x}_b | \hat{\mathcal{U}}_E(S) | \mathbf{x}_a \rangle = f_r(\mathbf{x}_b) f_l(\mathbf{x}_a) \int \mathcal{D}x(s) \int \frac{\mathcal{D}p(s)}{2\pi\hbar} \exp \left\{ \frac{i}{\hbar} \int_0^S ds [\mathbf{p}\mathbf{x}' - \mathcal{H}_E(\mathbf{p}, \mathbf{x})] \right\}. \quad (12.31)$$

The prime on $\mathbf{x}(s)$ denotes the derivative with respect to the pseudotime s .

For a standard Hamiltonian of the form

$$H = T(\mathbf{p}) + V(\mathbf{x}), \quad (12.32)$$

with the kinetic energy

$$T(\mathbf{p}) = \frac{\mathbf{p}^2}{2M}, \quad (12.33)$$

the momenta \mathbf{p}_n in (12.28) can be integrated out and we obtain the configuration space path integral

$$\langle \mathbf{x}_b | \hat{\mathcal{U}}_E^N(\epsilon_s(N+1)) | \mathbf{x}_a \rangle = \frac{f_r(\mathbf{x}_b) f_l(\mathbf{x}_a)}{\sqrt{2\pi i \epsilon_s f_l(\mathbf{x}_b) f_r(\mathbf{x}_a) \hbar / M}^D} \quad (12.34)$$

$$\times \prod_{n=1}^N \left[\int \frac{d^D x_n}{\sqrt{2\pi i \epsilon_s f(\mathbf{x}_n) \hbar / M}^D} \right] e^{i\mathcal{A}_E^N / \hbar},$$

with the sliced action

$$\mathcal{A}_E^N = \sum_{n=1}^{N+1} \left\{ \frac{M}{2\epsilon_s f_l(\mathbf{x}_n) f_r(\mathbf{x}_{n-1})} (\mathbf{x}_n - \mathbf{x}_{n-1})^2 - \epsilon_s f_l(\mathbf{x}_n) [V(\mathbf{x}_n) - E] f_r(\mathbf{x}_{n-1}) \right\}. \quad (12.35)$$

In the limit of large N , this may be written as a path integral

$$\langle \mathbf{x}_b | \hat{\mathcal{U}}_E(S) | \mathbf{x}_a \rangle = f_r(\mathbf{x}_b) f_l(\mathbf{x}_a) \int \mathcal{D}x(s) \exp \left\{ \frac{i}{\hbar} \int_0^S ds \left[\frac{M}{2f_l f_r} \mathbf{x}'^2 - f_l(V - E) f_r \right] \right\}, \quad (12.36)$$

with the slicing specification (12.35).

The path integral formula for the fixed-energy amplitude based on Eqs. (12.30) and (12.36) is independent of the particular choice of the functions $f_l(\mathbf{x})$, $f_r(\mathbf{x})$, just like the most general operator expression for the resolvent (12.21). Feynman's original time-sliced formula is, of course, recovered with the special choice $f_l(\mathbf{x}) \equiv f_r(\mathbf{x}) \equiv 1$.

When comparing (12.25) with (12.9), we see that for each infinitesimal pseudo-time slice, the thickness of the true time slices has the space-dependent value

$$dt = ds f_l(\mathbf{x}_n) f_r(\mathbf{x}_{n-1}). \quad (12.37)$$

The freedom in choosing $f(\mathbf{x})$ amounts to an *invariance under path-dependent time reparametrizations* of the fixed-energy amplitude (12.30). Note that the invariance is exact in the general operator formula (12.21) for the resolvent and in the continuum path integral formula based on (12.30) and (12.36). However, the finite pseudotime slicing in (12.34), (12.35) used to define the path integral, destroys this invariance. At a finite value of N , different choices of $f(\mathbf{x})$ produce different approximations to the matrix element of the operator $\hat{\mathcal{U}}_E(s) = f_r(\hat{\mathbf{x}}) e^{-is\hat{\mathcal{H}}_E(\hat{\mathbf{p}}, \hat{\mathbf{x}})/\hbar} f_l(\hat{\mathbf{x}})$. Their quality can vary greatly. In fact, if the potential is singular and the regulating functions $f_r(\mathbf{x})$, $f_l(\mathbf{x})$ are not suitably chosen, the Euclidean pseudotime-sliced expression may not exist at all. This is what happens in the Coulomb system if the functions $f_l(\mathbf{x})$ and $f_r(\mathbf{x})$ are both chosen to be unity as in Feynman's path integral formula.

The new reparametrization freedom gained by the functions $f_l(\mathbf{x})$, $f_r(\mathbf{x})$ is therefore not just a luxury. It is *essential* for stabilizing the Euclidean time-sliced orbital fluctuations in singular potentials.

In the case of the Coulomb system, any choice of the regulating functions $f_l(\mathbf{x})$, $f_r(\mathbf{x})$ with $f(\mathbf{x}) = r$ leads to a regular auxiliary Hamiltonian \mathcal{H}_E , and the

path integral expressions (12.27)–(12.36) are all well defined. This was the important discovery of Duru and Kleinert in 1979, to be described in detail in Chapter 13, which has made a large class of previously non-existing Feynman path integrals solvable. By a similar Duru-Kleinert transformation with $f_l(\mathbf{x}), f_r(\mathbf{x})$ with $f(\mathbf{x}) = \sqrt{f_l(\mathbf{x})f_r(\mathbf{x})} = r^2$, the earlier difficulties with the centrifugal barrier are resolved, as will be seen in Chapter 14.

12.3 Time-Dependent Regularization

Before treating specific cases, let us note that there exists a further generalization of the above path integral formula which is useful in systems with a time-dependent Hamiltonian $H(\mathbf{p}, \mathbf{x}, t)$. There we introduce an auxiliary Hamiltonian

$$\hat{\mathcal{H}} = f_l(\mathbf{x}, t)[H(\hat{\mathbf{p}}, \mathbf{x}, t) - \hat{E}]f_r(\mathbf{x}, t), \quad (12.38)$$

where \hat{E} is the differential operator for the energy which is canonically conjugate to the time t :

$$\hat{E} \equiv i\hbar\partial_t. \quad (12.39)$$

The auxiliary Hamiltonian acts on an extended Hilbert space, in which the states are localized in space *and* time. These states will be denoted by $|\mathbf{x}, t\rangle$. They satisfy the orthogonality and completeness relations

$$\{\mathbf{x}t|\mathbf{x}'t'\} = \delta^{(D)}(\mathbf{x} - \mathbf{x}')\delta(t - t'), \quad (12.40)$$

and

$$\int d^Dx \int dt |\mathbf{x}t\rangle\langle\mathbf{x}t| = 1, \quad (12.41)$$

respectively. By construction, the Hamiltonian \mathcal{H} does not depend explicitly on the pseudotime s . The pseudotime evolution operator is therefore obtained by a simple exponentiation, as in (12.25),

$$\hat{\mathcal{U}}(s) \equiv f_r(\mathbf{x}, t)e^{-isf_l(\mathbf{x}, t)(\hat{H} - \hat{E})f_r(\mathbf{x}, t)}f_l(\mathbf{x}, t). \quad (12.42)$$

The derivation of the path integral is then completely analogous to the time-independent case. The operator (12.42) is sliced into $N + 1$ pieces, and N completeness relations (12.41) are inserted to obtain the path integral

$$\begin{aligned} \{\mathbf{x}_b t_b|\hat{\mathcal{U}}^N(s)|\mathbf{x}_a t_a\} &= f_r(\mathbf{x}_b, t_b)f_l(\mathbf{x}_a, t_a) \\ &\times \prod_{n=1}^N \left[\int d^Dx_n dt_n \right] \prod_{n=1}^{N+1} \left[\int \frac{d^Dp_n}{(2\pi\hbar)^D} \frac{dE_n}{2\pi\hbar} \right] e^{i\mathcal{A}^N/\hbar}, \end{aligned} \quad (12.43)$$

with the pseudotime-sliced action

$$\begin{aligned} \mathcal{A}^N &= \sum_{n=1}^{N+1} \{ \mathbf{p}_n(\mathbf{x}_n - \mathbf{x}_{n-1}) - E_n(t_n - t_{n-1}) \\ &\quad - f_l(\mathbf{x}_n, t_n) [H(\mathbf{p}_n, \mathbf{x}_n, t_n) - E_n] f_r(\mathbf{x}_{n-1}, t_{n-1}) \}, \end{aligned} \quad (12.44)$$

where $\mathbf{x}_b = \mathbf{x}_{N+1}$, $t_b = t_{N+1}$; $\mathbf{x}_a = \mathbf{x}_0$, $t_a = t_0$. This describes orbital fluctuations in the phase space of spacetime which contains fluctuating worldlines $\mathbf{x}(s), t(s)$ and their canonically conjugate spacetime $\mathbf{p}(s), E(s)$. In the limit $N \rightarrow \infty$ we write this as

$$\begin{aligned} \{\mathbf{x}_b t_b | \hat{\mathcal{U}}(S) | \mathbf{x}_a t_a\} &= f_r(\mathbf{p}_b, \mathbf{x}_b, t_b) f_l(\mathbf{p}_a, \mathbf{x}_a, t_a) \\ &\times \int \mathcal{D}^D x(s) \mathcal{D}t(s) \int \frac{\mathcal{D}^D p(s)}{(2\pi\hbar)^D} \frac{\mathcal{D}E(s)}{2\pi\hbar} e^{iA/\hbar}, \end{aligned} \quad (12.45)$$

with the continuous action

$$\begin{aligned} \mathcal{A}[\mathbf{p}, \mathbf{x}, E, t] &= \int_0^S ds \{ \mathbf{p}(s) \mathbf{x}'(s) - E(s) t'(s) \\ &- f_l(\mathbf{p}(s), \mathbf{x}(s), t(s)) [H(\mathbf{p}(s), \mathbf{x}(s), t(s)) - E(s)] f_r(\mathbf{p}(s), \mathbf{x}(s), t(s)) \}. \end{aligned} \quad (12.46)$$

In the pseudotime-sliced formula (12.43), we can integrate out all intermediate energy variables E_n and obtain

$$\begin{aligned} \{\mathbf{x}_b t_b | \hat{\mathcal{U}}(S) | \mathbf{x}_a t_a\} &= \prod_{n=1}^N \left[\int d^D x_n \right] \prod_{n=1}^{N+1} \left[\int \frac{d^D p_n}{(2\pi\hbar)^D} \right] \\ &\times \delta \left(t_b - t_a - \epsilon_s \sum_{n=1}^{N+1} f_l(\mathbf{p}_n, \mathbf{x}_n, t_n) f_r(\mathbf{p}_{n-1}, \mathbf{x}_{n-1}, t_{n-1}) \right) e^{i\tilde{\mathcal{A}}^N/\hbar} \end{aligned} \quad (12.47)$$

with the action

$$\tilde{\mathcal{A}}^N = \sum_{n=1}^{N+1} [\mathbf{p}_n (\mathbf{x}_n - \mathbf{x}_{n-1}) - \epsilon_s f_l(\mathbf{p}_n, \mathbf{x}_n, t_n) H(\mathbf{p}_n, \mathbf{x}_n, t_n) f_r(\mathbf{p}_{n-1}, \mathbf{x}_{n-1}, t_{n-1})]. \quad (12.48)$$

This looks just like an ordinary time-sliced action with a time-dependent Hamiltonian. The constant width of the time slices $\epsilon = (t_b - t_a)/(N + 1)$, however, has now become variable and depends on phase space and time:

$$\epsilon \rightarrow \epsilon_s f_l(\mathbf{p}_n, \mathbf{x}_n, t_n) f_r(\mathbf{p}_{n-1}, \mathbf{x}_{n-1}, t_{n-1}). \quad (12.49)$$

The δ -function in (12.47) ensures the correct relation between the pseudotime s and the physical time t . In the continuum limit we may write (12.47) as

$$\{\mathbf{x}_b t_b | \hat{\mathcal{U}}(S) | \mathbf{x}_a t_a\} = \int \mathcal{D}^D x(s) \int \frac{\mathcal{D}^D p(s)}{(2\pi\hbar)^D} \delta(t_b - t_a - \int_0^S ds f(\mathbf{x}, t)) e^{i\tilde{\mathcal{A}}/\hbar}, \quad (12.50)$$

with the pseudotime action

$$\tilde{\mathcal{A}}[\mathbf{p}, \mathbf{x}, t] = \int_0^S ds [\mathbf{p} \mathbf{x}' - f_l(\mathbf{x}, t) H(\mathbf{p}, \mathbf{x}, t) f_r(\mathbf{x}, t)], \quad (12.51)$$

which is a functional of the s -dependent paths $\mathbf{x}(s), \mathbf{p}(s), t(s)$. Note that in the continuum formula, the splitting of the regulating function $f(\mathbf{x}, t)$ into $f_l(\mathbf{x}, t)$ and

$f_r(\mathbf{x}, t)$ according to the parameter λ in Eq. (12.22) cannot be expressed properly since f_l, H , and f_r are commuting c -number functions. We have written them in a way indicating their order in the time-sliced expressions (12.47), (12.48).

The integral over S yields the original time evolution amplitude

$$(\mathbf{x}_b t_b | \mathbf{x}_a t_a) = \int_0^\infty dS \{ \mathbf{x}_b t_b | \hat{\mathcal{U}}(S) | \mathbf{x}_a t_a \} = \left\{ \mathbf{x}_b t_b \left| \frac{i\hbar}{\hat{H} - \hat{E}} \right| \mathbf{x}_a t_a \right\}. \quad (12.52)$$

Indeed, by Fourier decomposing the scalar products $\{ \mathbf{x}_b t_b | \mathbf{x}_a t_a \}$,

$$\{ \mathbf{x}_b t_b | \mathbf{x}_a t_a \} = \int \frac{d^D p}{(2\pi\hbar)^D} \int \frac{dE}{2\pi\hbar} e^{i\mathbf{p}(\mathbf{x}_b - \mathbf{x}_a)/\hbar - iE(t_b - t_a)/\hbar}, \quad (12.53)$$

we see that the right-hand side satisfies the same Schrödinger equation as the left-hand side:

$$[H(-i\hbar\partial_{\mathbf{x}}, \mathbf{x}, t) - i\hbar\partial_t] (\mathbf{x} t | \mathbf{x}_a t_a) = -i\hbar\delta^{(D)}(\mathbf{x} - \mathbf{x}_a)\delta(t - t_a) \quad (12.54)$$

[recall (1.308) and (12.5)]. If the δ -function in (12.47) is written as a Fourier integral, ref(1.308)
we obtain a kind of spectral decomposition of the amplitude (12.52), lab(x1.327)
est(1.327)

$$(\mathbf{x}_b t_b | \mathbf{x}_a t_a) = \int_{-\infty}^{\infty} dE e^{-iE(t_b - t_a)/\hbar} \int_0^\infty dS \{ \mathbf{x}_b t_b | \hat{\mathcal{U}}_E(S) | \mathbf{x}_a t_a \}, \quad (12.55)$$

with the pseudotime evolution amplitude:

$$\hat{\mathcal{U}}_E(s) \equiv f_r(\hat{\mathbf{p}}, \mathbf{x}, t) e^{-is f_l(\hat{\mathbf{p}}, \mathbf{x}, t)(\hat{H} - E) f_r(\hat{\mathbf{p}}, \mathbf{x}, t)} f_l(\hat{\mathbf{p}}, \mathbf{x}, t). \quad (12.56)$$

12.4 Relation to Schrödinger Theory. Wave Functions

For completeness, consider also the ordinary Schrödinger quantum mechanics described by the pseudo-Hamiltonian $\hat{\mathcal{H}}$. This operator is the generator of translations of the system along the pseudotime axis s . Let $\phi(\mathbf{x}, t, s)$ be a solution of the pseudotime Schrödinger equation

$$\mathcal{H}(\hat{\mathbf{p}}, \mathbf{x}, \hat{E}, t) \phi(\mathbf{x}, t, s) = i\hbar\partial_s \phi(\mathbf{x}, t, s), \quad (12.57)$$

written more explicitly as

$$f_l(\mathbf{x}, t) [H(\hat{\mathbf{p}}, \mathbf{x}, t) - i\hbar\partial_t] f_r(\mathbf{x}, t) \phi(\mathbf{x}, t, s) = i\hbar\partial_s \phi(\mathbf{x}, t, s). \quad (12.58)$$

Since the left-hand side is independent of s , the s -dependence of $\phi(\mathbf{x}, t, s)$ can be factored out:

$$\phi(\mathbf{x}, t, s) = \phi_{\mathcal{E}}(\mathbf{x}, t) e^{-i\mathcal{E}s/\hbar}. \quad (12.59)$$

If H is independent of the time t , it is always possible to stabilize the path integral by a time-independent reparametrization function $f(\mathbf{x})$. Then we remove an oscillating factor $e^{-iEt/\hbar}$ from $\phi_{\mathcal{E}}(\mathbf{x}, t)$ and factorize

$$\phi_{\mathcal{E}}(\mathbf{x}, t) = \phi_{\mathcal{E}, E}(\mathbf{x}) e^{-iEt/\hbar}. \quad (12.60)$$

This leaves us with the time- and pseudotime-independent equation

$$\begin{aligned} \mathcal{H}(\hat{\mathbf{p}}, \mathbf{x}, E)\phi_{\mathcal{E}, E}(\mathbf{x}) &= f_l(\mathbf{x}) [H(\hat{\mathbf{p}}, \mathbf{x}) - E] f_r(\mathbf{x})\phi_{\mathcal{E}, E}(\mathbf{x}) \\ &= \mathcal{E}\phi_{\mathcal{E}, E}(\mathbf{x}). \end{aligned} \quad (12.61)$$

For each value of E , there will be a different spectrum of eigenvalues \mathcal{E}_n . This is indicated by writing the eigenvalues \mathcal{E}_n as $\mathcal{E}_n(E)$ and the associated eigenstates $\phi_{\mathcal{E}_n, E}(\mathbf{x})$ as $\phi_{\mathcal{E}_n(E)}$.

Suppose that we possess a complete set of such eigenstates at a fixed energy E labeled by a quantum number n (which is here assumed to take discrete values although it may include continuous values, as usual). We can then write down a spectral representation for the local matrix elements of the pseudotime evolution amplitude (12.25):

$$\langle \mathbf{x}_b | \hat{\mathcal{U}}_E(S) | \mathbf{x}_a \rangle = f_r(\mathbf{x}_b) f_l(\mathbf{x}_a) \sum_n \phi_{\mathcal{E}_n(E)}(\mathbf{x}_b) \phi_{\mathcal{E}_n(E)}^*(\mathbf{x}_a) e^{-iS\mathcal{E}_n(E)/\hbar}. \quad (12.62)$$

From this we find the expansion for the fixed-energy amplitude (12.24):

$$(\mathbf{x}_b | \mathbf{x}_a)_E = f_r(\mathbf{x}_b) f_l(\mathbf{x}_a) \sum_n \phi_{\mathcal{E}_n(E)}(\mathbf{x}_b) \phi_{\mathcal{E}_n(E)}^*(\mathbf{x}_a) \frac{i\hbar}{\mathcal{E}_n(E)}.$$

The time evolution amplitude is given by the Fourier transform

$$(\mathbf{x}_b t_b | \mathbf{x}_a t_a) = f_r(\mathbf{x}_b) f_l(\mathbf{x}_a) \int_{-\infty}^{\infty} \frac{dE}{2\pi\hbar} e^{iE(t_b - t_a)/\hbar} \sum_n \phi_{\mathcal{E}_n(E)}(\mathbf{x}_b) \phi_{\mathcal{E}_n(E)}^*(\mathbf{x}_a) \frac{i\hbar}{\mathcal{E}_n(E)}. \quad (12.63)$$

This is to be compared with the usual spectral representation of this amplitude for the time-independent Hamiltonian \hat{H}

$$(\mathbf{x}_b t_b | \mathbf{x}_a t_a) = \sum_n \psi_n(\mathbf{x}_b) \psi_n^*(\mathbf{x}_a) e^{-iE_n(t_b - t_a)/\hbar}, \quad (12.64)$$

where $\psi_n(\mathbf{x})$ are the solutions of the ordinary time-independent Schrödinger equation:

$$H(\hat{\mathbf{p}}, \mathbf{x})\psi_n(\mathbf{x}) = E_n\psi_n(\mathbf{x}). \quad (12.65)$$

The relation between the two representations (12.63) and (12.64) is found by observing that for the energy E coinciding with the energy E_n , the eigenvalue $\mathcal{E}_n(E)$ vanishes, i.e., $i\hbar/\mathcal{E}_n(E)$ has poles at $E = E_n$ of the form

$$\frac{i\hbar}{\mathcal{E}_n(E)} \approx \frac{1}{\mathcal{E}'_n(E_n)} \frac{i\hbar}{E - E_n + i\eta}. \quad (12.66)$$

These contribute to the energy integral in (12.63) with a sum

$$(\mathbf{x}_b t_b | \mathbf{x}_a t_a) \sim f_r(\mathbf{x}_b) f_l(\mathbf{x}_a) \sum_n \phi_{\mathcal{E}_n(E_n)}(\mathbf{x}_b) \phi_{\mathcal{E}_n(E_n)}^*(\mathbf{x}_a) e^{-iE_n(t_b - t_a)/\hbar}. \quad (12.67)$$

A comparison with (12.64) shows the relation between the bound-state wave functions of the ordinary and the pseudotime Schrödinger equation. In general, the function $i\hbar/\mathcal{E}_n(E)$ also has cuts whose discontinuities contain the continuum wave functions of the Schrödinger equation (12.65).

These observations will become more transparent in Section 13.8 when treating in detail the bound and continuum wave functions of the Coulomb system.

Notes and References

The general path integral formula with time reparametrization was introduced by H. Kleinert, Phys. Lett. A **120**, 361 (1987) (<http://www.physik.fu-berlin.de/~kleinert/163>). The stability aspects are discussed in H. Kleinert, Phys. Lett. B **224**, 313 (1989) (*ibid.*[http/195](http://195)).

13

Path Integral of Coulomb System

One of the most important successes of Schrödinger quantum mechanics is the explanation of the energy levels and transition amplitudes of the hydrogen atom. Within the path integral formulation of quantum mechanics, this fundamental system has resisted for many years all attempts at a solution. An essential advance was made in 1979 when Duru and Kleinert [1] recognized the need to work with a generalized pseudotime-sliced path integral of the type described in Chapter 12. After an appropriate coordinate transformation the path integral became harmonic and solvable. A generalization of this two-step transformation has meanwhile led to the solution of many other path integrals to be presented in Chapter 14. The final solution of the problem turned out to be quite subtle due to the nonholonomic nature of the subsequent coordinate transformation which required the development of a correct path integral in spaces with curvature and torsion [2], as done in Chapter 10. Only this made it possible to avoid unwanted fluctuation corrections in the Duru-Kleinert transformation of the Coulomb system, a problem in all earlier attempts.

The first consistent solution was presented in the first edition of this book in 1990.

13.1 Pseudotime Evolution Amplitude

Consider the path integral for the time evolution amplitude of an electron-proton system with a Coulomb interaction. If m_e and m_p denote the masses of the two particles whose reduced mass is $M = m_e m_p / (m_e + m_p)$, and if e is the electron charge, the system is governed by the Hamiltonian

$$H = \frac{p^2}{2M} - \frac{e^2}{r}. \quad (13.1)$$

The formal continuum path integral for the time evolution amplitude reads

$$\langle \mathbf{x}_b t_b | \mathbf{x}_a t_a \rangle = \int \mathcal{D}^3 x(t) \exp \left[\frac{i}{\hbar} \int_{t_b}^{t_a} dt (\mathbf{p}\dot{\mathbf{x}} - H) \right]. \quad (13.2)$$

As observed in the last chapter, its Euclidean version cannot be time-sliced into a finite number of integrals since the paths would collapse. The paths would stretch out into a straight line with $\dot{\mathbf{x}} \approx 0$ and slide down into the $1/r$ -abyss. A path integral whose Euclidean version is stable can be written down using the pseudotime evolution amplitude (12.28). A convenient family of regulating functions is

$$f_l(\mathbf{x}) = f(\mathbf{x})^{1-\lambda}, \quad f_r(\mathbf{x}) = f(\mathbf{x})^\lambda, \quad (13.3)$$

whose product satisfies $f_l(\mathbf{x})f_r(\mathbf{x}) = f(\mathbf{x}) = r$. Since the path integral represents the general resolvent operator (12.21), all results must be independent of the splitting parameter λ after going to the continuum limit. This independence is useful in checking the calculations.

Thus we consider the fixed-energy amplitude

$$\langle \mathbf{x}_b | \mathbf{x}_a \rangle_E = \int_0^\infty dS \langle \mathbf{x}_b | \hat{\mathcal{U}}_E(S) | \mathbf{x}_a \rangle, \quad (13.4)$$

with the pseudotime-evolution amplitude

$$\langle \mathbf{x}_b | \hat{\mathcal{U}}_E(S) | \mathbf{x}_a \rangle = r_b^\lambda r_a^{1-\lambda} \int \mathcal{D}^D x(s) \int \frac{\mathcal{D}^D p(s)}{(2\pi\hbar)^D} \exp \left\{ \frac{i}{\hbar} \int_0^S ds [\mathbf{p} \mathbf{x}' - r^{1-\lambda} (H - E) r^\lambda] \right\}, \quad (13.5)$$

where the prime denotes the derivative with respect to the pseudotime argument s . For the sake of generality, we have allowed for a general dimension D of orbital motion. After time slicing and with the notation $\Delta \mathbf{x}_n \equiv \mathbf{x}_n - \mathbf{x}_{n-1}$, $\epsilon_s \equiv S/(N+1)$, the amplitude (13.5) reads

$$\langle \mathbf{x}_b | \hat{\mathcal{U}}_E(S) | \mathbf{x}_a \rangle \approx r_b^\lambda r_a^{1-\lambda} \prod_{n=2}^{N+1} \left[\int_{-\infty}^{\infty} d^D \Delta x_n \right] \prod_{n=1}^{N+1} \left[\int_{-\infty}^{\infty} \frac{d^D p_n}{(2\pi\hbar)^D} \right] e^{i\mathcal{A}_E^N/\hbar}, \quad (13.6)$$

where the action is

$$\mathcal{A}_E^N[\mathbf{p}, \mathbf{x}] = \sum_{n=1}^{N+1} \left[\mathbf{p}_n \Delta \mathbf{x}_n - \epsilon_s r_n^{1-\lambda} r_{n-1}^\lambda \left(\frac{\mathbf{p}_n^2}{2M} - E \right) + \epsilon_s e^2 \right]. \quad (13.7)$$

The term $\epsilon_s e^2$ carries initially a factor $(r_{n-1}/r_n)^\lambda$ which is dropped, since it is equal to unity in the continuum limit. When integrating out the momentum variables, $N+1$ factors $1/(r_n^{1-\lambda} r_{n-1}^\lambda)^{D/2}$ appear. After rearranging these, the configuration space path integral becomes

$$\langle \mathbf{x}_b | \hat{\mathcal{U}}_E(S) | \mathbf{x}_a \rangle \approx \frac{r_b^\lambda r_a^{1-\lambda}}{\sqrt{2\pi i \epsilon_s \hbar r_b^{1-\lambda} r_a^\lambda / M}} \prod_{n=2}^{N+1} \left[\int \frac{d^D \Delta \mathbf{x}_n}{\sqrt{2\pi i \epsilon_s \hbar r_{n-1} / M}} \right] e^{i\mathcal{A}_E^N[\mathbf{x}, \mathbf{x}']/\hbar}, \quad (13.8)$$

with the pseudotime-sliced action

$$\mathcal{A}_E^N[\mathbf{x}, \mathbf{x}'] = (N+1)\epsilon_s e^2 + \sum_{n=1}^{N+1} \left[\frac{M}{2} \frac{(\Delta \mathbf{x}_n)^2}{\epsilon_s r_n^{1-\lambda} r_{n-1}^\lambda} + \epsilon_s r_n E \right]. \quad (13.9)$$

In the last term, we have replaced $r_n^{1-\lambda} r_{n-1}^\lambda$ by r_n without changing the continuum limit. The limiting action can formally be written as

$$\mathcal{A}_E[\mathbf{x}, \mathbf{x}'] = e^2 S + \int_0^S ds \left(\frac{M}{2r} \mathbf{x}'^2 + Er \right). \quad (13.10)$$

We now solve the Coulomb path integral first in two dimensions, assuming that the movement of the electron is restricted to a plane while the electric field extends into the third dimension. Afterwards we proceed to the physical three-dimensional system. The case of an arbitrary dimension D will be solved in Chapter 14. The one-dimensional case will not be treated here. The exact energy levels were found before at the end of Section 4.1 from a semiclassical expansion. For a long time, the one-dimensional Coulomb system was only of mathematical interest. Recently, however, it has received increased attention due to the possibility of forming hydrogen-like bound states in *quantum wires* [3].

13.2 Solution for the Two-Dimensional Coulomb System

First we observe that the kinetic pseudoenergy has a scale dimension $[rp^2] \sim [r^{-1}]$ which is precisely opposite to that of the potential term $[r^{+1}]$. The dimensional situation is similar to that of the harmonic oscillator, where the dimensions are $[p^2] = [r^{-2}]$ and $[r^{+2}]$, respectively. It is possible to make the correspondence perfect by describing the Coulomb system in terms of “square root coordinates”, i.e., by transforming $r \rightarrow u^2$. In two dimensions, the appropriate square root is given by the *Levi-Civita transformation*

$$\begin{aligned} x^1 &= (u^1)^2 - (u^2)^2, \\ x^2 &= 2u^1 u^2. \end{aligned} \quad (13.11)$$

If we imagine the vectors \mathbf{x} and \mathbf{u} to move in the complex planes parametrized by $x = x^1 + ix^2$ and $u = u^1 + iu^2$, the transformed variable u corresponds to the complex square root:

$$u = \sqrt{x}. \quad (13.12)$$

Let us also introduce the matrix

$$A(\mathbf{u}) = \begin{pmatrix} u^1 & -u^2 \\ u^2 & u^1 \end{pmatrix}, \quad (13.13)$$

and write (13.11) as a matrix equation:

$$\mathbf{x} = A(\mathbf{u})\mathbf{u}. \quad (13.14)$$

The Levi-Civita transformation is an integrable coordinate transformation which carries the flat x^i -space into a flat u^μ -space. We mention this fact since in the later treatment of the three-dimensional hydrogen atom, the transition to the “square root

coordinates" will require a nonintegrable (nonholonomic) coordinate transformation defined only differentially. As explained in Chapter 10, such mappings change, in general, a flat Euclidean space into a space with curvature and torsion. The generation of torsion is precisely the reason why the three-dimensional system remained unsolved until 1990. In two dimensions, this phenomenon happens to be absent.

If we write the transformation (13.11) in terms of a basis dyad $e^i_\mu(\mathbf{u})$ as $dx^i = e^i_\mu(\mathbf{u}) du^\mu$, this is given by

$$e^i_\mu(\mathbf{u}) = \frac{\partial x^i}{\partial u^\mu}(\mathbf{u}) = 2A^i_\mu(\mathbf{u}), \quad (13.15)$$

with the reciprocal dyad

$$e_i^\mu(\mathbf{u}) = \frac{1}{2}(A^{-1})^{T_i}{}^\mu(\mathbf{u}) = \frac{1}{2\mathbf{u}^2}A^i_\mu(\mathbf{u}). \quad (13.16)$$

The associated affine connection

$$\Gamma_{\mu\nu}{}^\lambda = e_i{}^\lambda \partial_\mu e^i{}_\nu = \frac{1}{\mathbf{u}^2}[(\partial_\mu A)^T A]_{\nu\lambda} \quad (13.17)$$

has the matrix elements $(\Gamma_\mu)_\nu{}^\lambda = \Gamma_{\mu\nu}{}^\lambda$:

$$\begin{aligned} (\Gamma_1)_\mu{}^\nu &= \frac{1}{\mathbf{u}^2} \begin{pmatrix} u^1 & -u^2 \\ u^2 & u^1 \end{pmatrix}_\mu{}^\nu = \frac{1}{2\mathbf{u}^2} A(\mathbf{u})^\mu{}_\nu, \\ (\Gamma_2)_\mu{}^\nu &= \frac{1}{\mathbf{u}^2} \begin{pmatrix} u^2 & u^1 \\ -u^1 & u^2 \end{pmatrix}_\mu{}^\nu. \end{aligned} \quad (13.18)$$

The affine connection satisfies the important identity

$$\Gamma_\mu{}^{\mu\lambda} \equiv 0, \quad (13.19)$$

which follows from the defining relation

$$\Gamma_\mu{}^{\mu\lambda} \equiv g^{\mu\nu} e_i{}^\lambda \partial_\mu e^i{}_\nu, \quad (13.20)$$

by inserting the obvious special property of e^i_μ

$$\partial_\mu e^i{}_\mu = \partial_{\mathbf{u}}^2 x^i(\mathbf{u}) = 0, \quad (13.21)$$

using the diagonality of $g^{\mu\nu} = \delta^{\mu\nu}/4r$.

The identity (13.19) will be shown in Section 13.6 to be the essential geometric reason for the absence of the time slicing corrections.

The torsion and the Riemann-Cartan curvature tensor vanish identically, the former because of the specific form of the matrix elements (13.18), the latter due to the linearity of the basis dyads $e^i_\mu(\mathbf{u})$ in \mathbf{u} which guarantees trivially the integrability conditions, i.e.,

$$e_i{}^\lambda (\partial_\mu e^i{}_\nu - \partial_\nu e^i{}_\mu) \equiv 0, \quad (13.22)$$

$$e_i{}^\kappa (\partial_\mu \partial_\nu - \partial_\nu \partial_\mu) e^i{}_\lambda \equiv 0, \quad (13.23)$$

and thus $S_{\mu\nu}{}^\lambda \equiv 0$, $R_{\mu\nu\lambda}{}^\kappa \equiv 0$.

In the continuum limit, the Levi-Civita transformation converts the action (13.10) into that of a harmonic oscillator. With

$$\mathbf{x}'^2 = 4\mathbf{u}^2 \mathbf{u}'^2 = 4r \mathbf{u}'^2 \quad (13.24)$$

we find

$$\mathcal{A}[\mathbf{x}] = e^2 S + \int_0^S ds \left(\frac{4M}{2} \mathbf{u}'^2 + E \mathbf{u}^2 \right). \quad (13.25)$$

Apart from the trivial term $e^2 S$, this is the action of a harmonic oscillator

$$\mathcal{A}_{\text{os}}[\mathbf{u}] = \int_0^S ds \frac{\mu}{2} (\mathbf{u}'^2 - \omega^2 \mathbf{u}^2), \quad (13.26)$$

which oscillates in the pseudotime s with an effective mass

$$\mu = 4M, \quad (13.27)$$

and a pseudofrequency

$$\omega = \sqrt{-E/2M}. \quad (13.28)$$

Note that ω has the dimension $1/s$ corresponding to $[\omega] = [r/t]$ (in contrast to a usual frequency whose dimension is $[1/t]$).

The path integral is well defined only as long as the energy E of the Coulomb system is negative, i.e., in the bound-state regime. The amplitude in the continuum regime with positive E will be obtained by analytic continuation.

In the regularized form, the pseudotime-sliced amplitude is calculated as follows. Choosing a splitting parameter $\lambda = 1/2$ and ignoring for the moment all complications due to the finite time slicing, we deduce from (13.14) that

$$d\mathbf{x} = 2A(\mathbf{u})d\mathbf{u}, \quad (13.29)$$

and hence

$$d^2 x_n = 4\mathbf{u}_n^2 d^2 u_n. \quad (13.30)$$

Since the \mathbf{x} - and the \mathbf{u} -space are both Euclidean, the integrals over $\Delta\mathbf{x}_n$ in (13.8) can be rewritten as integrals over \mathbf{x}_n , and transformed directly to \mathbf{u}_n variables. The result is

$$\langle \mathbf{x}_b | \hat{\mathcal{U}}_E(S) | \mathbf{x}_a \rangle = \frac{1}{4} e^{ie^2 S/\hbar} [(\mathbf{u}_b S | \mathbf{u}_a 0) + (-\mathbf{u}_b S | \mathbf{u}_a 0)], \quad (13.31)$$

where $(\mathbf{u}_b S | \mathbf{u}_a 0)$ denotes the time-sliced oscillator amplitude

$$\begin{aligned} (\mathbf{u}_b S | \mathbf{u}_a 0) &\approx \frac{1}{2\pi i \hbar \epsilon_s / \mu} \prod_{n=1}^N \left[\int \frac{d^2 u_n}{2\pi i \hbar \epsilon_s / \mu} \right] \\ &\times \exp \left\{ \frac{i}{\hbar} \sum_{n=1}^N \frac{\mu}{2} \left(\frac{1}{\epsilon_s} \Delta \mathbf{u}_n^2 - \epsilon_s \omega^2 \mathbf{u}_n^2 \right) \right\}. \end{aligned} \quad (13.32)$$

Figure 13.1 Illustration of associated final points in \mathbf{u} -space, to be summed in the oscillator amplitude. In \mathbf{x} -space, the paths run from \mathbf{x}_a to \mathbf{x}_b once directly and once after crossing the cut into the second sheet of the complex function $u = \sqrt{x}$.

The evaluation of the Gaussian integrals yields, in the continuum limit [recall (2.177)]:

$$(\mathbf{u}_b S | \mathbf{u}_a 0) = \frac{\mu\omega}{2\pi i \hbar \sin \omega S} \exp \left\{ \frac{i}{2\hbar} \frac{\mu\omega}{\sin \omega S} [(\mathbf{u}_b^2 + \mathbf{u}_a^2) \cos \omega S - 2\mathbf{u}_b \mathbf{u}_a] \right\}. \quad (13.33)$$

The symmetrization in \mathbf{u}_b in Eq. (13.31) is necessary since for each path from \mathbf{x}_a to \mathbf{x}_b , there are two paths in the square root space, one from \mathbf{u}_a to \mathbf{u}_b and one from \mathbf{u}_a to $-\mathbf{u}_b$ (see Fig. 13.1).

The fixed-energy amplitude is obtained by the integral (13.4) over the pseudo-time evolution amplitude (12.18):

$$(\mathbf{x}_b | \mathbf{x}_a)_E = \int_0^\infty dS e^{ie^2 S/\hbar} \frac{1}{4} [(\mathbf{u}_b S | \mathbf{u}_a 0) + (-\mathbf{u}_b S | \mathbf{u}_a 0)]. \quad (13.34)$$

By inserting (13.33), this becomes

$$\begin{aligned} (\mathbf{x}_b | \mathbf{x}_a)_E &= \frac{1}{2} \int_0^\infty dS \exp(i e^2 S/\hbar) F^2(S) \\ &\times \exp \left[-\pi F^2(S) (\mathbf{u}_b^2 + \mathbf{u}_a^2) \cos \omega S \right] \cosh \left[2\pi F^2(S) \mathbf{u}_b \mathbf{u}_a \right], \end{aligned} \quad (13.35)$$

with the abbreviation

$$F(S) = \sqrt{\mu\omega/2\pi i \hbar \sin \omega S}, \quad (13.36)$$

for the one-dimensional fluctuation factor [recall (2.171)]. The coordinates \mathbf{u}_b and \mathbf{u}_a on the right-hand side are related to $\mathbf{x}_b, \mathbf{x}_a$ on the left-hand side by

$$\mathbf{u}_{a,b}^2 = r_{a,b}, \quad \mathbf{u}_b \mathbf{u}_a = \sqrt{(r_b r_a + \mathbf{x}_b \mathbf{x}_a)/2}. \quad (13.37)$$

When performing the integral over S , we have to pass around the singularities in $F(S)$ in accordance with the $i\eta$ -prescription, replacing $\omega \rightarrow \omega - i\eta$. Equivalently, we

can rotate the contour of S -integration to make it run along the negative imaginary semi-axis,

$$S = -i\sigma, \quad \sigma \in (0, \infty).$$

This amounts to going over to the Euclidean amplitude of the harmonic oscillator in which the singularities are completely avoided. The amplitude is rewritten in a more compact form by introducing the variables

$$\varrho \equiv e^{-2i\omega S} = e^{-2\omega\sigma}, \quad (13.38)$$

$$\kappa \equiv \frac{\mu\omega}{2\hbar} = \frac{2M\omega}{\hbar} = \sqrt{-2ME/\hbar^2}, \quad (13.39)$$

$$\nu \equiv \frac{e^2}{2\omega\hbar} = \sqrt{\frac{e^4 M}{-2\hbar^2 E}}. \quad (13.40)$$

Then

$$\pi F^2(S) = \kappa \frac{2\sqrt{\varrho}}{1-\varrho}, \quad (13.41)$$

$$e^{ie^2 s/\hbar} F^2(S) = \frac{2}{\pi} \kappa \frac{\varrho^{1/2-\nu}}{1-\varrho}, \quad (13.42)$$

and the fixed-energy amplitude of the two-dimensional Coulomb system takes the form

$$\begin{aligned} (\mathbf{x}_b|\mathbf{x}_a)_E = & -i \frac{M}{\pi\hbar} \int_0^1 d\varrho \frac{\varrho^{-1/2-\nu}}{1-\varrho} \cos \left[2\kappa \frac{2\sqrt{\varrho}}{1-\varrho} \sqrt{(r_b r_a + \mathbf{x}_b \mathbf{x}_a)/2} \right] \\ & \times \exp \left[-\kappa \frac{1+\varrho}{1-\varrho} (r_b + r_a) \right]. \end{aligned} \quad (13.43)$$

Note that the integral converges only for $\nu < 1/2$. Expanding the integrand in powers of ϱ the integral can be done and yields a sum over terms $1/(\nu - 1/2), 1/(\nu - 3/2), \dots$. The residues can be factorized into a sum $e^{im\phi_b} e^{-im\phi_a} + e^{-im\phi_b} e^{im\phi_a}$, where ϕ are the azimuthal angle of the two-dimensional vectors \mathbf{x} . Thus we obtain a spectral decomposition of the amplitude:

$$(\mathbf{x}_b|\mathbf{x}_a)_E = \sum_{n=1}^{\infty} \frac{i\hbar}{E - E_n} \sum_{m=0}^{n-1} \left[\psi_{n_r, m}(\mathbf{x}_b) \psi_{n_r, m}^*(\mathbf{x}_a) + \psi_{n_r, -m}(\mathbf{x}_b) \psi_{n_r, -m}^*(\mathbf{x}_a) \right], \quad (13.44)$$

where

$$\psi_{n_r, m}(\mathbf{x}) = \frac{1}{\sqrt{r}} R_{n_r, |m|}(r) \frac{1}{\sqrt{2\pi}} e^{im\phi}, \quad r \equiv \quad (13.45)$$

are the wave functions and

$$E_n = -\frac{Me^4}{\hbar^4} \frac{1}{(n - \frac{1}{2})^2} \quad (13.46)$$

the energy eigenvalues. The *principal quantum number* n is related to the radial quantum number $n_r = 0, 1, 2, 3, \dots$ and the azimuthal quantum number m by $n = n_r + |m| + 1$. The radial eigenfunctions are expressed in terms of confluent hypergeometric functions (9.45) as

$$\frac{1}{\sqrt{r}} R_{n_r, |m|}(r) = N_{n_r, |m|} \left(\frac{2r}{r_n} \right)^{|m|} e^{-r/r_n} {}_1F_1(-n + |m| + 1, 2|m| + 1, 2r/r_n), \quad (13.47)$$

where $r_n \equiv (n - \frac{1}{2})r_H = (n - 1/2)Me^2/\hbar^2$, and [5]

$$N_{n_r, |m|} \equiv \frac{2}{r_n} \frac{1}{2|m|!} \sqrt{\frac{(n + |m| - 1)!}{(2n - 1)(n - |m| - 1)!}}. \quad (13.48)$$

It is possible to write down another integral representation converging for all $\nu \neq 1/2, 3/2, 5/2, \dots$. To do this we change the variable of integrations to

$$\zeta \equiv \frac{1 + \varrho}{1 - \varrho}, \quad (13.49)$$

so that

$$\frac{d\varrho}{(1 - \varrho)^2} = \frac{1}{2} d\zeta, \quad \varrho = \frac{\zeta - 1}{\zeta + 1}. \quad (13.50)$$

This leads to

$$\begin{aligned} (\mathbf{x}_b | \mathbf{x}_a)_E &= -i \frac{M}{\pi \hbar} \frac{1}{2} \int_1^\infty d\zeta (\zeta - 1)^{-\nu-1/2} (\zeta + 1)^{\nu-1/2} \\ &\quad \times \cos \left\{ 2\kappa \sqrt{\zeta^2 - 1} \sqrt{(r_b r_a + \mathbf{x}_b \mathbf{x}_a)/2} \right\} e^{-\kappa \zeta (r_b + r_a)}. \end{aligned} \quad (13.51)$$

The integrand has a cut in the complex ζ -plane extending from $z = -1$ to $-\infty$ and from $\zeta = 1$ to ∞ . The integral runs along the right-hand cut. The integral is transformed into an integral along a contour C which encircles the right-hand cut in the clockwise sense. Since the cut is of the type $(\zeta - 1)^{-\nu-1/2}$, we may replace

$$\int_1^\infty d\zeta (\zeta - 1)^{-\nu-1/2} \dots \rightarrow \frac{\pi e^{i\pi(\nu+1/2)}}{\sin[\pi(\nu+1/2)]} \frac{1}{2\pi i} \int_C d\zeta (\zeta - 1)^{-\nu-1/2} \dots, \quad (13.52)$$

and the fixed-energy amplitude reads

$$\begin{aligned} (\mathbf{x}_b | \mathbf{x}_a)_E &= -i \frac{M}{\pi \hbar} \frac{1}{2} \frac{\pi e^{i\pi(\nu+1/2)}}{\sin[\pi(\nu+1/2)]} \int_C \frac{d\zeta}{2\pi i} (\zeta - 1)^{-\nu-1/2} (\zeta + 1)^{\nu-1/2} \\ &\quad \times \cos \left[2\kappa \sqrt{\zeta^2 - 1} \sqrt{(r_b r_a + \mathbf{x}_b \mathbf{x}_a)/2} \right] e^{-\kappa \zeta (r_b + r_a)}. \end{aligned} \quad (13.53)$$

13.3 Absence of Time Slicing Corrections for $D = 2$

We now convince ourselves that the finite thickness of the pseudotime slices in the intermediate formulas does not change the time evolution amplitude obtained in the last section [6]. The reader who is unaware of the historic difficulties which had to be overcome may not be interested in the upcoming technical discussion. He may skip this section and be satisfied with a brief argument given in Section 13.6.

The potential term in the action (13.9) can be ignored since it is of order ϵ_s and the time slicing can only produce higher than linear correction terms in ϵ_s which do not contribute in the continuum limit $\epsilon_s \rightarrow 0$. The crucial point where corrections might enter is in the transformation of the measure and the pseudotime-sliced kinetic terms in (13.8), (13.9). In vector notation, the coordinate transformation reads, at every time slice n ,

$$\mathbf{x}_n = A(\mathbf{u}_n)\mathbf{u}_n. \quad (13.54)$$

Among the equivalent possibilities offered in Section 11.2 to transform a time-sliced path integral we choose the Taylor expansion (11.56) to map $\Delta\mathbf{x}$ into $\Delta\mathbf{u}$. After inserting (13.15) into (11.56) we find

$$\Delta x^i = 2A^i{}_{\mu}(\mathbf{u})\Delta u^\mu - \partial_\nu A^i{}_{\mu}(\mathbf{u})\Delta u^\mu \Delta u^\nu. \quad (13.55)$$

Since the mapping $\mathbf{x}(\mathbf{u})$ is quadratic in \mathbf{u} , there are no higher-order expansion terms. Note that due to the absence of curvature and torsion in the \mathbf{u} -space, the coordinate transformation is holonomic and $\Delta\mathbf{x}$ can also be calculated directly from $\mathbf{x}(\mathbf{u}) - \mathbf{x}(\mathbf{u} - \Delta\mathbf{u})$. Indeed, using the linearity of $A(\mathbf{u})$ in \mathbf{u} , we find from (13.54)

$$\Delta\mathbf{x}_n = A(\mathbf{u}_n)\mathbf{u}_n - A(\mathbf{u}_{n-1})\mathbf{u}_{n-1} = 2A(\mathbf{u}_n - \frac{1}{2}\Delta\mathbf{u}_n)\Delta\mathbf{u}_n = 2A(\bar{\mathbf{u}}_n)\Delta\mathbf{u}_n, \quad (13.56)$$

where $\bar{\mathbf{u}}_n$ is average across the slice. The Taylor expansion of $A(\mathbf{u}_n - \frac{1}{2}\Delta\mathbf{u}_n)$ has only two terms and leads to (13.55).

Using (13.56) we can write

$$(\Delta\mathbf{x}_n)^2 = 4\bar{\mathbf{u}}_n^2(\Delta\mathbf{u}_n)^2, \quad (13.57)$$

$$\bar{\mathbf{u}}_n \equiv (\mathbf{u}_n + \mathbf{u}_{n-1})/2. \quad (13.58)$$

The kinetic term of the short-time action in the n th time slice of Eq. (13.9) therefore becomes

$$\mathcal{A}^\epsilon = \frac{M}{2\epsilon_s} \frac{(\Delta\mathbf{x}_n)^2}{r_n^{1-\lambda} r_{n-1}^\lambda} = \frac{M}{2\epsilon_s} \frac{4\bar{\mathbf{u}}_n^2}{(\mathbf{u}_n^2)^{1-\lambda} (\mathbf{u}_{n-1}^2)^\lambda} (\Delta\mathbf{u}_n)^2. \quad (13.59)$$

This is expanded around the postpoint and yields

$$\bar{\mathbf{u}}_n = \mathbf{u}_n - \frac{1}{2}\Delta\mathbf{u}_n, \quad (13.60)$$

$$\mathbf{u}_{n-1} = \mathbf{u}_n - \Delta\mathbf{u}_n, \quad (13.61)$$

$$\begin{aligned} \frac{\bar{\mathbf{u}}_n^2}{(\mathbf{u}_n^2)^{1-\lambda} (\mathbf{u}_{n-1}^2)^\lambda} &= 1 + (2\lambda - 1) \frac{\mathbf{u}_n \Delta\mathbf{u}_n}{\mathbf{u}_n^2} + \left(\frac{1}{4} - \lambda\right) \frac{\Delta\mathbf{u}_n^2}{\mathbf{u}_n^2} \\ &\quad + 2\lambda^2 \left(\frac{\mathbf{u}_n \Delta\mathbf{u}_n}{\mathbf{u}_n^2}\right)^2. \end{aligned} \quad (13.62)$$

It is useful to separate the short-time action into a leading term

$$\mathcal{A}_0^\epsilon(\Delta\mathbf{u}_n) = 4M \frac{(\Delta\mathbf{u}_n)^2}{2\epsilon_s}, \quad (13.63)$$

plus correction terms

$$\begin{aligned} \Delta \mathcal{A}^\epsilon &= 4M \frac{(\Delta \mathbf{u}_n)^2}{2\epsilon_s} \\ &\times \left[(2\lambda - 1) \frac{\mathbf{u}_n \Delta \mathbf{u}_n}{\mathbf{u}_n^2} + \left(\frac{1}{4} - \lambda \right) \frac{\Delta \mathbf{u}_n^2}{\mathbf{u}_n^2} + 2\lambda^2 \left(\frac{\mathbf{u}_n \Delta \mathbf{u}_n}{\mathbf{u}_n^2} \right)^2 \right], \end{aligned} \quad (13.64)$$

which will be treated perturbatively.

In order to perform the transformation of the measure of integration in (13.8), we expand $\Delta \mathbf{x}$ accordingly:

$$\begin{aligned} \Delta x^i &= 2A^i{}_\mu(\mathbf{u} - \frac{1}{2}\Delta \mathbf{u})\Delta u^\mu \\ &= 2A^i{}_\mu(\mathbf{u})\Delta u^\mu - \partial_\nu A^i{}_\mu(\mathbf{u})\Delta u^\mu \Delta u^\nu. \end{aligned} \quad (13.65)$$

The indices n have been suppressed, for brevity. This expression has, of course, the general form (10.96), after inserting there

$$e^i{}_\mu(\mathbf{u}) = 2A^i{}_\mu(\mathbf{u}). \quad (13.66)$$

Since the transformation matrix $A^i{}_\mu(\mathbf{u})$ in (13.15) is linear in \mathbf{u} , the matrix $e^i{}_\mu(\mathbf{u})$ has no second derivatives, and the Jacobian action (11.60) and (10.145) reduce to

$$\begin{aligned} \frac{i}{\hbar} \mathcal{A}_J^\epsilon &= -e_i{}^\mu e^i{}_{\{\mu,\nu\}} \Delta u^\nu - \frac{1}{2} e_i{}^\mu e^i{}_{\{\kappa,\nu\}} e_j{}^\kappa e^j{}_{\mu,\lambda} \Delta u^\nu \Delta u^\lambda \\ &= -\Gamma_{\{\nu\mu\}}{}^\mu \Delta u^\nu - \frac{1}{2} \Gamma_{\{\nu\kappa\}}{}^\mu \Gamma_{\{\mu\lambda\}}{}^\kappa \Delta u^\nu \Delta u^\lambda. \end{aligned} \quad (13.67)$$

The expansion coefficients are easily calculated using the reciprocal basis dyad

$$e_i{}^\kappa = \frac{1}{2\mathbf{u}^2} e^i{}_\kappa, \quad (13.68)$$

as

$$\begin{aligned} \Gamma_{\nu\mu}{}^\mu &= e_i{}^\mu \partial_\nu e^i{}_\mu = \frac{2u^\nu}{\mathbf{u}^2}, \\ \Gamma_{\mu\nu}{}^\mu &= -e^i{}_\nu \partial_\mu e_i{}^\mu = \frac{2u^\nu}{\mathbf{u}^2}, \\ \Gamma_{\nu\kappa}{}^\mu \Gamma_{\lambda\mu}{}^\kappa &= -\partial_\lambda e_i{}^\kappa \partial_\nu e^i{}_\kappa = -\frac{2}{\mathbf{u}^4} (\delta^{\nu\lambda} \mathbf{u}^2 - 2u^\nu u^\lambda). \end{aligned} \quad (13.69)$$

The second equation is found directly from

$$-\partial_\mu e_i{}^\mu = -\partial_\mu (2\mathbf{u}^2)^{-1} e^i{}_\mu = e_i{}^\mu 2u^\mu \mathbf{u}^{-2}, \quad (13.70)$$

which, in turn, follows from the obvious identity $\partial_\mu e^i{}_\mu = 0$. Note that the third expression in (13.69) is automatically equal to $\Gamma_{\{\nu\kappa\}}{}^\sigma \Gamma_{\{\lambda\sigma\}}{}^\kappa$, i.e., of the form required in (13.67), since the u^μ -space has no torsion and $\Gamma_{\nu\kappa}{}^\sigma = \Gamma_{\kappa\nu}{}^\sigma$. After inserting Eqs. (13.69) into the right-hand side of (13.67), we find the postpoint expansion

$$\frac{i}{\hbar} \mathcal{A}_J^\epsilon = - \left[2 \frac{\mathbf{u}_n \Delta \mathbf{u}_n}{\mathbf{u}_n^2} - \frac{\Delta \mathbf{u}_n^2}{\mathbf{u}_n^2} + 2 \left(\frac{\mathbf{u}_n \Delta \mathbf{u}_n}{\mathbf{u}_n^2} \right)^2 + \dots \right]. \quad (13.71)$$

The measure of integration in (13.8) contains additional factors r_b, r_n, r_a which require a further treatment. First we rewrite it as

$$\begin{aligned} \frac{(r_b/r_a)^{2\lambda-1}}{2\pi i \epsilon_s \hbar} \prod_{n=1}^N \left[\int \frac{d^2 \Delta x_n}{2\pi i \epsilon_s r_{n-1} / M} \right] &\approx \frac{1}{2\pi i \epsilon_s \hbar} \prod_{n=1}^N \left[\int \frac{d^2 \Delta x_n}{2\pi i \epsilon_s \hbar r_n / M} \right] \prod_{n=1}^{N+1} \left(\frac{r_n}{r_{n-1}} \right)^{2\lambda} \\ &= \frac{1}{2\pi i \epsilon_s \hbar} \prod_{n=2}^{N+1} \left[\int \frac{d^2 \Delta x_n}{2\pi i \epsilon_s \hbar r_n / M} \right] e^{i\mathcal{A}_f^N / \hbar}. \end{aligned} \quad (13.72)$$

On the left-hand side, we have shifted the labels n by one unit making use of the fact that with $\Delta \mathbf{x}_n = \mathbf{x}_n - \mathbf{x}_{n-1}$ we can certainly write $\prod_{n=2}^{N+1} \int d^2 \Delta x_n = \prod_{n=1}^N \int d^2 \Delta x_n$. In the first expression on the right-hand side we have further shifted the subscripts of the factors $1/r_{n-1}$ in the integral measure from $n - 1$ to n and compensated for this by an overall factor $\prod_{n=1}^{N+1} (r_n/r_{n-1})$. Together with the prefactor $(r_b/r_a)^{2\lambda-1}$, this can be expressed as a product $\prod_{n=1}^{N+1} (r_n/r_{n-1})^{2\lambda}$. There is only a negligible error of order ϵ_s^2 at the upper end [this being the reason for writing the symbol \approx rather than $=$ in (13.72)]. In the last part of the equation we have introduced an effective action

$$\mathcal{A}_f^N \equiv \sum_{n=1}^{N+1} \mathcal{A}_f^\epsilon \tag{13.73}$$

due to the $(r_n/r_{n-1})^{2\lambda}$ factors, with

$$\frac{i}{\hbar} \mathcal{A}_f^\epsilon = 2\lambda \log \frac{r_n^2}{r_{n-1}^2} = 2\lambda \log \frac{\mathbf{u}_n^2}{\mathbf{u}_{n-1}^2}. \tag{13.74}$$

The subscript f indicates that the general origin of this term lies in the rescaling factors $f_l(\mathbf{x}_b), f_r(\mathbf{x}_a)$.

We now go over from $\Delta \mathbf{x}_n$ - to $\Delta \mathbf{u}_n$ -integrations using the relation

$$d^2 \Delta x = 4\mathbf{u}^2 d^2 \Delta u \exp\left(\frac{i}{\hbar} \mathcal{A}_f^\epsilon\right). \tag{13.75}$$

The measure becomes

$$\frac{1}{2} \times \frac{4}{2 \cdot 2\pi i \epsilon_s \hbar} \prod_{n=1}^N \left[\int \frac{4d^2 \Delta u_n}{2 \cdot 2\pi i \epsilon_s \hbar / M} \right] \exp\left[\frac{i}{\hbar} (\mathcal{A}_J^N + \mathcal{A}_f^N)\right], \tag{13.76}$$

where \mathcal{A}_J^N is the sum over all time-sliced Jacobian action terms \mathcal{A}_J^ϵ of (13.71):

$$\mathcal{A}_J^N \equiv \sum_{n=1}^{N+1} \mathcal{A}_J^\epsilon. \tag{13.77}$$

The extra factors 2 in the measure denominators of (13.76) are introduced to let the \mathbf{u}_n -integrations run over the entire \mathbf{u} -space, in which case the \mathbf{x} -space is traversed twice.

The time-sliced expression (13.76) has an important feature which was absent in the continuous formulation. It receives dominant contributions not only from the region neighborhood $\mathbf{u}_n \sim \mathbf{u}_{n-1}$, in which case $(\Delta \mathbf{u}_n)^2$ is of order ϵ_s , but also from $\mathbf{u}_n \sim -\mathbf{u}_{n-1}$ where $(\bar{\mathbf{u}}_n)^2$ is of order ϵ_s . This is understandable since both configurations correspond to \mathbf{x}_n being close to \mathbf{x}_{n-1} and must be included. Fortunately, for symmetry reasons, they give identical contributions so that we need to discuss only the case $\mathbf{u}_n \sim \mathbf{u}_{n-1}$, the contribution from the second case being simply included by dropping the factors 2 in the measure denominators.

To process the measure further, we expand the action \mathcal{A}_f^ϵ (13.76) around the postpoint and find

$$\frac{i}{\hbar} \mathcal{A}_f^\epsilon = 2\lambda \log \left(\frac{\mathbf{u}_n^2}{\mathbf{u}_{n-1}^2} \right) = 2\lambda \left[2 \frac{\mathbf{u}_n \Delta \mathbf{u}_n}{\mathbf{u}_n^2} - \frac{\Delta \mathbf{u}_n^2}{\mathbf{u}_n^2} + 2 \left(\frac{\mathbf{u}_n \Delta \mathbf{u}_n}{\mathbf{u}_n^2} \right)^2 + \dots \right]. \tag{13.78}$$

A comparison with (13.71) shows that adding $(i/\hbar) \mathcal{A}_f^\epsilon$ and $(i/\hbar) \mathcal{A}_J^\epsilon$ merely changes 2λ in \mathcal{A}_f^ϵ into $2\lambda - 1$.

Thus, altogether, the time-slicing produces the short-time action

$$\mathcal{A}^\epsilon = \mathcal{A}_0^\epsilon + \Delta_{\text{corr}} \mathcal{A}^\epsilon, \tag{13.79}$$

with the leading free-particle action

$$\mathcal{A}_0^\epsilon(\Delta \mathbf{u}_n) = 4M \frac{(\Delta \mathbf{u}_n)^2}{2\epsilon_s}, \quad (13.80)$$

and the total correction term

$$\begin{aligned} \frac{i}{\hbar} \Delta_{\text{corr}} \mathcal{A}^\epsilon &\equiv \frac{i}{\hbar} (\Delta \mathcal{A}^\epsilon + \mathcal{A}_J^\epsilon + \mathcal{A}_f^\epsilon) \\ &= \frac{i}{\hbar} 4M \frac{\Delta \mathbf{u}_n^2}{2\epsilon_s} \left[(2\lambda - 1) \frac{\mathbf{u}_n \Delta \mathbf{u}_n}{\mathbf{u}_n^2} + \left(\frac{1}{4} - \lambda \right) \frac{\Delta \mathbf{u}_n^2}{\mathbf{u}_n^2} + 2\lambda^2 \left(\frac{\mathbf{u}_n \Delta \mathbf{u}_n}{\mathbf{u}_n^2} \right)^2 \right] \\ &\quad + (2\lambda - 1) \left[2 \frac{\mathbf{u}_n \Delta \mathbf{u}_n}{\mathbf{u}_n^2} - \frac{\Delta \mathbf{u}_n^2}{\mathbf{u}_n^2} + 2 \left(\frac{\mathbf{u}_n \Delta \mathbf{u}_n}{\mathbf{u}_n^2} \right)^2 \right] + \dots \end{aligned} \quad (13.81)$$

We now show that the action $\Delta_{\text{corr}} \mathcal{A}^\epsilon$ is equivalent to zero by proving that the kernel associated with the short-time action

$$K^\epsilon(\Delta \mathbf{u}) = \frac{4}{2 \cdot 2\pi i \epsilon_s \hbar / M} \exp \left[\frac{i}{\hbar} (\mathcal{A}_0^\epsilon + \Delta_{\text{corr}} \mathcal{A}^\epsilon) \right] \quad (13.82)$$

is equivalent to the zeroth-order free-particle kernel

$$K_0^\epsilon(\Delta \mathbf{u}) = \frac{4}{2 \cdot 2\pi i \epsilon_s \hbar / M} \exp \left[\frac{i}{\hbar} \mathcal{A}_0^\epsilon \right]. \quad (13.83)$$

The equivalence is established by checking the equivalence relations (11.71) and (11.72). For the kernel (13.82), the correction (11.71) is

$$C_1 = C \equiv \exp \left(\frac{i}{\hbar} \Delta_{\text{corr}} \mathcal{A}^\epsilon \right) - 1. \quad (13.84)$$

It has to be compared with the trivial factor of the kernel (13.83):

$$C_2 = 0. \quad (13.85)$$

Thus, the equivalence requires showing that

$$\begin{aligned} \langle C \rangle_0 &= 0, \\ \langle C(\mathbf{p} \Delta \mathbf{u}) \rangle_0 &= 0. \end{aligned} \quad (13.86)$$

The basic correlation functions due to $K_0^\epsilon(\Delta \mathbf{u})$ are

$$\langle \Delta u^\mu \Delta u^\nu \rangle_0 \equiv \frac{i\hbar\epsilon_s}{4M} \delta^{\mu\nu}, \quad (13.87)$$

$$\langle \Delta u^{\mu_1} \dots \Delta u^{\mu_{2n}} \rangle_0 = \left(\frac{i\hbar\epsilon_s}{4M} \right)^n \delta^{\mu_1 \dots \mu_{2n}}, \quad n > 1, \quad (13.88)$$

where the contraction tensors $\delta^{\mu_1 \dots \mu_{2n}}$ of Eq. (8.64), determined recursively from

$$\delta^{\mu_1 \dots \mu_{2n}} \equiv \delta^{\mu_1 \mu_2} \delta^{\mu_3 \mu_4 \dots \mu_{2n}} + \delta^{\mu_1 \mu_3} \delta^{\mu_2 \mu_4 \dots \mu_{2n}} + \dots + \delta^{\mu_1 \mu_{2n}} \delta^{\mu_2 \mu_3 \dots \mu_{2n-1}}. \quad (13.89)$$

They consist of $(2n - 1)!!$ products of pair contractions $\delta^{\mu_i \mu_j}$. More specifically, we encounter, in calculating (13.86), expectations of the type

$$\langle (\Delta \mathbf{u})^{2k} (\mathbf{u} \Delta \mathbf{u})^{2l} \rangle_0 = \left(\frac{i\hbar\epsilon_s}{4M} \right)^{k+l} \frac{[D + 2(k+l-1)]!!}{(D + 2l - 2)!!} (2l - 1)!! (\mathbf{u}^2)^l, \quad (13.90)$$

and

$$\langle (\Delta \mathbf{u})^{2k} (\mathbf{u} \Delta \mathbf{u})^{2l} (\mathbf{u} \Delta \mathbf{u}) (\mathbf{p} \Delta \mathbf{u}) \rangle_0 = \left(\frac{i \hbar \epsilon_s}{4M} \right)^{k+l+1} \frac{[D + 2(k+l)]!!}{(D + 2l)!!} (2l - 1)!! (\mathbf{u} \mathbf{p}), \tag{13.91}$$

where we have allowed for a general \mathbf{u} -space dimension D . Expanding (13.86) we now check that, up to first order in ϵ_s , the expectations $\langle C \rangle_0$ and $\langle C (\mathbf{p} \Delta \mathbf{u}) \rangle_0$ vanish:

$$\langle C \rangle_0 = \frac{i}{\hbar} \langle \Delta_{\text{corr}} \mathcal{A}^\epsilon \rangle_0 + \frac{1}{2!} \left(\frac{i}{\hbar} \right)^2 \langle (\Delta_{\text{corr}} \mathcal{A}^\epsilon)^2 \rangle_0 = 0, \tag{13.92}$$

$$\langle C (\mathbf{p} \Delta \mathbf{u}) \rangle_0 = \frac{i}{\hbar} \langle \Delta_{\text{corr}} \mathcal{A}^\epsilon (\mathbf{p} \Delta \mathbf{u}) \rangle_0 = 0. \tag{13.93}$$

Indeed, the first term in (13.92) becomes

$$\frac{i}{\hbar} \langle \Delta_{\text{corr}} \mathcal{A}^\epsilon \rangle_0 = 2i \frac{\hbar \epsilon_s}{M} \left[- \left(\frac{1}{4} - \lambda \right) \frac{(D + 2)D}{16} - 2\lambda^2 \frac{D + 2}{16} \right], \tag{13.94}$$

and reduces for $D = 2$ to

$$\frac{i}{\hbar} \langle \Delta_{\text{corr}} \mathcal{A}^\epsilon \rangle_0 = -i \frac{\hbar \epsilon_s}{M} \left(\lambda - \frac{1}{2} \right)^2. \tag{13.95}$$

This is canceled identically in λ by the second term in (13.92), which is equal to

$$\frac{1}{2!} \left(\frac{i}{\hbar} \right)^2 \langle (\Delta_{\text{corr}} \mathcal{A}^\epsilon)^2 \rangle_0 = \frac{i \hbar \epsilon_s}{2M} \left[4(2\lambda - 1)^2 \frac{(D + 4)(D + 2)}{64} + 4(2\lambda - 1)^2 \frac{1}{4} - 8(2\lambda - 1)^2 \frac{D + 2}{16} \right], \tag{13.96}$$

and reduces for $D = 2$ to

$$\frac{1}{2!} \left(\frac{i}{\hbar} \right)^2 \langle (\Delta_{\text{corr}} \mathcal{A}^\epsilon)^2 \rangle_0 = i \frac{\hbar \epsilon_s}{M} \left(\lambda - \frac{1}{2} \right)^2. \tag{13.97}$$

Similarly, the expectation (13.93),

$$\langle \Delta_{\text{corr}} \mathcal{A}^\epsilon (\mathbf{p} \Delta \mathbf{u}) \rangle_0 = -\frac{\hbar^2 \epsilon_s}{4M} [(2\lambda - 1)(D + 2)/4 - (2\lambda - 1)], \tag{13.98}$$

is seen to vanish identically in λ for $D = 2$.

Thus there is no finite time slicing correction to the naive transformation formula (13.34) for the Coulomb path integral in two dimensions.

13.4 Solution for the Three-Dimensional Coulomb System

We now turn to the physically relevant Coulomb system in three dimensions. The first problem is to find again some kind of “square root” coordinates to convert the potential $-Er$ in the pseudotime Hamiltonian in the exponent of Eq. (13.5) into a harmonic potential. In two dimensions, the answer was a complex square root. Here, it is a “quaternionic square root” known as the *Kustaanheimo-Stiefel transformation*, which was used extensively in celestial mechanics [7]. To apply this transformation, the three-vectors \mathbf{x} must first be mapped into a four-dimensional u^μ -space ($\mu = 1, 2, 3, 4$) via the equations

$$x^i = \bar{z} \sigma^i z, \quad r = \bar{z} z. \tag{13.99}$$

Here σ^i are the Pauli matrices (1.448), and z, \bar{z} the two-component objects

$$z = \begin{pmatrix} z_1 \\ z_2 \end{pmatrix}, \quad \bar{z} = (z_1^*, z_2^*), \quad (13.100)$$

called “spinors”. Their components are related to the four-vectors u^μ by

$$z_1 = (u^1 + iu^2), \quad z_2 = (u^3 + iu^4). \quad (13.101)$$

The coordinates u^μ can be parametrized in terms of the spherical angles of the three-vector \mathbf{x} and an additional arbitrary angle γ as follows:

$$\begin{aligned} z_1 &= \sqrt{r} \cos(\theta/2) e^{-i[(\varphi+\gamma)/2]}, \\ z_2 &= \sqrt{r} \sin(\theta/2) e^{i[(\varphi-\gamma)/2]}. \end{aligned}$$

In Eqs. (13.99), the angle γ obviously cancels. Each point in \mathbf{x} -space corresponds to an entire curve in u^μ -space along which the angle γ runs through the interval $[0, 4\pi]$.

We can write (13.99) also in a matrix form

$$\begin{pmatrix} x^1 \\ x^2 \\ x^3 \end{pmatrix} = A(\vec{u}) \begin{pmatrix} u^1 \\ u^2 \\ u^3 \\ u^4 \end{pmatrix}, \quad (13.102)$$

with the 3×4 matrix

$$A(\vec{u}) = \begin{pmatrix} u^3 & u^4 & u^1 & u^2 \\ u^4 & -u^3 & -u^2 & u^1 \\ u^1 & u^2 & -u^3 & -u^4 \end{pmatrix}. \quad (13.103)$$

Since

$$r = (u^1)^2 + (u^2)^2 + (u^3)^2 + (u^4)^2 \equiv (\vec{u})^2, \quad (13.104)$$

this transformation certainly makes the potential $-Er$ in the pseudotime Hamiltonian harmonic in \vec{u} . The arrow on top indicates the four-vector nature of u^μ .

Consider now the kinetic term $\int ds (M/2r) (d\mathbf{x}/ds)^2$ in the action (13.10). Each path $\mathbf{x}(s)$ is associated with an infinite set of paths $\vec{u}(s)$ in \vec{u} -space, depending on the choice of a dummy path $\gamma(s)$ in parameter space. The mapping of the tangent vectors du^μ into dx^i is given by

$$\begin{pmatrix} dx^1 \\ dx^2 \\ dx^3 \end{pmatrix} = 2 \begin{pmatrix} u^3 & u^4 & u^1 & u^2 \\ u^4 & -u^3 & -u^2 & u^1 \\ u^1 & u^2 & -u^3 & -u^4 \end{pmatrix} \begin{pmatrix} du^1 \\ du^2 \\ du^3 \\ du^4 \end{pmatrix}. \quad (13.105)$$

To make the mapping unique we must prescribe at least some differential equation for the dummy angle $d\gamma$. This is done most simply by replacing $d\gamma$ by a parameter

which is more naturally related to the components dx^i on the left-hand side. We embed the tangent vector (dx^1, dx^2, dx^3) into a fictitious four-dimensional space and define a new, fourth component dx^4 by an additional fourth row in the matrix $A(\vec{u})$, thereby extending (13.29) to the four-vector equation

$$d\vec{x} = 2A(\vec{u})d\vec{u}. \quad (13.106)$$

The arrow on top of x indicates that x has become a four-vector. For symmetry reasons, we choose the 4×4 matrix $A(\vec{u})$ as

$$A(\vec{u}) = \begin{pmatrix} u^3 & u^4 & u^1 & u^2 \\ u^4 & -u^3 & -u^2 & u^1 \\ u^1 & u^2 & -u^3 & -u^4 \\ u^2 & -u^1 & u^4 & -u^3 \end{pmatrix}. \quad (13.107)$$

The fourth row implies the following relation between dx^4 and $d\gamma$:

$$\begin{aligned} dx^4 &= 2(u^2 du^1 - u^1 du^2 + u^4 du^3 - u^3 du^4) \\ &= r(\cos\theta d\varphi + d\gamma). \end{aligned} \quad (13.108)$$

Now we make the important observation that this relation is not integrable since $\partial x^4/\partial u^1 = 2u^2$, $\partial x^4/\partial u^2 = -2u^1$, and hence

$$(\partial_{u^1}\partial_{u^2} - \partial_{u^2}\partial_{u^1})x^4(u^\mu) = -4, \quad (\partial_{u^3}\partial_{u^4} - \partial_{u^4}\partial_{u^3})x^4(u^\mu) = -4, \quad (13.109)$$

implying that $x^4(u^\mu)$ does not satisfy the integrability criterion of Schwarz [recall (10.19)]. The mapping is nonholonomic and changes the Euclidean geometry of the four-dimensional \vec{x} -space into a non-Euclidean \vec{u} -space with curvature and torsion. This will be discussed in detail in the next section. The impossibility of finding a unique mapping between the *points* of \vec{x} - and \vec{u} -space has the consequence that the mapping between *paths* is multivalued with respect to the initial point. After having chosen a specific image for the initial point, the mapping (13.107) determines the image path uniquely.

We now incorporate the dummy fourth dimension into the action by replacing \mathbf{x} in the kinetic term by the four-vector \vec{x} and extending the kinetic action to

$$\mathcal{A}_{\text{kin}}^N \equiv \sum_{n=1}^{N+1} \frac{M (\vec{x}_n - \vec{x}_{n-1})^2}{2 \epsilon_s r_n^{1-\lambda} r_{n-1}^\lambda}. \quad (13.110)$$

The additional contribution of the fourth components $x_n^4 - x_{n-1}^4$ can be eliminated trivially from the final pseudotime evolution amplitude by integrating each time slice over dx_{n-1}^4 with the measure

$$\prod_{n=1}^{N+1} \int_{-\infty}^{\infty} \frac{d(\Delta x^4)_n}{\sqrt{2\pi i \epsilon_s \hbar r_n^{1-\lambda} r_{n-1}^\lambda / M}}. \quad (13.111)$$

Note that in these integrals, the radial coordinates r_n are fixed numbers. In contrast to the spatial integrals d^3x_{n-1} , the fourth coordinate must be integrated also over the initial auxiliary coordinate $x_0^4 = x_a^4$. Thus we use the trivial identity

$$\prod_{n=1}^{N+1} \left[\int_{-\infty}^{\infty} \frac{d(\Delta x^4)_n}{\sqrt{2\pi i \epsilon_s \hbar r_n^{1-\lambda} r_{n-1}^\lambda / M}} \right] \exp \left[\frac{i}{\hbar} \sum_{n=1}^{N+1} \frac{M}{2} \frac{(\Delta x_n^4)^2}{\epsilon_s r_n^{1-\lambda} r_{n-1}^\lambda} \right] = 1. \quad (13.112)$$

Hence the pseudotime evolution amplitude of the Coulomb system in three dimensions can be rewritten as the four-dimensional path integral

$$\begin{aligned} \langle \mathbf{x}_b | \hat{\mathcal{U}}_E(S) | \mathbf{x}_a \rangle &= \int dx_a^4 \frac{r_b^\lambda r_a^{1-\lambda}}{(2\pi i \epsilon_s \hbar r_b^{1-\lambda} r_a^\lambda / M)^2} \\ &\times \prod_{n=2}^{N+1} \left[\int_{-\infty}^{\infty} \frac{d^4 \Delta x_n}{(2\pi i \epsilon_s \hbar r_{n-1} / M)^2} \right] \exp \left(\frac{i}{\hbar} \mathcal{A}_E^N \right), \end{aligned} \quad (13.113)$$

where \mathcal{A}_E^N is the action (13.9) in which the three-vectors \mathbf{x}_n are replaced by the four-vectors \vec{x}_n , although r is still the length of the spatial part of \vec{x} . By distributing the factors r_b, r_n, r_a evenly over the intervals, shifting the subscripts n of the factors $1/r_n$ in the measure to $n+1$, and using the same procedure as in Eq. (13.72), we arrive at the pseudotime evolution amplitude

$$\begin{aligned} \langle \mathbf{x}_b | \hat{\mathcal{U}}_E(S) | \mathbf{x}_a \rangle &= \frac{1}{(2\pi i \epsilon_s \hbar / M)^2} \int_{-\infty}^{\infty} \frac{dx_a^4}{r_a} \\ &\times \prod_{n=2}^{N+1} \left[\int \frac{d^4 \Delta \vec{x}_n}{(2\pi i \epsilon_s \hbar r_n / M)^2} \right] \exp \left[\frac{i}{\hbar} (\mathcal{A}_E^N + \mathcal{A}_f^N) \right], \end{aligned} \quad (13.114)$$

with the sliced action

$$\mathcal{A}_E^N[\vec{x}, \vec{x}'] = (N+1)\epsilon_s e^2 + \sum_{n=1}^{N+1} \left[\frac{M}{2} \frac{(\Delta \vec{x}_n)^2}{\epsilon_s r_n^{1-\lambda} r_{n-1}^\lambda} + \epsilon_s r_n^{1-\lambda} r_{n-1}^\lambda E \right]. \quad (13.115)$$

The action \mathcal{A}_f^N accounts for all remaining factors in the integral measure. The prefactor is now $(r_b/r_a)^{3\lambda-2}$ and can be written as a product $\prod_1^{N+1} (r_n/r_{n-1})^{3\lambda-2}$. The index shift in the factor $1/r$ changes the power $3\lambda-2$ to 3λ

$$\frac{i}{\hbar} \mathcal{A}_f^N = 3\lambda \sum_{n=1}^{N+1} \log \left(\frac{\vec{u}_n^2}{\vec{u}_{n-1}^2} \right) \quad (13.116)$$

[compare (13.73)]. As in the two-dimensional case we shall at first ignore the subtleties due to the time slicing. Thus we set $\lambda = 0$ and apply the transformation formally to the continuum limit of the action \mathcal{A}_E^N , which has the form (13.10), except that \mathbf{x} is replaced by \vec{x} . Using the properties of the matrix (13.107)

$$\begin{aligned} A^T &= \vec{u}^2 A^{-1}, \\ \det A &= \sqrt{\det(AA^T)} = r^2, \end{aligned} \quad (13.117)$$

we see that

$$\vec{x}^{\prime 2} = 4\vec{u}^2 \vec{u}^{\prime 2} = 4r \vec{u}^{\prime 2}, \quad (13.118)$$

$$d^4x = 16r^2 d^4u. \quad (13.119)$$

In this way, we find the formal relation

$$\langle \mathbf{x}_b | \hat{\mathcal{U}}_E(S) | \mathbf{x}_a \rangle = e^{ie^2 S/\hbar} \frac{1}{16} \int \frac{dx_a^4}{r_a} (\vec{u}_b S | \vec{u}_a 0) \quad (13.120)$$

to the time evolution amplitude of the four-dimensional harmonic oscillator

$$(\vec{u}_b S | \vec{u}_a 0) = \int \mathcal{D}^4 u(s) \exp\left(\frac{i}{\hbar} \mathcal{A}_{\text{os}}\right), \quad (13.121)$$

with the action

$$\mathcal{A}_{\text{os}} = \int_0^S ds \frac{\mu}{2} (\vec{u}^{\prime 2} - \omega^2 \vec{u}^2). \quad (13.122)$$

The parameters are, as in (13.27) and (13.28),

$$\mu = 4M, \quad \omega = \sqrt{-E/2M}. \quad (13.123)$$

The relation (13.120) is the analog of (13.31). Instead of a sum over the two images of each point \mathbf{x} in \mathbf{u} -space, there is now an integral $\int dx_a^4/r_a$ over the infinitely many images in the four-dimensional \vec{u} -space. This integral can be rewritten as an integral over the third Euler angle γ using the relation (13.108). Since \mathbf{x} and thus the polar angles θ, φ remain fixed during the integration, we have directly $\int dx_a^4/r_a = \int d\gamma_a$. As far as the range of integration is concerned, we observe that it may be restricted to a single period $\gamma_a \in [0, 4\pi]$. The other periods can be included in the oscillator amplitude. By specifying a four-vector \vec{u}_b , all paths are summed which run either to the final Euler angle γ_b or to all its periodic repetitions [which by (13.102) have the same \vec{u}_b]. This was the lesson learned in Section 6.1. Equation (13.120) contains, instead, a sum over all initial periods which is completely equivalent to this. Thus the relation (13.120) reads, more specifically,

$$\langle \mathbf{x}_b | \hat{\mathcal{U}}_E(S) | \mathbf{x}_a \rangle = e^{ie^2 S/\hbar} \frac{1}{16} \int_0^{4\pi} d\gamma_a (\vec{u}_b S | \vec{u}_a 0). \quad (13.124)$$

The reason why the other periods in (13.120) must be omitted can best be understood by comparison with the two-dimensional case. There we observed a two-fold degeneracy of contributions to the time-sliced path integral which cancel all factors 2 in the measure (13.76). Here the same thing happens except with an infinite degeneracy: When integrating over all images d^4u_n of d^4x_n in the oscillator path integral we cover the original \mathbf{x} -space once for $\gamma_n \in [0, 4\pi]$ and repeat doing so for all periods $\gamma_n \in [4\pi l, 4\pi(l+1)]$. This suggests that each volume element d^4u_n must be divided

by an infinite factor to remove this degeneracy. However, this is not necessary since the gradient term produces precisely the same infinite factor. Indeed,

$$(\vec{u}_n + \vec{u}_{n-1})^2(\vec{u}_n - \vec{u}_{n-1})^2 \tag{13.125}$$

is small for $\vec{x}_n \approx \vec{x}_{n-1}$ at infinitely many places of $\gamma_n - \gamma_{n-1}$, once for each periodic repetition of the interval $[0, 4\pi]$. The infinite degeneracy cancels the infinite factor in the denominator of the measure. The only place where this cancellation does not occur is in the integral $\int dx_a^4/r_a$. Here the infinite factor in the denominator is still present, but it can be removed by restricting the integration over γ_a in (13.124) to a single period [8].

Note that a shift of γ_a by a half-period 2π changes \vec{u} to $-\vec{u}$ and thus corresponds to the two-fold degeneracy in the previous two-dimensional system.

The time-sliced path integral for the harmonic oscillator can, of course, be done immediately, the amplitude being the four-dimensional version of (13.33) [recall (2.177)]:

$$\begin{aligned} (\vec{u}_b S | \vec{u}_a 0) &= \frac{1}{(2\pi i \hbar \epsilon_s / \mu)^2} \prod_{n=1}^N \left[\int \frac{d^4 \Delta u_n}{2\pi i \hbar \epsilon_s / \mu} \right] \exp \left[\frac{i}{\hbar} \sum_{n=1}^N \frac{\mu}{2} \left(\frac{1}{\epsilon_s} \Delta \vec{u}_n^2 - \epsilon_s \omega^2 \vec{u}_n^2 \right) \right] \\ &= \frac{\omega^2}{(2\pi i \hbar \sin \omega S / \mu)^2} \exp \left\{ \frac{i}{2\hbar} \frac{\mu \omega}{\sin \omega S} [(\vec{u}_b^2 + \vec{u}_a^2) \cos \omega S - 2\vec{u}_b \vec{u}_a] \right\}. \end{aligned} \tag{13.126}$$

To find the fixed-energy amplitude we have to integrate this over S :

$$(\mathbf{x}_b | \mathbf{x}_a)_E = \int_0^\infty dS e^{ie^2 S / \hbar} \frac{1}{16} \int_0^{4\pi} d\gamma_a (\vec{u}_b S | \vec{u}_a 0). \tag{13.127}$$

Just like (13.35), the integral is written most conveniently in terms of the variables (13.38), (13.40), so that we obtain the fixed-energy amplitude of the three-dimensional Coulomb system

$$\begin{aligned} (\mathbf{x}_b | \mathbf{x}_a)_E &= \frac{1}{16} \int_0^\infty dS e^{ie^2 S / \hbar} \int_0^{4\pi} d\gamma_a (\vec{u}_b S | \vec{u}_a 0) \\ &= -i \frac{\omega M^2}{2\pi^2 \hbar^2} \int_{-\infty}^\infty \frac{dx_a^4}{r_a} \int_0^1 d\varrho \frac{\varrho^{-\nu}}{(1-\varrho)^2} \exp \left(2\kappa \frac{2\sqrt{\varrho}}{1-\varrho} \vec{u}_b \vec{u}_a \right) \exp \left[-\kappa \frac{1+\varrho}{1-\varrho} (r_b + r_a) \right]. \end{aligned}$$

In order to perform the integral over dx_b^4 , we now express $\vec{u}_b \vec{u}_a$ in terms of the polar angles

$$\begin{aligned} \vec{u}_b \vec{u}_a &= \sqrt{r_b r_a} \{ \cos(\theta_b/2) \cos(\theta_a/2) \cos[(\varphi_b - \varphi_a + \gamma_b - \gamma_a)/2] \\ &\quad + \sin(\theta_b/2) \sin(\theta_a/2) \cos[(\varphi_b - \varphi_a - \gamma_b + \gamma_a)/2] \}. \end{aligned} \tag{13.128}$$

A trigonometric rearrangement brings this to the form

$$\begin{aligned} \vec{u}_b \vec{u}_a &= \sqrt{r_b r_a} \{ \cos[(\theta_b - \theta_a)/2] \cos[(\varphi_b - \varphi_a)/2] \cos[(\gamma_b - \gamma_a)/2] \\ &\quad - \cos[(\theta_b + \theta_a)/2] \sin[(\varphi_b - \varphi_a)/2] \sin[(\gamma_b - \gamma_a)/2] \}, \end{aligned} \tag{13.129}$$

and further to

$$\vec{u}_b \vec{u}_a = \sqrt{(r_b r_a + \mathbf{x}_b \mathbf{x}_a)/2} \cos[(\gamma_b - \gamma_a + \beta)/2], \quad (13.130)$$

where β is defined by

$$\tan \frac{\beta}{2} = \frac{\cos[(\theta_b + \theta_a)/2] \sin[(\varphi_b - \varphi_a)/2]}{\cos[(\theta_b - \theta_a)/2] \cos[(\varphi_b - \varphi_a)/2]}, \quad (13.131)$$

or

$$\cos \frac{\beta}{2} = \cos \frac{\theta_b - \theta_a}{2} \cos \frac{\varphi_b - \varphi_a}{2} \sqrt{\frac{r_b r_a}{(r_b r_a + \mathbf{x}_b \mathbf{x}_a)/2}}. \quad (13.132)$$

The integral $\int_0^{4\pi} d\gamma_a$ can now be done at each fixed \mathbf{x} . This gives the fixed-energy amplitude of the Coulomb system [1, 9, 11, 10].

$$\begin{aligned} (\mathbf{x}_b | \mathbf{x}_a)_E &= -i \frac{M\kappa}{\pi\hbar} \int_0^1 d\varrho \frac{\varrho^{-\nu}}{(1-\varrho)^2} I_0 \left(2\kappa \frac{2\sqrt{\varrho}}{1-\varrho} \sqrt{(r_b r_a + \mathbf{x}_b \mathbf{x}_a)/2} \right) \\ &\times \exp \left[-\kappa \frac{1+\varrho}{1-\varrho} (r_b + r_a) \right], \end{aligned} \quad (13.133)$$

where κ and ν are the same parameters as in Eqs. (13.40).

The integral converges only for $\nu < 1$, as in the two-dimensional case. It is again possible to write down another integral representation which converges for all $\nu \neq 1, 2, 3, \dots$ by changing the variables of integration to $\zeta \equiv (1 + \varrho)/(1 - \varrho)$ and transforming the integral over ζ into a contour integral encircling the cut from $\zeta = 1$ to ∞ in the clockwise sense. Since the cut is now of the type $(\zeta - 1)^{-\nu}$, the replacement rule is

$$\int_1^\infty d\zeta (\zeta - 1)^{-\nu} \dots \rightarrow \frac{\pi e^{i\pi\nu}}{\sin \pi\nu} \int_C \frac{d\zeta}{2\pi i} (\zeta - 1)^{-\nu} \dots \quad (13.134)$$

This leads to the representation

$$\begin{aligned} (\mathbf{x}_b | \mathbf{x}_a)_E &= -i \frac{M\kappa}{\pi\hbar} \frac{\pi e^{i\pi\nu}}{2 \sin \pi\nu} \int_C \frac{d\zeta}{2\pi i} (\zeta - 1)^{-\nu} (\zeta + 1)^\nu \\ &\times I_0(2\kappa \sqrt{\zeta^2 - 1} \sqrt{(r_b r_a + \mathbf{x}_b \mathbf{x}_a)/2}) e^{-\kappa\zeta(r_b + r_a)}. \end{aligned} \quad (13.135)$$

13.5 Absence of Time Slicing Corrections for $D = 3$

Let us now prove that for the three-dimensional Coulomb system also, the finite time-slicing procedure does not change the formal result of the last section. The reader not interested in the details is again referred to the brief argument in Section 13.6. The action \mathcal{A}_E^N in the time-sliced path integral has to be supplemented, in each slice, by the Jacobian action [as in (13.67)]

$$\begin{aligned} \frac{i}{\hbar} \mathcal{A}_J^\epsilon &= -e^\mu e^i_{\{\mu,\nu\}} \Delta u^\nu - e_i^\mu e^i_{\{\kappa,\nu\}} e_j^\kappa e^i_{\{\mu,\lambda\}} \Delta u^\nu \Delta u^\lambda \\ &= -\Gamma_{\{\nu\mu\}}^\mu \Delta u^\nu - \frac{1}{2} \Gamma_{\{\nu\kappa\}}^\sigma \Gamma_{\{\lambda\sigma\}}^\kappa \Delta u^\nu \Delta u^\lambda. \end{aligned} \quad (13.136)$$

The basis tetrad

$$e^i{}_{\mu} = \partial x^i / \partial u^{\mu} = 2A^i{}_{\mu}(\vec{u}), \quad i = 1, 2, 3, 4, \quad (13.137)$$

is now given by the 4×4 matrix (13.107), with the reciprocal tetrad

$$e_i{}^{\mu} = \frac{1}{2\vec{u}^2} e^i{}_{\mu}. \quad (13.138)$$

From this we find the matrix components of the connection [compare (13.18)]

$$\begin{aligned} (\Gamma_1)_{\mu}{}^{\nu} &= \frac{1}{\vec{u}^2} \begin{pmatrix} u^1 & u^2 & -u^3 & -u^4 \\ -u^2 & u^1 & -u^4 & u^3 \\ u^3 & u^4 & u^1 & u^2 \\ u^4 & -u^3 & -u^2 & u^1 \end{pmatrix}_{\mu}{}^{\nu}, \\ (\Gamma_2)_{\mu}{}^{\nu} &= \frac{1}{\vec{u}^2} \begin{pmatrix} u^2 & -u^1 & u^4 & -u^3 \\ u^1 & u^2 & -u^3 & -u^4 \\ -u^4 & u^3 & u^2 & -u^1 \\ u^3 & u^4 & u^1 & u^2 \end{pmatrix}_{\mu}{}^{\nu}, \\ (\Gamma_3)_{\mu}{}^{\nu} &= \frac{1}{\vec{u}^2} \begin{pmatrix} u^3 & u^4 & u^1 & u^2 \\ -u^4 & u^3 & u^2 & -u^1 \\ -u^1 & -u^2 & u^3 & u^4 \\ -u^2 & u^1 & -u^4 & u^3 \end{pmatrix}_{\mu}{}^{\nu}, \\ (\Gamma_4)_{\mu}{}^{\nu} &= \frac{1}{\vec{u}^2} \begin{pmatrix} u^4 & -u^3 & -u^2 & u^1 \\ u^3 & u^4 & u^1 & u^2 \\ u^2 & -u^1 & u^4 & -u^3 \\ -u^1 & -u^2 & u^3 & u^4 \end{pmatrix}_{\mu}{}^{\nu}. \end{aligned} \quad (13.139)$$

As in the two-dimensional case [see Eq. (13.19)], the connection satisfies the important identity

$$\Gamma_{\mu}{}^{\mu\nu} \equiv 0, \quad (13.140)$$

which is again a consequence of the relation [compare (13.21)]

$$\partial_{\mu} e^i{}_{\mu} = 0. \quad (13.141)$$

In Section 13.6, this will be shown to be the essential reason for the absence of the time slicing corrections being proved in this section.

However, there is now an important difference with respect to the two-dimensional case. The present mapping $dx^i = e^i{}_{\mu}(u) du^{\mu}$ is not integrable. Taking the antisymmetric part of $\Gamma_{\mu\nu}{}^{\lambda}$ we find the u^{μ} -space to carry a torsion $S_{\mu\nu}{}^{\lambda}$ whose only nonzero components are

$$S_{12}{}^{\lambda} = S_{34}{}^{\lambda} = \frac{1}{\vec{u}^2} (-u^2, u^1, -u^4, u^3)^{\lambda}. \quad (13.142)$$

The once-contracted torsion is

$$S_{\mu} = S_{\mu\nu}{}^{\nu} = \frac{u^{\mu}}{\vec{u}^2}. \quad (13.143)$$

For this reason, the contracted connections

$$\begin{aligned} \Gamma_{\nu\mu}{}^{\mu} &= e_i{}^{\mu} \partial_{\nu} e^i{}_{\mu} = \frac{4u^{\nu}}{\vec{u}^2}, \\ \Gamma_{\mu\nu}{}^{\mu} &= -e^i{}_{\nu} \partial_{\mu} e_i{}^{\mu} = \frac{2u^{\nu}}{\vec{u}^2} \end{aligned} \quad (13.144)$$

are no longer equal, as they were in (13.69). Symmetrization in the lower indices gives

$$\Gamma_{\{\nu\mu\}}^\mu = \frac{3u^\nu}{\vec{u}^2}. \tag{13.145}$$

Due to this, the $\Delta u^\nu \Delta u^\lambda$ -terms in (13.136) are, in contrast to the two-dimensional case, not given directly by

$$\Gamma_{\nu\kappa}^\sigma \Gamma_{\lambda\sigma}^\kappa = -\frac{4}{\vec{u}^4}(\delta^{\nu\lambda} \vec{u}^2 - 2u^\nu u^\lambda). \tag{13.146}$$

The symmetrization in the lower indices is necessary and yields

$$\begin{aligned} \Gamma_{\{\nu\kappa\}}^\sigma \Gamma_{\{\lambda\sigma\}}^\kappa &= \Gamma_{\nu\kappa}^\sigma \Gamma_{\lambda\sigma}^\kappa - 2\Gamma_{\nu\kappa}^\sigma S_{\lambda\sigma}^\kappa + S_{\nu\kappa}^\sigma S_{\lambda\sigma}^\kappa \\ &= \Gamma_{\nu\kappa}^\sigma \Gamma_{\lambda\sigma}^\kappa - 2(-\delta_{\nu\lambda} \vec{u}^2 + 2u_\nu u_\lambda)/\vec{u}^4 + u_\nu u_\lambda/\vec{u}^4. \end{aligned} \tag{13.147}$$

Collecting all terms, the Jacobian action (13.136) becomes

$$\frac{i}{\hbar} \mathcal{A}_J^\epsilon = - \left[3 \frac{\vec{u}_n \Delta \vec{u}_n}{\vec{u}_n^2} - \frac{\Delta \vec{u}_n^2}{\vec{u}_n^2} + \frac{5}{2} \left(\frac{\vec{u}_n \Delta \vec{u}_n}{\vec{u}_n^2} \right)^2 + \dots \right]. \tag{13.148}$$

In contrast to the two-dimensional equation (13.71), this cannot be incorporated into \mathcal{A}_f^ϵ . Although the two expressions contain the same terms, their coefficients are different [see (13.116)]:

$$\begin{aligned} \frac{i}{\hbar} \mathcal{A}_f^\epsilon &= 3\lambda \log \left(\frac{\vec{u}_n^2}{\vec{u}_{n-1}^2} \right) \\ &= 3\lambda \left[2 \frac{\vec{u}_n \Delta \vec{u}_n}{\vec{u}_n^2} - \frac{\Delta \vec{u}_n^2}{\vec{u}_n^2} + 2 \left(\frac{\vec{u}_n \Delta \vec{u}_n}{\vec{u}_n^2} \right)^2 + \dots \right]. \end{aligned} \tag{13.149}$$

It is then convenient to rewrite (omitting the subscripts n)

$$\begin{aligned} \frac{i}{\hbar} \mathcal{A}_J^\epsilon &= -2 \log \left[\frac{\vec{u}^2}{(\vec{u} - \Delta \vec{u})^2} \right] + \frac{\vec{u} \Delta \vec{u}}{\vec{u}^2} \\ &\quad - \frac{\Delta \vec{u}^2}{\vec{u}^2} + \frac{3}{2} \left(\frac{\vec{u} \Delta \vec{u}}{\vec{u}^2} \right)^2 + \dots, \end{aligned} \tag{13.150}$$

and absorb the first term into \mathcal{A}_f^ϵ , which changes 3λ to $(3\lambda - 2)$. Thus, we obtain altogether the additional action [to be compared with (13.81)]

$$\begin{aligned} \frac{i}{\hbar} \Delta_{\text{corr}} \mathcal{A}^\epsilon &= \frac{i}{\hbar} 4M \frac{\Delta \vec{u}^2}{2\epsilon} \left[(2\lambda - 1) \frac{\vec{u} \Delta \vec{u}}{\vec{u}^2} + \left(\frac{1}{4} - \lambda \right) \frac{\Delta \vec{u}^2}{\vec{u}^2} + 2\lambda^2 \left(\frac{\vec{u} \Delta \vec{u}}{\vec{u}^2} \right)^2 \right] \\ &\quad + (3\lambda - 2) \left[2 \frac{\vec{u} \Delta \vec{u}}{\vec{u}^2} - \frac{\Delta \vec{u}^2}{\vec{u}^2} + 2 \left(\frac{\vec{u} \Delta \vec{u}}{\vec{u}^2} \right)^2 \right] \\ &\quad + \frac{\vec{u} \Delta \vec{u}}{\vec{u}^2} - \frac{(\Delta \vec{u})^2}{\vec{u}^2} + \frac{3}{2} \left(\frac{\vec{u} \Delta \vec{u}}{\vec{u}^2} \right)^2 + \dots. \end{aligned} \tag{13.151}$$

Using this we now show that the expansion of the correction term

$$C = \exp \left(\frac{i}{\hbar} \Delta_{\text{corr}} \mathcal{A}^\epsilon \right) - 1 \tag{13.152}$$

has the vanishing expectations

$$\begin{aligned} \langle C \rangle_0 &= 0, \\ \langle C (\vec{p} \Delta \vec{u}) \rangle_0 &= 0, \end{aligned} \tag{13.153}$$

i.e.,

$$\frac{i}{\hbar} \langle \Delta_{\text{corr}} \mathcal{A}^\epsilon \rangle_0 + \frac{1}{2} \left(\frac{i}{\hbar} \right)^2 \langle (\Delta_{\text{corr}} \mathcal{A}^\epsilon)^2 \rangle_0 = 0, \quad (13.154)$$

$$\frac{i}{\hbar} \langle \Delta_{\text{corr}} \mathcal{A} (\vec{p} \Delta \vec{u}) \rangle_0 = 0, \quad (13.155)$$

as in (13.92), (13.93). In fact, using formula (13.91) the expectation (13.155) is immediately found to be proportional to

$$i \left[-2(2\lambda - 1) \frac{D+2}{16} + 2(3\lambda - 2) \frac{1}{4} + \frac{1}{4} \right], \quad (13.156)$$

which vanishes identically in λ for $D = 4$. Similarly, using formula (13.90), the first term in (13.154) has an expectation proportional to

$$i \left[-2 \left(\frac{1}{4} - \lambda \right) \frac{(D+2)D}{16} - 4\lambda^2 \frac{D+2}{16} - (3\lambda - 2) \left(\frac{D}{4} - \frac{2}{4} \right) - \left(\frac{D}{4} - \frac{3}{8} \right) \right], \quad (13.157)$$

i.e., for $D = 4$,

$$-i \frac{3}{8} (2\lambda - 1)^2, \quad (13.158)$$

to which the second term adds

$$i \frac{1}{2} \left[4(2\lambda - 1)^2 \frac{(D+4)(D+2)}{64} + 9(2\lambda - 1)^2 \frac{1}{4} - 12(2\lambda - 1)^2 \frac{D+2}{16} \right], \quad (13.159)$$

which cancels (13.159) for $D = 4$. Thus the sum of all time slicing corrections vanishes also in the three-dimensional case.

13.6 Geometric Argument for Absence of Time Slicing Corrections

As mentioned before, the basic reason for the absence of the time slicing corrections can be shown to be the property of the connection

$$\Gamma_{\mu}^{\mu\lambda} = g^{\mu\nu} e_i^\lambda \partial_\mu e^i_\nu = 0, \quad (13.160)$$

which, in turn, follows from the basic identity $\partial_\mu e^i_\mu = 0$ satisfied by the basis tetrad, and from the diagonality of the metric $g^{\mu\nu} \propto \delta^{\mu\nu}$. Indeed, it is possible to apply the techniques of Sections 10.1, 10.2 to the general pseudotime evolution amplitude (12.28) with the regulating functions

$$f_l = f(\mathbf{x}), \quad f_r \equiv 1. \quad (13.161)$$

Since this regularization affects only the postpoints at each time slice, it is straightforward to repeat the derivation of an equivalent short-time amplitude given in Section 11.3. The result can be expressed in the form (dropping subscripts n)

$$K^\epsilon(\Delta q) = \frac{\sqrt{g(q)}}{\sqrt{2\pi i \epsilon \hbar f / M^D}} \exp \left[\frac{i}{\hbar} (\mathcal{A}^\epsilon + \mathcal{A}_J^\epsilon) \right], \quad (13.162)$$

where f abbreviates the postpoint value $f(\mathbf{x}_n)$ and \mathcal{A}^ϵ is the short-time action

$$\mathcal{A}^\epsilon = \frac{M}{2\epsilon f} g_{\mu\nu}(q) \Delta q^\mu \Delta q^\nu. \quad (13.163)$$

There exists now a simple expression for the Jacobian action. Using formula (11.75), it becomes simply

$$\frac{i}{\hbar} \mathcal{A}_J^\epsilon = \frac{1}{2} \Gamma_{\mu}^{\mu}{}_{\nu} \Delta q^\nu - i\epsilon \frac{\hbar f}{8M} (\Gamma_{\mu}^{\mu}{}_{\nu})^2. \quad (13.164)$$

In the postpoint formulation, the measure needs no further transformation. This can be seen directly from the time-sliced expression (13.8) for $\lambda = 0$ or, more explicitly, from the vanishing of the extra action \mathcal{A}_f^ϵ in (13.74) for $D = 2$ and in (13.149) for $D = 3$. As a result, the vanishing contracted connection appearing in (13.164) makes *all* time-slicing corrections vanish. Only the basic short-time action (13.163) survives:

$$\Delta \mathcal{A}^\epsilon = 4M \frac{(\Delta \mathbf{u})^2}{2\epsilon_s}. \quad (13.165)$$

Thanks to this fortunate circumstance, the formal solution found in 1979 by Duru and Kleinert happens to be correct.

13.7 Comparison with Schrödinger Theory

For completeness, let us also show the significance of the geometric property $\Gamma_{\mu}^{\mu\lambda} = 0$ within the Schrödinger theory. Consider the Schrödinger equation of the Coulomb system

$$\left(-\frac{1}{2M} \hbar^2 \nabla^2 - E \right) \psi(\mathbf{x}) = \frac{e^2}{r} \psi(\mathbf{x}), \quad (13.166)$$

to be transformed to that of a harmonic oscillator. The postpoint regularization of the path integral with the functions (13.161) corresponds to multiplying the Schrödinger equation with $f_t = r$ from the left. This gives

$$\left(-\frac{1}{2M} \hbar^2 r \nabla^2 - Er \right) \psi(\mathbf{x}) = e^2 \psi(\mathbf{x}). \quad (13.167)$$

We now go over to the square root coordinates u^μ transforming $-Er$ into the harmonic potential $-E(u^\mu)^2$ and the Laplacian ∇^2 into $g^{\mu\nu} \partial_\mu \partial_\nu - \Gamma_{\mu}^{\mu\lambda} \partial_\lambda$. The geometric property $\Gamma_{\mu}^{\mu\lambda} = 0$ ensures now the absence of the second term and the result is simply $g^{\mu\nu} \partial_\mu \partial_\nu$. Since $g^{\mu\nu} = \delta^{\mu\nu}/4r$, the Schrödinger equation (13.167) takes the simple form

$$\left[-\frac{1}{8M} \hbar^2 \partial_\mu^2 - E(u^\mu)^2 \right] \psi(u^\mu) = e^2 \psi(u^\mu). \quad (13.168)$$

Due to the factor $(u^\mu)^2$ accompanying the energy E , the physical scalar product in which the states of different energies are orthogonal to each other is given by

$$\langle \psi' | \psi \rangle = \int d^4 u \psi'(u^\mu) (u^\mu)^2 \psi(u). \quad (13.169)$$

This corresponds precisely to the scalar product given in Eq. (11.95) with the purpose of making the Laplace operator (here $\Delta = (1/4\mathbf{u}^2) \partial_{\mathbf{u}}^2$) hermitian in the u^μ -space

with torsion. Indeed, the once-contracted torsion tensor $S_\mu = S_{\mu\nu}{}^\nu$ can be written as a gradient of a scalar function:

$$S_\mu = \partial_\mu \sigma(\vec{u}), \quad \sigma(\vec{u}) = \frac{1}{2} \log \vec{u}^2. \quad (13.170)$$

Quite generally, we have shown in Eq. (11.104) that if $S_\mu(q)$ is a partial derivative of a scalar field $\sigma(q)$, the physical scalar product is given by (11.95):

$$\langle \psi_2 | \psi_1 \rangle_{\text{phys}} \equiv \int d^D q \sqrt{g(q)} e^{-2\sigma(q)} \psi_2^*(q) \psi_1(q). \quad (13.171)$$

From (13.137), we have

$$\sqrt{g} = 16\vec{u}^4, \quad (13.172)$$

so that the physical scalar product is

$$\langle \psi_2 | \psi_1 \rangle_{\text{phys}} = \int d^4 u \sqrt{g} e^{-2\sigma} \psi_2^*(\vec{u}) \psi_1(\vec{u}) = \int d^4 u 16\vec{u}^2 \psi_2^*(\vec{u}) \psi_1(\vec{u}). \quad (13.173)$$

The Laplace operator obtained from ∂_x^2 by the nonholonomic Kustaanheimo-Stiefel transformation is $\Delta = (1/4\vec{u}^2)\partial_\mu^2$. This is Hermitian in the physical scalar product (13.173), but not in the naive one (11.90) with the integral measure $\int d^4 u 16\vec{u}^4$.

In two dimensions, the torsion vanishes and the physical scalar product reduces to the naive one:

$$\langle \psi_2 | \psi_1 \rangle_{\text{phys}} = \int d^2 u \sqrt{g} \psi_2^*(\mathbf{u}) \psi_1(\mathbf{u}) = \int d^2 u 4\mathbf{u}^2 \psi_2^*(\mathbf{u}) \psi_1(\mathbf{u}). \quad (13.174)$$

With $\mu = 4M$ and $-E = \mu\omega^2/2$, Eq. (13.168) is the Schrödinger equation of a harmonic oscillator:

$$\left[-\frac{1}{2\mu} \hbar^2 \partial_\mu^2 + \frac{\mu}{2} \omega^2 (u^\mu)^2 \right] \psi(u^\mu) = \mathcal{E} \psi(u^\mu). \quad (13.175)$$

The eigenvalues of the pseudoenergy \mathcal{E} are

$$\mathcal{E}_N = \hbar\omega(N + D_u/2), \quad (13.176)$$

where $D_u = 4$ is the dimension of u^μ -space,

$$N = \sum_{i=1}^{D_u} n_i \quad (13.177)$$

sums up the integer principal quantum numbers of the factorized wave functions in each direction of the u^μ -space. The multivaluedness of the mapping from \mathbf{x} to u^μ allows only symmetric wave functions to be associated with Coulomb states. Hence

N must be even and can be written as $N = 2(n - 1)$. The pseudoenergy spectrum is therefore

$$\mathcal{E}_n = \hbar\omega 2(n + D_u/4 - 1), \quad n = 1, 2, 3, \dots \quad (13.178)$$

According to (13.175), the Coulomb wave functions must all have a pseudoenergy

$$\mathcal{E}_n = e^2. \quad (13.179)$$

The two equations are fulfilled if the oscillator frequency has the discrete values

$$\omega = \omega_n \equiv \frac{e^2}{2(n + D_u/4 - 1)}, \quad n = 1, 2, 3, \dots \quad (13.180)$$

With $\omega^2 = -E/2M$ and $D_u = 4$, this yields the Coulomb energies

$$E_n = -2M\omega_n^2 = -\frac{Me^4}{\hbar^2} \frac{1}{2n^2} = -Mc^2 \frac{\alpha^2}{2n^2}, \quad (13.181)$$

showing that the number $N/2 = n - 1$ corresponds to the usual principal quantum number of the Coulomb wave functions.

Let us now focus our attention upon the three-dimensional Coulomb system where $D_u = 4$. In this case, not all even oscillator wave functions correspond to Coulomb bound-state wave functions. This follows from the fact that the Coulomb wave functions do not depend on the dummy fourth coordinate x^4 (or the dummy angle γ). Thus they satisfy the constraint $\partial_{x^4}\psi = 0$, implying in u^μ -space [recall (13.137)]

$$\begin{aligned} -ir\partial_{x^4}\psi(\mathbf{x}) &= -ire_4^\mu\partial_\mu\psi(u^\mu) = -i\frac{1}{2}[(u^2\partial_1 - u^1\partial_2) + (u^4\partial_3 - u^3\partial_4)]\psi(u^\mu) \\ &= -i\partial_\gamma\psi(u^\mu) = 0. \end{aligned} \quad (13.182)$$

The explicit construction of the oscillator and Coulomb bound-state wave functions is most conveniently done in terms of the complex coordinates (13.101). In terms of these, the constraint (13.182) reads

$$\frac{1}{2}[\bar{z}\partial_{\bar{z}} - z\partial_z]\psi(z, z^*) = 0. \quad (13.183)$$

This will be used below to select the Coulomb states.

To solve the Schrödinger equation (13.175) we simplify the notation by going over to *atomic natural units*, where $\hbar = 1$, $M = 1$, $e^2 = 1$, $\mu = 4M = 4$. All lengths are measured in units of the Bohr radius (4.376), whose numerical value is $a_H = \hbar^2/Me^2 = 5.2917 \times 10^{-9}$ cm, all energies in units of $E_H \equiv e^2/a_H = Me^4/\hbar^2 = 4.359 \times 10^{-11}$ erg = 27.210 eV, and all frequencies ω in units of $\omega_H \equiv$

$Me^4/\hbar^3 = 4.133 \times 10^{16}/\text{sec}$ ($= 4\pi \times$ Rydberg frequency ν_R). Then (13.175) reads (after multiplication by $4M/\hbar^2$)

$$\hat{h}\psi(u^\mu) \equiv \frac{1}{2} \left[-\partial_\mu^2 + 16\omega^2(u^\mu)^2 \right] \psi(u^\mu) = 4\psi(u^\mu). \quad (13.184)$$

The spectrum of the operator \hat{h} is obviously $4\omega(N+2) = 8\omega n$. To satisfy the equation, the frequency ω has to be equal to $\omega_n = 1/2n$.

We now observe that the operator \hat{h} can be brought to the standard form

$$\hat{h}^s = \frac{1}{2} \left[-\partial_\mu^2 + 4(u^\mu)^2 \right], \quad (13.185)$$

with the help of the ω -dependent transformation

$$\hat{h} = 4\omega e^{i\vartheta\hat{D}} \hat{h}^s e^{-i\vartheta\hat{D}}, \quad (13.186)$$

in which the operator \hat{D} is an infinitesimal *dilation operator* which in this context is called *tilt operator* [12, 13]:

$$\hat{D} \equiv -\frac{1}{2} iu^\mu \partial_\mu, \quad (13.187)$$

and ϑ is the *tilt angle*

$$\vartheta = \log(2\omega). \quad (13.188)$$

The Coulomb wave functions are therefore given by the rescaled solutions of the standardized Schrödinger equation (13.185):

$$\psi(u^\mu) = e^{i\vartheta\hat{D}} \psi^s(u^\mu) = \psi^s(\sqrt{2\omega}u^\mu). \quad (13.189)$$

Note that for a solution with a principal quantum number n the scale parameter $\sqrt{2\omega}$ depends on n :

$$\psi_n(u^\mu) = \psi_n^s(u^\mu/\sqrt{n}). \quad (13.190)$$

The standardized wave functions $\psi_n^s(u^\mu)$ are constructed most conveniently by means of four sets of creation and annihilation operators $\hat{a}_1^\dagger, \hat{a}_2^\dagger, \hat{b}_1^\dagger, \hat{b}_2^\dagger$, and $\hat{a}_1, \hat{a}_2, \hat{b}_1, \hat{b}_2$. They are combinations of z_1, z_2 , their complex-conjugates, and the associated differential operators $\partial_{z_1}, \partial_{z_2}, \partial_{z_1^*}, \partial_{z_2^*}$. The combinations are the same as in (9.127), (9.128), written down once for z_1 and once for z_2 . In addition, we choose the indices so that a_i and b_i transform by the same spinor representation of the rotation group. If c_{ij} is the 2×2 matrix

$$c = i\sigma^2 = \begin{pmatrix} 0 & 1 \\ -1 & 0 \end{pmatrix}, \quad (13.191)$$

then $c_{ij}z_j$ transforms like z_i^* . We therefore define the creation operators

$$\begin{aligned} \hat{a}_1^\dagger &\equiv -\frac{1}{\sqrt{2}}(-\partial_{z_2^*} + z_2), & \hat{b}_1^\dagger &\equiv \frac{1}{\sqrt{2}}(-\partial_{z_1} + z_1^*), \\ \hat{a}_2^\dagger &\equiv \frac{1}{\sqrt{2}}(-\partial_{z_1^*} + z_1), & \hat{b}_2^\dagger &\equiv \frac{1}{\sqrt{2}}(-\partial_{z_2} + z_2^*), \end{aligned} \quad (13.192)$$

and the annihilation operators

$$\begin{aligned} \hat{a}_1 &\equiv -\frac{1}{\sqrt{2}}(\partial_{z_2} + z_2^*), & \hat{b}_1 &\equiv \frac{1}{\sqrt{2}}(\partial_{z_1^*} + z_1), \\ \hat{a}_2 &\equiv \frac{1}{\sqrt{2}}(\partial_{z_1} + z_1^*), & \hat{b}_2 &\equiv \frac{1}{\sqrt{2}}(\partial_{z_2^*} + z_2). \end{aligned} \quad (13.193)$$

Note that $\partial_z^\dagger = -\partial_{z^*}$. The standardized oscillator Hamiltonian is then

$$\hat{h}^s = 2(\hat{a}^\dagger \hat{a} + \hat{b}^\dagger \hat{b} + 2), \quad (13.194)$$

where we have used the same spinor notation as in (13.99). The ground state of the four-dimensional oscillator is annihilated by \hat{a}_1, \hat{a}_2 and \hat{b}_1, \hat{b}_2 . It has therefore the wave function

$$\langle z, z^* | 0 \rangle = \psi_{s,0000}(z, z^*) = \frac{1}{\sqrt{\pi}} e^{-z_1 z_1^* - z_2 z_2^*} = \frac{1}{\sqrt{\pi}} e^{-(u^\mu)^2}. \quad (13.195)$$

The complete set of oscillator wave functions is obtained, as usual, by applying the creation operators to the ground state,

$$|n_1^a, n_2^a, n_1^b, n_2^b\rangle = N_{n_1^a, n_2^a, n_1^b, n_2^b} \hat{a}_1^{\dagger n_1^a} \hat{a}_2^{\dagger n_2^a} \hat{b}_1^{\dagger n_1^b} \hat{b}_2^{\dagger n_2^b} |0\rangle, \quad (13.196)$$

with the normalization factor

$$N_{n_1^a, n_2^a, n_1^b, n_2^b} = \frac{1}{\sqrt{n_1^a! n_2^a! n_1^b! n_2^b!}}. \quad (13.197)$$

The eigenvalues of \hat{h}^s are obtained from the sum of the number of a - and b -quanta as

$$2(n_1^a + n_2^a + n_1^b + n_2^b + 2) = 2(N + 2) = 4n. \quad (13.198)$$

The Coulomb bound-state wave functions are in one-to-one correspondence with those oscillator wave functions which satisfy the constraint (13.183), which may now be written as

$$\hat{L}_{05} = -\frac{1}{2}(\hat{a}^\dagger \hat{a} - \hat{b}^\dagger \hat{b})\psi^s = 0. \quad (13.199)$$

These states carry an equal number of a - and b -quanta. They diagonalize the (mutually commuting) a - and b -spins

$$\hat{L}_i^a \equiv \frac{1}{2} \hat{a}^\dagger \sigma_i \hat{a}, \quad \hat{L}_i^b \equiv \frac{1}{2} \hat{b}^\dagger \sigma_i \hat{b}, \quad (13.200)$$

with the quantum numbers

$$\begin{aligned} l^a &= (n_1^a + n_2^a)/2, & m^a &= (n_1^a - n_2^a)/2, \\ l^b &= (n_1^b + n_2^b)/2, & m^b &= (n_1^b - n_2^b)/2, \end{aligned} \quad (13.201)$$

where l, m are the eigenvalues of \hat{L}^2, \hat{L}_3 . By defining

$$\begin{aligned} n_1^a &\equiv n_1 + m, & n_2^a &\equiv n_2, & n_1^b &\equiv n_2 + m, & n_2^b &\equiv n_1, & \text{for } m \geq 0, \\ n_1^a &\equiv n_1, & n_2^a &\equiv n_2 - m, & n_1^b &\equiv n_2, & n_2^b &\equiv n_1 - m, & \text{for } m \leq 0, \end{aligned} \quad (13.202)$$

we establish contact with the eigenstates $|n_1, n_2, m\rangle$ which arise naturally when diagonalizing the Coulomb Hamiltonian in parabolic coordinates. The relation between these states and the usual Coulomb wave function of a given angular momentum $|nlm\rangle$ is obvious since the angular momentum operator \hat{L}_i is equal to the sum of a - and b -spins. The rediagonalization is achieved by the usual vector coupling coefficients (see the last equation in Appendix 13A).

Note that after the tilt transformation (13.189), the exponential behavior of the oscillator wave functions $\psi_n^s(u^\mu) \propto \text{polynomial}(u^\mu) \times e^{-(u^\mu)^2}$ goes correctly over into the exponential r -dependence of the Coulomb wave functions $\psi(\mathbf{x}) \propto \text{polynomial}(\mathbf{x}) \times e^{-r/n}$.

It is important to realize that although the dilation operator \hat{D} is Hermitian and the operator $e^{i\vartheta\hat{D}}$ at a *fixed* angle ϑ is unitary, the Coulomb bound states ψ_n , arising from the complete set of oscillator states ψ_n^s by applying $e^{i\vartheta\hat{D}}$, do *not* span the Hilbert space. Due to the n -dependence of the tilt angle $\vartheta_n = \log(1/n)$, a section of the Hilbert space is not reached. The continuum states of the Coulomb system, which are obtained by tilting another complete set of states, precisely fill this section. Intuitively we can understand this incompleteness simply as follows. The wave functions $\psi_n^s(u^\mu)$ have for increasing n spatial oscillations with shorter and shorter wavelength. These allow the completeness sum $\sum_n \psi_n^s(u^\mu)\psi_n^{s*}(u^\mu)$ to build up a δ -function which is necessary to span the Hilbert space. In contrast, when forming the sum of the dilated wave functions

$$\sum_n \psi_n^s(u^\mu/\sqrt{n})\psi_n^{s*}(u^\mu/\sqrt{n}),$$

the terms of larger n have increasingly stretched spatial oscillations which are *not* sufficient to build up an infinitely narrow distribution.

A few more algebraic properties of the creation and annihilation operator representation of the Coulomb wave functions are collected in Appendix 13A and 13.10.

13.8 Angular Decomposition of Amplitude, and Radial Wave Functions

Let us also give an angular decomposition of the fixed-energy amplitude. This serves as a convenient starting point for extracting the radial wave functions of the

Coulomb system which will, in Chapter 14, enable us to find the Coulomb amplitude to D dimensions. We begin with the expression (13.133),

$$\begin{aligned}
 (\mathbf{x}_b|\mathbf{x}_a)_E &= -i\frac{M\kappa}{\pi\hbar} \int_0^1 d\varrho \frac{\varrho^{-\nu}}{(1-\varrho)^2} I_0\left(2\kappa\frac{2\sqrt{\varrho}}{1-\varrho}\sqrt{(r_b r_a + \mathbf{x}_b \mathbf{x}_a)/2}\right) \\
 &\quad \times \exp\left\{-\kappa\frac{1+\varrho}{1-\varrho}(r_b + r_a)\right\}, \tag{13.203}
 \end{aligned}$$

and rewrite the Bessel function as $I_0(z \cos(\theta/2))$, where θ is the relative angle between \mathbf{x}_a and \mathbf{x}_b , and

$$z \equiv 2\kappa\sqrt{r_b r_a} \frac{2\sqrt{\varrho}}{1-\varrho}. \tag{13.204}$$

Now we make use of the expansion¹

$$\left(\frac{1}{2}kz\right)^{\mu-\nu} I_\nu(kz) = k^\mu \sum_{l=0}^{\infty} \frac{1}{l!} \frac{\Gamma(l+\mu)}{\Gamma(1+\nu)} (2l+\mu) F(-l, l+\mu; 1+\nu; k^2) (-)^l I_{2l+\mu}(z). \tag{13.205}$$

Setting $k = \cos(\theta/2)$, $\nu = 2q > 0$, $\mu = 1 + 2q$, and using formulas (1.445), (1.446) for the rotation functions, this becomes

$$I_{2q}(z \cos(\theta/2)) = \frac{2}{z} \sum_{l=|q|}^{\infty} (2l+1) d_{qq}^l(\theta) I_{2l+1}(z), \tag{13.206}$$

reducing for $q = 0$ to

$$I_0(z \cos(\theta/2)) = \frac{2}{z} \sum_{l=0}^{\infty} (2l+1) P_l(\cos \theta) I_{2l+1}(z). \tag{13.207}$$

After inserting this into (13.133) and substituting $y = -\frac{1}{2} \log \varrho$, so that

$$\varrho = e^{-2y}, \quad z = 2\kappa\sqrt{r_b r_a} \frac{1}{\sinh y}, \tag{13.208}$$

we expand the fixed-energy amplitude into spherical harmonics

$$\begin{aligned}
 (\mathbf{x}_b|\mathbf{x}_a)_E &= \frac{1}{r_b r_a} \sum_{l=0}^{\infty} (r_b|r_a)_{E,l} \frac{2l+1}{4\pi} P_l(\cos \theta) \\
 &= \frac{1}{r_b r_a} \sum_{l=0}^{\infty} (r_b|r_a)_{E,l} \sum_{m=-l}^l Y_{lm}(\hat{\mathbf{x}}_b) Y_{lm}^*(\hat{\mathbf{x}}_a), \tag{13.209}
 \end{aligned}$$

¹G.N. Watson, *Theory of Bessel Functions*, Cambridge University Press, London, 1966, 2nd ed., p.140, formula (3).

with the radial amplitude

$$(r_b|r_a)_{E,l} = -i\sqrt{r_b r_a} \frac{2M}{\hbar} \int_0^\infty dy \frac{1}{\sinh y} e^{2\nu y} \quad (13.210)$$

$$\times \exp[-\kappa \coth y (r_b + r_a)] I_{2l+1} \left(2\kappa \sqrt{r_b r_a} \frac{1}{\sinh y} \right).$$

Now we apply the integral formula (9.29) and find

$$(r_b|r_a)_{E,l} = -i \frac{M}{\hbar \kappa} \frac{\Gamma(-\nu + l + 1)}{(2l + 1)!} W_{\nu, l+1/2}(2\kappa r_b) M_{\nu, l+1/2}(2\kappa r_a). \quad (13.211)$$

On the right-hand side the energy E is contained in the parameters $\kappa = \sqrt{-2ME/\hbar^2}$ and $\nu = e^2/2\omega\hbar = \sqrt{-e^4 M/2\hbar^2 E}$. The Gamma function has poles at $\nu = n$ with $n = l + 1, l + 2, l + 3, \dots$. These correspond to the bound states of the Coulomb system at the energy eigenvalues

$$E_n = -\frac{Me^4}{\hbar^2} \frac{1}{2n^2} = -Mc^2 \frac{\alpha^2}{2n^2}. \quad (13.212)$$

Writing

$$\kappa = \frac{1}{a_H} \frac{1}{\nu}, \quad (13.213)$$

with the Bohr radius

$$a_H \equiv \frac{\hbar^2}{Me^2} \quad (13.214)$$

(for the electron, $a_H \approx 0.529 \times 10^{-8}$ cm), we have the approximations near the poles at $\nu \approx n$,

$$\Gamma(-\nu + l + 1) \approx -\frac{(-)^{n_r}}{n_r!} \frac{1}{\nu - n},$$

$$\frac{1}{\nu - n} \approx \frac{2}{n} \frac{\hbar^2 \kappa^2}{2M} \frac{1}{E - E_n},$$

$$\kappa \approx \frac{1}{a_H} \frac{1}{n}, \quad (13.215)$$

where $n_r = n - l - 1$. Hence

$$-i\Gamma(-\nu + l + 1) \frac{M}{\hbar \kappa} \approx \frac{(-)^{n_r}}{n^2 n_r!} \frac{1}{a_H} \frac{i\hbar}{E - E_n}. \quad (13.216)$$

Let us expand the pole parts of the spectral representation of the radial fixed-energy amplitude in the form

$$(r_b|r_a)_{E,l} = \sum_{n=l+1}^{\infty} \frac{i\hbar}{E - E_n} R_{nl}(r_b) R_{nl}(r_a) + \dots \quad (13.217)$$

The radial wave functions defined by this expansion correspond to the normalized bound-state wave functions

$$\psi_{nlm}(\mathbf{x}) = \frac{1}{r} R_{n,l}(r) Y_{lm}(\hat{\mathbf{x}}). \tag{13.218}$$

By comparing the pole terms of (13.211) and (13.217) [using (13.216) and formula (9.48) for the Whittaker functions, together with (9.50)], we identify the radial wave functions as

$$\begin{aligned} R_{nl}(r) &= \frac{1}{a_H^{1/2} n} \frac{1}{(2l+1)!} \sqrt{\frac{(n+l)!}{(n-l-1)!}} \\ &\times (2r/na_H)^{l+1} e^{-r/na_H} M(-n+l+1, 2l+2, 2r/na_H) \\ &= \frac{1}{a_H^{1/2} n} \sqrt{\frac{(n-l-1)!}{(n+l)!}} e^{-r/na_H} (2r/na_H)^{l+1} L_{n-l-1}^{2l+1}(2r/na_H). \end{aligned} \tag{13.219}$$

To obtain the last expression we have used formula (9.53).² It must be noted that the normalization integrals of the wave functions $R_{nl}(r)$ differ by a factor $z/2n = (2r/na_H)/2n$ from those of the harmonic oscillator (9.54), which are contained in integral tables. However, due to the recursion relation for the Laguerre polynomials

$$zL_n^\mu(z) = (2n + \mu + 1)L_n^\mu(z) - (n + \mu)L_{n-1}^\mu(z) - (n + 1)L_{n+1}^\mu(z), \tag{13.220}$$

the factor $z/2n$ leaves the values of the normalization integrals unchanged. The orthogonality of the wave functions with different n is much harder to verify since the two Laguerre polynomials in the integrals have different arguments. Here the group-theoretic treatment of Appendix 13A provides the simplest solution. The orthogonality is shown in Eq. (13A.28).

We now turn to the continuous wave functions. The fixed-energy amplitude has a cut in the energy plane for positive energy where $\kappa = -ik$ and $\nu = i/a_H k$ are imaginary. In this case we write $\nu = i\nu'$. From the discontinuity we can extract the scattering wave functions. The discontinuity is given by

$$\begin{aligned} \text{disc}(r_b|r_a)_{E,l} &= (r_b|r_a)_{E+i\eta,l} - (r_b|r_a)_{E-i\eta,l} \\ &= \frac{M}{\hbar k} \left[\frac{\Gamma(-i\nu' + l + 1)}{(2l + 1)!} W_{i\nu',l+1/2}(-2ikr_b) M_{i\nu',l+1/2}(-2ikr_a) + (\nu' \rightarrow -\nu') \right]. \end{aligned} \tag{13.221}$$

In the second term, we replace

$$M_{i\nu',l+1/2}(-2ikr) = e^{-i\pi(l+1)} M_{-i\nu',l+1/2}(2ikr), \tag{13.222}$$

and use the relation, valid for $\arg z \in (-\pi/2, 3\pi/2)$, $2\mu \neq -1, -2, -3, \dots$,

$$M_{\lambda,\mu}(z) = \frac{\Gamma(2\mu + 1)}{\Gamma(\mu + \lambda + 1/2)} e^{i\pi\lambda} e^{-i\pi(\mu+1/2)} W_{\lambda,\mu}(z) + \frac{\Gamma(2\mu + 1)}{\Gamma(\mu - \lambda + 1/2)} e^{i\pi\lambda} W_{-\lambda,\mu}(e^{i\pi}z), \tag{13.223}$$

²Compare L.D. Landau and E.M. Lifshitz, *Quantum Mechanics*, Pergamon, London, 1965, p. 119. Note the different definition of our Laguerre polynomials $L_n^\mu = [(-)^\mu / (n + \mu)!] L_{n+\mu}^\mu|_{\text{L.L.}}$.

to find

$$\text{disc}(r_b|r_a)_{E,l} = \frac{M}{\hbar k} \frac{|\Gamma(-i\nu' + l + 1)|^2}{(2l + 1)!} e^{\pi\nu'} M_{i\nu', l+1/2}(-2ikr_b) M_{-i\nu', l+1/2}(2ikr_a). \quad (13.224)$$

The continuum states enter the completeness relation as

$$\int_0^\infty \frac{dE}{2\pi\hbar} \text{disc}(r_b|r_a)_{E,l} + \sum_{n=l+1}^\infty R_{nl}(r_b) R_{nl}^*(r_a) = \delta(r_b - r_a) \quad (13.225)$$

[compare (1.330)]. Inserting (13.221) and replacing the continuum integral $\int_0^\infty dE/2\pi\hbar$ by the momentum integral $\int_{-\infty}^\infty dk k \hbar/2\pi M$, the continuum part of the completeness relation becomes

$$\int_{-\infty}^\infty dk R_{kl}(r_b) R_{kl}^*(r_a), \quad (13.226)$$

with the radial wave functions

$$R_{kl}(r) = \sqrt{\frac{1}{2\pi}} \frac{|\Gamma(-i\nu' + l + 1)|}{(2l + 1)!} e^{\pi\nu'/2} M_{i\nu', l+1/2}(-2ikr). \quad (13.227)$$

By expressing the Whittaker function $M_{\lambda,\mu}(z)$ in terms of the confluent hypergeometric functions, the Kummer functions $M(a, b, z)$, as

$$M_{\lambda,\mu}(z) = z^{\mu+1/2} e^{-z/2} M(\mu - \lambda + 1/2, 2\mu + 1, z), \quad (13.228)$$

we recover the well-known result of Schrödinger quantum mechanics:³

$$R_{kl}(r) = \sqrt{\frac{1}{2\pi}} \frac{|\Gamma(-i\nu' + l + 1)|}{(2l + 1)!} e^{\pi\nu'/2} e^{ikr} (-2ikr)^{l+1} M(-i\nu' + l + 1, 2l + 2, -2ikr). \quad (13.229)$$

13.9 Remarks on Geometry of Four-Dimensional u^μ -Space

A few remarks are in order on the Riemann geometry of the \vec{u} -space in four dimensions with the metric $g_{\mu\nu} = 4\vec{u}^2 \delta_{\mu\nu}$. As in two dimensions, the Cartan curvature tensor $R_{\mu\nu\lambda}{}^\kappa$ vanishes trivially since $e^i{}_\mu(\vec{u})$ is linear in \vec{u} :

$$(\partial_\mu \partial_\nu - \partial_\nu \partial_\mu) e^i{}_\lambda(\vec{u}) = 0. \quad (13.230)$$

In contrast to two dimensions, however, the Riemann curvature tensor $\bar{R}_{\mu\nu\lambda}{}^\kappa$ is nonzero. The associated Ricci tensor [see (10.41)], has the matrix elements

$$\begin{aligned} \bar{R}_{\nu\lambda} &= \bar{R}_{\mu\nu\lambda}{}^\mu \\ &= -\frac{3}{2\vec{u}^6} (\delta_{\nu\lambda} \vec{u}^2 - \vec{u}_\nu \vec{u}_\lambda), \end{aligned} \quad (13.231)$$

³L.D. Landau and E.M. Lifshitz, op. cit., p. 120.

yielding the scalar curvature

$$\bar{R} = g^{\nu\lambda} \bar{R}_{\nu\lambda} = -\frac{9}{2\bar{u}^4}. \quad (13.232)$$

In general, a diagonal metric of the form

$$g_{\mu\nu}(q) = \Omega^2(q) \delta_{\mu\nu} \quad (13.233)$$

is called *conformally flat* since it can be obtained from a flat space with a unit metric $g_{\mu\nu} = \delta_{\mu\nu}$ by a *conformal transformation* a la Weyl

$$g_{\mu\nu}(q) \rightarrow \Omega^2(q) g_{\mu\nu}(q). \quad (13.234)$$

Under such a transformation, the Christoffel symbol changes as follows:

$$\bar{\Gamma}_{\mu\nu}^{\lambda} \rightarrow \bar{\Gamma}_{\mu\nu}^{\lambda} + \Omega_{,\mu} \delta_{\nu}^{\lambda} + \Omega_{,\nu} \delta_{\mu}^{\lambda} - g_{\mu\nu} g^{\lambda\kappa} \Omega_{,\kappa}, \quad (13.235)$$

the subscript separated by a comma indicating a differentiation, i.e., $\Omega_{,\mu} \equiv \partial_{\mu} \Omega$.

In D dimensions, the Ricci tensor changes according to

$$\begin{aligned} \bar{R}_{\mu\nu} &\rightarrow \Omega^{-2} \bar{R}_{\mu\nu} - (D-2)(\Omega^{-3} \Omega_{;\mu\nu} - 2\Omega^{-4} \Omega_{,\mu} \Omega_{,\nu}) \\ &\quad - g_{\mu\nu} g^{\lambda\kappa} \left[(D-3)\Omega^{-4} \Omega_{,\lambda} \Omega_{,\kappa} + \Omega^{-3} \Omega_{;\lambda\kappa} \right] \\ &= \Omega^{-2} \bar{R}_{\mu\nu} + (D-2)\Omega^{-1} (\Omega^{-1})_{;\mu\nu} - g_{\mu\nu} (D-2)^{-1} \Omega^{-D} (\Omega^{D-2})_{;\lambda\kappa} g^{\lambda\kappa}. \end{aligned} \quad (13.236)$$

A subscript separated by a semicolon denotes the covariant derivative formed with Riemann connection, i.e.,

$$\Omega_{;\mu\nu} = D_{\nu} \Omega_{,\mu} = \Omega_{\mu\nu} - \bar{\Gamma}_{\mu\nu}^{\lambda} \Omega_{,\lambda}. \quad (13.237)$$

The curvature scalar goes over into

$$\bar{R} \rightarrow \bar{R}^{\Omega} = \Omega^{-2} \left[\bar{R} - 2(D-1)\Omega^{-1} \Omega_{;\mu\nu} g^{\mu\nu} - (D-1)(D-4)\Omega^{-2} \Omega_{,\mu} \Omega_{,\nu} g^{\mu\nu} \right]. \quad (13.238)$$

The metric $g_{\mu\nu} = 4\bar{u}^2 \delta_{\mu\nu}$ in the \bar{u} -space description of the hydrogen atom is conformally flat, so that we can use the above relations to obtain all geometric quantities from the initially trivial metric $g_{\mu\nu} = \delta_{\mu\nu}$ with $\bar{R}_{\mu\nu} = 0$ by inserting $\Omega = 2|\bar{u}|$, so that

$$\Omega_{,\mu} = 2 \frac{u^{\mu}}{|\bar{u}|}, \quad \Omega_{;\mu\nu} = \frac{2}{|\bar{u}|^3} (\delta^{\mu\nu} \bar{u}^2 - u^{\mu} u^{\nu}). \quad (13.239)$$

From the right-hand sides of (13.236) and (13.238) we obtain

$$\begin{aligned} \bar{R}_{\mu\nu} &= -3(D-2) \frac{1}{4\bar{u}^6} (\delta_{\mu\nu} \bar{u}^2 - \bar{u}_{\mu} \bar{u}_{\nu}), \\ \bar{R} &= -3(D-1)(D-2) \frac{1}{4\bar{u}^4}. \end{aligned} \quad (13.240)$$

For $D = 4$, these agree with (13.231) and (13.232). For $D = 2$, they vanish.

In the Coulomb system, the conformally flat metric (13.234) arose from the non-holonomic coordinate transformation (13.106) with the basis tetrads (13.137) and their inverses (13.138), which produced the torsion tensor (13.142). In the notation (13.234), the torsion tensor has a contraction

$$S_\mu(q) \equiv S_{\mu\nu\lambda}(q) = \frac{1}{2\Omega^2(q)} \partial_\mu \Omega^2(q). \quad (13.241)$$

Note that although $S_\mu(q)$ is the gradient of a scalar field, the torsion tensor (13.142) is not a so-called *gradient torsion*, which is defined by the general form

$$S_{\mu\nu}{}^\lambda(q) = \frac{1}{2} [\delta_\mu{}^\lambda \partial_\nu s(q) - \delta_\nu{}^\lambda \partial_\mu s(q)]. \quad (13.242)$$

For a gradient torsion, $S_\mu(q)$ is also a gradient: $S_\mu(q) = \partial_\mu \sigma(q)$ where $\sigma(q) = (D-1)s(q)/2$. But it is, of course, not the only tensor, for which $S_\mu(q)$ is a gradient.

Note that under a conformal transformation a la Weyl, a massless scalar field $\phi(q)$ is transformed as

$$\phi(q) \rightarrow \Omega^{1-D/2}(q) \phi(q). \quad (13.243)$$

The Laplace-Beltrami differential operator $\Delta = \bar{D}^2$ applied to $\phi(q)$ goes over into $\Omega^{1-D/2}(q) \Delta^\Omega \phi(q)$ where

$$\Delta^\Omega = \Omega^{-2} \left[\Delta - \frac{1}{2} (D-2) \Omega^{-1} \Omega_{;\mu\nu} g^{\mu\nu} - \frac{1}{4} (D-2)(D-4) \Omega^{-2} \Omega_{;\mu} \Omega_{;\nu} g^{\mu\nu} \right]. \quad (13.244)$$

Comparison with (13.240) shows that there exists a combination of $\Delta = \bar{D}^2$ and the Riemann curvature scalar \bar{R} which may be called *Weyl-covariant Laplacian*. This combination is

$$\Delta - \frac{1}{4} \frac{D-2}{D-1} \bar{R}. \quad (13.245)$$

When applied to the scalar field it transforms as

$$\left(\Delta - \frac{1}{4} \frac{D-2}{D-1} \bar{R} \right) \phi(q) \longrightarrow \Omega^{-1-D/2} \left(\Delta - \frac{1}{4} \frac{D-2}{D-1} \bar{R} \right) \phi(q). \quad (13.246)$$

Thus we can define a massless scalar field in a conformally invariant way by requiring the vanishing of (13.246) as a wave equation. This symmetry property has made the combination (13.245) a favorite Laplacian operator in curved spaces [14].

13.10 Runge-Lenz-Pauli Group of Degeneracy

A well-known symmetry of the Kepler problem was used by Pauli to find the spectrum of the Coulomb problem by purely algebraic manipulations. There exists a vector operator $\hat{\mathbf{M}}$ constructed from the Hamilton operator \hat{H} of (13.1), the momentum operator \mathbf{p} , the angular momentum operator $\hat{\mathbf{L}} \equiv \mathbf{x} \times \hat{\mathbf{p}}$, and the operator $\hat{p}_E \equiv \sqrt{-2M\hat{H}}$. This is the *Runge-Lenz-Pauli vector*:

$$\hat{\mathbf{M}} = \frac{M}{\hat{p}_E} \left[\frac{1}{2M} (\hat{\mathbf{p}} \times \hat{\mathbf{L}} - \hat{\mathbf{L}} \times \hat{\mathbf{p}}) - e^2 \frac{\mathbf{r}}{r} \right], \quad (13.247)$$

which commutes with \hat{H} and is therefore a conserved quantity. Together with $\hat{\mathbf{L}}$ it forms the algebra of rotations $O(4)$ in a four-dimensional space

$$[\hat{L}_i, \hat{L}_j] = i\epsilon_{ijk}\hat{L}_k, \quad [\hat{L}_i, \hat{M}_j] = i\epsilon_{ijk}\hat{M}_k, \quad [\hat{M}_i, \hat{M}_j] = i\epsilon_{ijk}\hat{M}_k. \quad (13.248)$$

The vector $\hat{\mathbf{M}}$ is orthogonal to $\hat{\mathbf{L}}$,

$$\hat{\mathbf{M}} \cdot \hat{\mathbf{L}} = \hat{\mathbf{L}} \cdot \hat{\mathbf{M}} = 0, \quad (13.249)$$

and satisfies

$$\hat{\mathbf{L}}^2 + \hat{\mathbf{M}}^2 + \hbar^2 = -e^4 \frac{M}{2\hat{H}} = e^4 \frac{M^2}{\hat{p}_E^2}. \quad (13.250)$$

The combinations

$$\hat{\mathbf{J}}^{(1,2)} \equiv \frac{1}{2}(\hat{\mathbf{L}} \pm \hat{\mathbf{M}}) \quad (13.251)$$

generate commuting Lie algebras of three-dimensional rotations $O(3)$, so that the squares $(\hat{\mathbf{J}}^{(1,2)})^2$ have the eigenvalues $j^{(1,2)}(j^{(1,2)} + 1)$. The condition (13.249) implies that $j^{(1)} = j^{(2)} = j$. Hence (13.250) becomes

$$\hat{\mathbf{L}}^2 + \hat{\mathbf{M}}^2 + \hbar^2 = 4(\hat{\mathbf{L}} \pm \hat{\mathbf{M}})^2 + \hbar^2 = [4j(j+1) + 1]\hbar^2 = e^4 \frac{M^2}{\hat{p}_E^2} = -\hbar^2 \alpha^2 \frac{Mc^2}{2\hat{H}}. \quad (13.252)$$

From this follows that \hat{p}_E has the eigenvalues $(2j+1)\alpha Mc$, and \hat{H} the eigenvalues $E_j = -Mc^2\alpha^2/(2j+1)^2$. Thus we identify the principal quantum number as $n = 2j+1 = 0, 1, 2, \dots$. For each n , the magnetic quantum numbers m_1 and m_2 of $\hat{\mathbf{J}}^{(1)}$ and $\hat{\mathbf{J}}^{(2)}$ can run from $-j$ to j , so that each level is $(2j+1)^2 = n^2$ -times degenerate.

The wave functions of the hydrogen atom of principal quantum number n are direct products of eigenstates of $\hat{\mathbf{J}}^{(1)}$ and $\hat{\mathbf{J}}^{(2)}$:

$$|n m_1 m_2\rangle = |j m_1\rangle^{(1)} \otimes |j m_2\rangle^{(2)}. \quad (13.253)$$

In atomic physics, one prefers combinations of these which diagonalize the orbital angular momentum $\hat{\mathbf{L}} = \hat{\mathbf{J}}^{(1)} + \hat{\mathbf{J}}^{(2)}$. This done with the help of the Clebsch-Gordan coefficients $(j, m_1; j, m_2 | l, m)$ [18] which couple spin j with spin j to spin $l = 0, 1, \dots, 2j$:

$$|n l m\rangle = \sum_{m_1, m_2 = -j, \dots, j} |j m_1\rangle^{(1)} \otimes |j m_2\rangle^{(2)} (j, m_1; j, m_2 | l, m). \quad (13.254)$$

13.11 Solution in Momentum Space

The path integral for a point particle in a Coulomb potential can also be solved in momentum space.

13.11.1 Pseudotime Path Integral

As in the coordinate space treatment in Section 13.1, we shall calculate the matrix elements of the pseudotime displacement amplitude associated with the the resolvent operator $\hat{R} \equiv i/(E - \hat{H})$. As in Eq. (12.19), we shall rewrite it in the form

$$\hat{R} = \frac{i}{\hat{f}(E - \hat{H})} \hat{f} \quad (13.255)$$

where f is an arbitrary function of space, momentum. Rewriting the the path integral (12.31) in the momentum space representation (2.34), we shall evaluate the canonical path integral for the pseudotime displacement amplitude with $M = 1$:

$$\begin{aligned} \langle \mathbf{p}_b | \hat{\mathcal{U}}_E(S) | \mathbf{p}_a \rangle &= \int \mathcal{D}^3 x(s) \int \frac{\mathcal{D}^3 p(s)}{2\pi\hbar} \\ &\times \exp \left\{ i \int_0^S ds \left[-\mathbf{p}' \cdot \mathbf{x} - f \left(\frac{\mathbf{p}^2}{2} - E \right) + f \frac{\alpha}{r} \right] \right\} f_a. \end{aligned} \quad (13.256)$$

From this we find the fixed-energy amplitude via the integral [compare (13.4)]

$$(\mathbf{p}_b | \mathbf{p}_a)_E^f = \int_0^\infty dS \langle \mathbf{p}_b | \hat{\mathcal{U}}_E(S) | \mathbf{p}_a \rangle. \quad (13.257)$$

The left-hand side carries a superscript f to remind us of the presence of f on the right-hand side, although the amplitude does not really depend on f . This freedom of choice may be viewed as a gauge invariance [17] of (13.257) under $f \rightarrow f'$. Such an invariance permits us to subject (13.257) to an additional path integration over f , as long as a gauge-fixing functional $\Phi[f]$ ensures that only a specific “gauge” contributes. Thus we shall calculate the amplitude (13.257) as a path integral

$$(\mathbf{p}_b | \mathbf{p}_a)_E = \int \mathcal{D}f \Phi[f] (\mathbf{p}_b | \mathbf{p}_a)_E^f. \quad (13.258)$$

The only condition on $\Phi[f]$ is that it must be normalized to have a unit integral: $\int \mathcal{D}f \Phi[f] = 1$. The choice which leads to the desired solution of the path integral is

$$\Phi[f] = \prod_s \frac{1}{r} \exp \left\{ -\frac{i}{2r^2} \left[f - r^2 \left(\frac{\mathbf{p}^2}{2} - E \right) \right]^2 \right\}. \quad (13.259)$$

With this, the total action in the path integral (13.258) becomes

$$\mathcal{A}[\mathbf{p}, \mathbf{x}, f] = \int_0^S ds \left[-\mathbf{p}' \cdot \mathbf{x} - \frac{r^2}{2} \left(\frac{\mathbf{p}^2}{2} - E \right)^2 - \frac{1}{2r^2} f^2 + \frac{f}{r} \alpha \right]. \quad (13.260)$$

The path integrals over f and \mathbf{x} in (13.258) are Gaussian and can be done, in this order, yielding a new action

$$\mathcal{A}[\mathbf{p}] = \frac{1}{2} \int_0^S ds \left[\frac{4\mathbf{p}'^2}{(\mathbf{p}^2 + p_E^2)^2} + \alpha^2 \right], \quad (13.261)$$

where we have introduced $p_E \equiv \sqrt{-2E}$, assuming E to be negative. The positive regime can later be obtained by analytic continuation.

At this point we go to a more symmetric coordinate system in momentum space by projecting the three-vectors \mathbf{p} stereographically to the four-dimensional unit vectors $\vec{\pi} \equiv (\boldsymbol{\pi}, \pi_4)$:

$$\boldsymbol{\pi} \equiv \frac{2p_E \mathbf{p}}{\mathbf{p}^2 + p_E^2}, \quad \pi_4 \equiv \frac{\mathbf{p}^2 - p_E^2}{\mathbf{p}^2 + p_E^2}. \tag{13.262}$$

This brings (13.261) to the form

$$\mathcal{A}[\vec{\pi}] = \frac{1}{2} \int_0^S ds \left(\frac{1}{p_E^2} \vec{\pi}'^2 + \alpha^2 \right). \tag{13.263}$$

The vector $\vec{\pi}$ describes a point particle with pseudomass $\mu = 1/p_E^2$ moving on a four-dimensional unit sphere. The pseudotime evolution amplitude of this system is

$$(\vec{\pi}_b S | \vec{\pi}_a 0) = \int \frac{\mathcal{D}\vec{\pi}}{(2\pi)^{3/2} p_E^3} e^{i\mathcal{A}[\vec{\pi}]}. \tag{13.264}$$

Let us see how the measure arises. When integrating out the spatial fluctuations in going from (13.260) to (13.261), the canonical measure in each time slice $[d^3 p_n / (2\pi)^3] d^3 x_n$ becomes $[d^3 p_n / (2\pi)^3] [(2\pi)^{1/2} / (\mathbf{p}_n^2 + p_E^2)]^3$. From the stereographic projection (13.262) we see that this is equal to $d\vec{\pi}_n / (2\pi)^{3/2} p_E^3$, where $d\vec{\pi}_n$ denotes the product of integrals over the solid angle on the surface of the unit sphere in four dimensions. The integral $\int d\vec{\pi}$ yields the total surface $2\pi^2$. Alternatively we may rewrite as in Eq. (1.560), $\int d\vec{\pi}_n = \int d^4 \pi_n \delta(|\vec{\pi}_n| - 1) = 2 \int d^4 \pi_n \delta(\vec{\pi}_n^2 - 1)$, or use an explicit angular form of the type (8.120) or (8.124).

The expression (13.264) was obtained by purely formal manipulations on the continuum pseudotime axis and needs, therefore, pseudotime-slicing corrections similar to Section 13.5. For the motion on a spherical surface these have to be evaluated by the methods of Chapter 10. There we learned that the proper sliced path integral we know that in a curved space, the time-sliced measure of path integration is given by the product of invariant integrals $\int dq_n \sqrt{g(q_n)}$ at each time slice, multiplied by an effective action contribution $\exp(i\mathcal{A}_{\text{eff}}^\epsilon(q_n)) = \exp(i\epsilon \bar{R}(q_n) / 6\mu)$, where \bar{R} is the scalar curvature. For a sphere of radius r in D dimensions, $\bar{R} = (D-1)(D-2)/r^2$, implying here for $D = 4$ that $\exp(i\mathcal{A}_{\text{eff}}^\epsilon) = \exp(i\epsilon/\mu) = \exp(i\epsilon p_E^2)$. Thus, when transforming the time-sliced measure in the path integral (13.256) to the time-sliced measure on the sphere in (13.264), a factor $e^{iS p_E^2}$ is by definition contained in the measure of the path integral (13.264) [compare (10.153), (10.154)]. This has to be compensated by a prefactor $e^{-iS p_E^2}$. A careful calculation of the time slicing corrections gives an additional factor $e^{iS p_E^2/2}$. The correct version of (13.264) is therefore

$$(\vec{\pi}_b S | \vec{\pi}_a 0) = e^{-iS p_E^2/2} \int \frac{\mathcal{D}\vec{\pi}}{(2\pi)^{3/2} p_E^3} e^{i\mathcal{A}[\vec{\pi}]}, \tag{13.265}$$

with the integral measure defined as in Eqs. (10.153) and (10.154).

The path integral for the motion near the surface of a sphere in four dimensions was solved Subsection 8.7. The energies were brought on the sphere in Section 8.9. The spectral representation was given explicitly in Eq. (8.162) in terms of rotation matrices. Here we shall use the ultra-spherical harmonics $Y_{lm_1m_2}(\vec{\pi})$ defined in Eq. (8.125). From these we construct combinations appropriate for the hydrogen atom to be denoted by $Y_{n,l,m}(\vec{\pi})$, where n, l, m are the quantum numbers of the hydrogen atom with the well-known ranges ($n = 1, 2, 3, \dots$, $l = 0, \dots, n - 1$, $m = -l, \dots, l$). Explicitly, these combinations are formed with the help of Clebsch-Gordan coefficients $(j, m_1; j, m_2 | l, m)$ [18] which couple spin j with spin j to spin $l = 0, 1, \dots, 2j$, where j is related to the principal quantum number by $n = 2j + 1$ [compare (13.254)]:

$$Y_{nlm}(\vec{\pi}) = \sum_{m_1, m_2 = -j, \dots, j} Y_{2j, m_1, m_2}(\vec{\pi}) (j, m_1; j, m_2 | l, m). \quad (13.266)$$

The orthonormality and completeness relations are

$$\int d\vec{\pi} Y_{n'l'm'}^*(\vec{\pi}) Y_{nlm}(\vec{\pi}) = \delta_{nn'} \delta_{ll'} \delta_{mm'}, \quad \sum_{n,l,m} Y_{nlm}(\vec{\pi}') Y_{nlm}(\vec{\pi}) = \delta^{(4)}(\vec{\pi}' - \vec{\pi}), \quad (13.267)$$

where the δ -function satisfies $\int d\vec{\pi} \delta^{(4)}(\vec{\pi}' - \vec{\pi}) = 1$. When restricting the complete sum to l and m only we obtain the four-dimensional analog of the Legendre polynomial:

$$\sum_{l,m} Y_{nlm}(\vec{\pi}') Y_{nlm}(\vec{\pi}) = \frac{n^2}{2\pi^2} P_n(\cos \vartheta), \quad P_n(\cos \vartheta) = \frac{\sin n\vartheta}{n \sin \vartheta}, \quad (13.268)$$

where ϑ is the angle between the four-vectors $\vec{\pi}_b$ and $\vec{\pi}_a$:

$$\cos \vartheta = \vec{\pi}_b \vec{\pi}_a = \frac{(\mathbf{p}_b^2 - p_E^2)(\mathbf{p}_a^2 - p_E^2) + 4p_E^2 \mathbf{p}_b \cdot \mathbf{p}_a}{(\mathbf{p}_b^2 + p_E^2)(\mathbf{p}_a^2 + p_E^2)}. \quad (13.269)$$

Adapting the solution of the path integral for a particle on the surface of a sphere in Eqs. (8.162) with the energy correction of Section 10.4 to the present case we obtain for the path integral in Eq. (13.265) the spectral representation

$$(\vec{\pi}_b S | \vec{\pi}_a 0) = (2\pi)^{3/2} p_E^3 \sum_{n=1}^{\infty} \frac{n^2}{2\pi^2} P_n(\cos \vartheta) \exp \left\{ \left[-i(p_E^2 n^2 - \alpha^2) \right] \frac{S}{2} \right\}. \quad (13.270)$$

For the path integral in (13.265) itself, the exponential contains the eigenvalues of the squared angular-momentum operator $\hat{L}^2/2\mu$ which in D dimensions are $l(l + D - 2)/2\mu$, $l = 0, 1, 2, \dots$. For the particle on a sphere in four dimensions and with the identification $l = 2j = n - 1$, the eigenvalues of \hat{L}^2 are $n^2 - 1$, leading to an exponential $e^{-i[p_E^2(n^2-1) - \alpha^2]S/2}$. Together with the exponential prefactor in (13.265), we obtain the exponential in (13.270).

Inserting the spectral representation (13.270) into (13.257), we can immediately perform the integral over S , and arrive at the amplitude at zero fixed pseudoenergy

$$(\vec{\pi}_b|\vec{\pi}_a)_0 = (2\pi)^{3/2} p_E^3 \sum_{n=1}^{\infty} \frac{n^2}{2\pi^2} P_n(\cos\vartheta) \frac{2i}{2En^2 + \alpha^2}. \quad (13.271)$$

This has poles displaying the hydrogen spectrum at energies:

$$E_n = -\frac{\alpha^2}{2n^2}, \quad n = 1, 2, 3, \dots \quad (13.272)$$

More details on the wave functions are listed in Appendix 13B.

The solution in momentum space was first given by Schwinger [?, 20, 21].

13.11.2 Another Form of Action

Consider the following generalization of the action (13.261) containing an arbitrary function h depending on \mathbf{p} and s :

$$\mathcal{A}[\mathbf{p}] = \frac{1}{2} \int_0^S ds \left[\frac{4\mathbf{p}^2}{h(\mathbf{p}^2 + p_E^2)^2} + \alpha^2 h \right]. \quad (13.273)$$

This action is invariant under reparametrizations $s \rightarrow s'$ if one transforms simultaneously $h \rightarrow hds/ds'$. The path integral with the action (13.261) in the exponent may thus be viewed as a path integral with the gauge-invariant action (13.273) and an additional path integral $\int df \Phi[f]$ with an arbitrary gauge-fixing functional $\Phi[h]$. The parameter s may be chosen to be the physical time t . By going to the extremum in h , the action reduces to

$$\mathcal{A}[\mathbf{p}] = 2\alpha \int_{\tau_a}^{\tau_b} d\tau \sqrt{\frac{\dot{\mathbf{p}}^2}{(\mathbf{p}^2 + p_E^2)^2}}. \quad (13.274)$$

This is the manifestly reparametrization invariant form of an action in a curved space with a metric $g^{\mu\nu} = \delta^{\mu\nu} / (\mathbf{p}^2 + p_E^2)^2$. In fact, this action coincides with the classical eikonal in momentum space:

$$S(\mathbf{p}_b, \mathbf{p}_a; E) = - \int_{\mathbf{p}_a}^{\mathbf{p}_b} d\tau \dot{\mathbf{p}} \cdot \mathbf{x}. \quad (13.275)$$

The eikonal (13.275), and thus the action (13.274), determines the classical orbits via the first extremal principle of theoretical mechanics found in 1744 by Maupertius (see p. 380 and [22]).

Appendix 13A Dynamical Group of Coulomb States

The subspace of oscillator wave functions $\psi^s(u^\mu/\sqrt{n})$ in the standardized form (13.189), which do not depend on x^4 (i.e., on γ), is obtained by applying an equal number of creation operators a^\dagger

and b^\dagger to the ground state wave function (13.195). They are equal to the scalar products between the localized bra states $\langle z, z^* |$ and the ket states $|n_1^a, n_2^a, n_1^b, n_2^b\rangle$ of (13.196).

These ket states form an irreducible representation of the dynamical group $O(4,2)$, the orthogonal group of six-dimensional flat space whose metric g_{AB} has four positive and two negative entries $(1, 1, 1, 1, -1, -1)$.

The 15 generators $\hat{L}_{AB} \equiv -\hat{L}_{BA}$, $A, B = 1, \dots, 6$, of this group are constructed from the spinors

$$\hat{a} \equiv \begin{pmatrix} \hat{a}_1 \\ \hat{a}_2 \end{pmatrix}, \quad \hat{b} \equiv \begin{pmatrix} \hat{b}_1 \\ \hat{b}_2 \end{pmatrix}, \quad (13A.1)$$

and their Hermitian-adjoints, using the Pauli σ -matrices and $c \equiv i\sigma^2$, as follows (since L_{ij} carry subscripts, we define $\sigma_i \equiv \sigma^i$):

$$\begin{aligned} \hat{L}_{ij} &= \frac{1}{2} \left(\hat{a}^\dagger \sigma_k \hat{a} + \hat{b}^\dagger \sigma_k \hat{b} \right) \quad i, j, k = 1, 2, 3 \text{ cyclic}, \\ \hat{L}_{i4} &= \frac{1}{2} \left(\hat{a}^\dagger \sigma_i \hat{a} - \hat{b}^\dagger \sigma_i \hat{b} \right), \\ \hat{L}_{i5} &= \frac{1}{2} \left(\hat{a}^\dagger \sigma_i c \hat{b}^\dagger - \hat{a} c \sigma_i \hat{b} \right), \\ \hat{L}_{i6} &= \frac{i}{2} \left(\hat{a}^\dagger \sigma_i c \hat{b}^\dagger + \hat{a} c \sigma_i \hat{b} \right), \\ \hat{L}_{45} &= \frac{1}{2i} \left(\hat{a}^\dagger c \hat{b}^\dagger - \hat{a} c \hat{b} \right), \\ \hat{L}_{46} &= \frac{1}{2} \left(\hat{a}^\dagger c \hat{b}^\dagger + \hat{a} c \hat{b} \right), \\ \hat{L}_{56} &= \frac{1}{2} \left(\hat{a}^\dagger \hat{a} + \hat{b}^\dagger \hat{b} + 2 \right). \end{aligned} \quad (13A.2)$$

The eigenvalues of \hat{L}_{56} on the states with an equal number of a - and b -quanta are obviously

$$\frac{1}{2} (n_1^a + n_2^a + n_1^b + n_2^b + 2) = n. \quad (13A.3)$$

The commutation rules between these operators are

$$[\hat{L}_{AB}, \hat{L}_{AC}] = ig_{AA} \hat{L}_{BC}, \quad (13A.4)$$

where n is the principal quantum number [see (13.198)]. It can be verified that the following combinations of position and momentum operators in a three-dimensional Euclidean space are elements of the Lie algebra of $O(4,2)$:

$$\begin{aligned} r &= \hat{L}_{56} - \hat{L}_{46}, \\ x^i &= \hat{L}_{i5} - \hat{L}_{i4}, \\ -i(\mathbf{x}\partial_{\mathbf{x}} + 1) &= \hat{L}_{45}, \\ -ir\partial_{x^i} &= \hat{L}_{i6}. \end{aligned} \quad (13A.5)$$

The last equation follows from the transformation formula [recall (13.138)]

$$\partial_{x^i} = \frac{1}{2u^2} e^i{}_\mu \partial_\mu \quad (13A.6)$$

together with

$$\begin{aligned} u^1 &= \frac{1}{2}(z_1 + z_1^*), & u^2 &= \frac{1}{2i}(z_1 - z_1^*), \\ u^3 &= \frac{1}{2}(z_2 + z_2^*), & u^4 &= \frac{1}{2i}(z_2 - z_2^*), \end{aligned} \quad (13A.7)$$

and

$$\begin{aligned}\partial_1 &= (\partial_{z_1} + \partial_{z_1^*}), & \partial_2 &= i(\partial_{z_1} - \partial_{z_1^*}), \\ \partial_3 &= (\partial_{z_2} + \partial_{z_2^*}), & \partial_4 &= i(\partial_{z_2} - \partial_{z_2^*}).\end{aligned}\quad (13A.8)$$

Hence

$$-ir\partial_{x^i} = -\frac{i}{2}(\bar{z}\sigma_i\partial_{\bar{z}} + \partial_z\sigma_i z). \quad (13A.9)$$

By analogy with (13A.2), the generators \hat{L}_{AB} can be expressed in terms of the z, z^* -variables as follows:

$$\begin{aligned}\hat{L}_{ij} &= \frac{1}{2}(\bar{z}\sigma_k\partial_{\bar{z}} - \partial_z\sigma_k z), \\ \hat{L}_{i4} &= -\frac{1}{2}(\bar{z}\sigma_i z - \partial_z\sigma_i\partial_{\bar{z}}), \\ \hat{L}_{i5} &= \frac{1}{2}(\bar{z}\sigma_i z + \partial_z\sigma_i\partial_{\bar{z}}), \\ \hat{L}_{i6} &= -\frac{i}{2}(\bar{z}\sigma_i\partial_{\bar{z}} + \partial_z\sigma_i z), \\ \hat{L}_{45} &= -\frac{i}{2}(\bar{z}\partial_{\bar{z}} + \partial_z z), \\ \hat{L}_{46} &= -\frac{1}{2}(\bar{z}z + \partial_z\partial_{\bar{z}}), \\ \hat{L}_{56} &= \frac{1}{2}(\bar{z}z - \partial_z\partial_{\bar{z}}).\end{aligned}\quad (13A.10)$$

Going over to the operators x^i, ∂_{x^i} , they become

$$\begin{aligned}\hat{L}_{ij} &= -i(x_i\partial_{x^j} - x_j\partial_{x^i}), \\ \hat{L}_{i4} &= \frac{1}{2}(-x^i\partial_{\mathbf{x}}^2 - x^i + 2\partial_{x^i}\mathbf{x}\partial_{\mathbf{x}}), \\ \hat{L}_{i5} &= \frac{1}{2}(-x^i\partial_{\mathbf{x}}^2 + x^i + 2\partial_{x^i}\mathbf{x}\partial_{\mathbf{x}}), \\ \hat{L}_{i6} &= -ir\partial_{x^i}, \\ \hat{L}_{45} &= -i(x^i\partial_{x^i} + 1), \\ \hat{L}_{46} &= \frac{1}{2}(-r\partial_{\mathbf{x}}^2 - r), \\ \hat{L}_{56} &= \frac{1}{2}(-r\partial_{\mathbf{x}}^2 + r),\end{aligned}\quad (13A.11)$$

where the purely spatial operators $\partial_{\mathbf{x}}^2$ and $\mathbf{x}\partial_{\mathbf{x}}$ are equal to $\partial_{x^\mu}^2$ and $x^\mu\partial_{x^\mu}$ because of the constraint (13.182).

The Lie algebra of the differential operators (13A.11) is isomorphic to the Lie algebra of the conformal group in four spacetime dimensions, which is an extension of the *inhomogeneous Lorentz group* or *Poincaré group*, defined by the commutators in Minkowski space ($\mu, \nu = 0, 1, 2, 3$), whose metric has the diagonal elements $(+1, -1, -1, -1)$,

$$[P_\mu, P_\nu] = 0, \quad (13A.12)$$

$$[L_{\mu\nu}, P_\lambda] = -i(g_{\mu\lambda}P_\nu - g_{\nu\lambda}P_\mu), \quad (13A.13)$$

$$[L_{\mu\nu}, L_{\lambda\kappa}] = -i(g_{\mu\lambda}L_{\nu\kappa} - g_{\nu\lambda}L_{\mu\kappa} - g_{\mu\kappa}L_{\nu\lambda} - g_{\nu\kappa}L_{\mu\lambda}). \quad (13A.14)$$

The extension involves the generators D of *dilatations* $x^\mu \rightarrow \rho x^\mu$ and K_μ of *special conformal transformations*⁴

$$x^\mu \rightarrow \frac{x^\mu - c^\mu x^2}{1 - 2cx + c^2 x^2}, \quad (13A.15)$$

⁴Note the difference with respect to the conformal transformations à la Weyl in Eq. (13.234). They correspond to local dilatations.

with the additional commutation rules

$$[D, P_\mu] = -iP_\mu, \quad [D, K_\mu] = iK_\mu, \quad [D, L_{\mu\nu}] = 0, \quad (13A.16)$$

$$[K_\mu, K_\nu] = 0, \quad [K_\mu, P_\nu] = -2i(g_{\mu\nu}D + L_{\mu\nu}), \quad [K_\mu, L_{\nu\lambda}] = i(g_{\mu\nu}K_\lambda - g_{\mu\lambda}K_\nu). \quad (13A.17)$$

The commutation rules can be represented by the differential operators

$$\hat{P}_\mu = i\partial_\mu, \quad \hat{M}_{\mu\nu} = i(x_\mu\partial_\nu - x_\nu\partial_\mu), \quad \hat{D} = ix^\mu\partial_\mu, \quad (13A.18)$$

$$\hat{K}_\mu = i(2x_\mu x^\nu\partial_\nu - x^2\partial_\mu). \quad (13A.19)$$

Their combinations

$$J_{\mu\nu} \equiv L_{\mu\nu}, \quad J_{\mu 5} \equiv \frac{1}{2}(P_\mu - K_\mu), \quad J_{\mu 6} \equiv \frac{1}{2}(P_\mu + K_\mu), \quad J_{56} \equiv D, \quad (13A.20)$$

satisfy the commutation relation of O(4,2):

$$[J_{AB}, J_{CD}] = -i(\bar{g}_{AC}J_{BD} - \bar{g}_{BC}J_{AD} + \bar{g}_{BD}J_{AC} - \bar{g}_{CD}J_{AB}), \quad (13A.21)$$

where the metric \bar{g}_{AB} has the diagonal values (+1, -1, -1, -1, -1, +1).

When working with oscillator wave functions which are factorized in the four u^μ -coordinates, the most convenient form of the generators is

$$\begin{aligned} \hat{L}_{12} &= i(u^1\partial_2 - u^2\partial_1 - u^3\partial_4 + u^4\partial_3)/2, \\ \hat{L}_{13} &= i(u^1\partial_3 + u^2\partial_4 - u^3\partial_1 - u^4\partial_2)/2, \\ \hat{L}_{14} &= -(u^1u^3 + u^2u^4) + (\partial_1\partial_3 + \partial_2\partial_4)/4, \\ \hat{L}_{15} &= (u^1u^3 + u^2u^4) + (\partial_1\partial_3 + \partial_2\partial_4)/4, \\ \hat{L}_{16} &= -i(u^1\partial_3 + u^2\partial_4 + u^3\partial_1 + u^4\partial_2)/2, \\ \hat{L}_{23} &= i(u^1\partial_4 - u^2\partial_3 + u^3\partial_2 - u^4\partial_1)/2, \\ \hat{L}_{24} &= -(u^1u^4 - u^2u^3) + (\partial_1\partial_4 - \partial_2\partial_3)/4, \\ \hat{L}_{25} &= (u^1u^4 + u^2u^3) + (\partial_1\partial_4 - \partial_2\partial_3)/4, \\ \hat{L}_{26} &= -i(u^1\partial_4 - u^2\partial_3 - u^3\partial_2 + u^4\partial_1)/2, \\ \hat{L}_{34} &= [(u^1)^2 + (u^2)^2 - (u^3)^2 - (u^4)^2]/2 + (\partial_1^2 + \partial_2^2 - \partial_3^2 - \partial_4^2)/8, \\ \hat{L}_{35} &= -[(u^1)^2 + (u^2)^2 - (u^3)^2 - (u^4)^2]/2 + (\partial_1^2 + \partial_2^2 - \partial_3^2 - \partial_4^2)/8, \\ \hat{L}_{36} &= -i(u^1\partial_1 + u^2\partial_2 - u^3\partial_3 - u^4\partial_4)/2, \\ \hat{L}_{45} &= -i(u^1\partial_1 + u^2\partial_2 + u^3\partial_3 + u^4\partial_4 + 2)/2, \\ \hat{L}_{46} &= -(u^\mu)^2/2 - \partial_\mu^2/8, \\ \hat{L}_{56} &= (u^\mu)^2/2 - \partial_\mu^2/8. \end{aligned} \quad (13A.22)$$

The commutation rules (13A.4) between these generators make the solution of the Schrödinger equation very simple. Rewriting (13.167) as

$$\left(-\frac{a_H}{2}r\nabla^2 - \frac{E}{E_H}\frac{r}{a_H} - 1 \right) \psi(\mathbf{x}) = 0, \quad (13A.23)$$

and going to atomic natural units with $a_H = 1$, $E_H = 1$, we express $r\partial_{\mathbf{x}}^2$ and r in terms of \hat{L}_{46} , \hat{L}_{56} via (13A.11). This gives

$$\left[\frac{1}{2}(\hat{L}_{56} + \hat{L}_{46}) - E(\hat{L}_{56} - \hat{L}_{46}) - 1 \right] \psi = 0. \quad (13A.24)$$

With the help of Lie's expansion formula

$$e^{i\hat{A}}\hat{B}e^{-i\hat{A}} = 1 + i[\hat{A}, \hat{B}] + \frac{i^2}{2!}[\hat{A}, [\hat{A}, \hat{B}]] + \dots$$

for $\hat{A} = \hat{L}_{45}$ and $\hat{B} = \hat{L}_{56}$ and the commutators $[\hat{L}_{45}, \hat{L}_{56}] = iL_{45}$ and $[\hat{L}_{45}, \hat{L}_{46}] = i\hat{L}_{56}$, this can be rewritten as

$$\left[e^{i\vartheta\hat{L}_{45}} \hat{L}_{56} e^{-i\vartheta\hat{L}_{45}} - 1 \right] \psi = 0, \tag{13A.25}$$

with

$$\vartheta = \frac{1}{2} \log(-2E). \tag{13A.26}$$

If ψ_n denotes the eigenstates of \hat{L}_{56} with an eigenvalue n , the solutions of (13A.25) are obviously given by the tilted eigenstates $e^{i\vartheta\hat{L}_{45}}\psi_n$ of the generator \hat{L}_{56} whose eigenvalues are $n = 1, 2, 3, \dots$ [as follows directly from the representation (13A.2)]. For these states, the parameter ϑ takes the values

$$\vartheta = \vartheta_n = -\log n, \tag{13A.27}$$

with the energies $E_n = -1/2n^2$.

Since the energy E in the Schrödinger equation (13A.24) is accompanied by a factor $\hat{L}_{46} - \hat{L}_{56}$, the physical scalar product between Coulomb states is

$$\langle \psi'_{n'}^H | \psi_n^H \rangle_{\text{phys}} \equiv \langle \psi'_{n'}^s | (\hat{L}_{56} - \hat{L}_{46}) | \psi_n^s \rangle = \delta_{n'n}. \tag{13A.28}$$

Within this scalar product, the Coulomb wave functions

$$\psi_n^H(\mathbf{x}) = \frac{1}{\sqrt{n}} e^{i\vartheta_n \hat{D}} \psi_n^s(u^\mu) = \frac{1}{\sqrt{n}} \psi_n^s(u^\mu / \sqrt{n}) \tag{13A.29}$$

are orthonormal.

The physical scalar product (13A.28) agrees of course with the scalar product (13.169) and with the scalar product (11.95) derived for a space with torsion in Section 11.4, apart from a trivial constant factor.

It is now easy to calculate the physical matrix elements of the dipole operator x^i and the momentum operator $-i\partial_{x^i}$ using the representations (13A.5). Only operations within the Lie algebra of the group $O(4,2)$ have to be performed. This is why $O(4,2)$ is called the *dynamical group* of the Coulomb system [13].

For completeness, let us state the relation between the states in the oscillator basis $|n_1 n_2 m\rangle$ and the eigenstates of a fixed angular momentum $|nlm\rangle$ of (13.219), which is analogous to the combination (13.254)

$$\begin{aligned} |nlm\rangle &= \sum_{n_1+n_2+m=(n-1)/2} \\ &\times |n_1 n_2 m\rangle \langle \frac{1}{2}(n-l), \frac{1}{2}(n_2-n_1+m); \frac{1}{2}(n-l), \frac{1}{2}(n_1-n_2+m) | l, m \rangle. \end{aligned} \tag{13A.30}$$

Appendix 13B Wave Functions in Three-Dimensional Momentum Space

Let us introduce the Bohr momentum $p_H \equiv \hbar/a_H = Me^2/\hbar$ and go to units where $p_H = 1$. Then the radial wave functions $F_{nl}(p)$ with unit normalization $\int_0^\infty dp p^2 F_{nlm}^2(p) = 1$ are given by []

$$F_{nl}(p) = \sqrt{\frac{2}{\pi}} \sqrt{\frac{(n-l-1)!}{(n-l)!} n^2 2^{2(l+1)} l!} \frac{n^l p^l}{(n^2 p^2 + 1)^{l+2}} C_{n-l-1}^{(l+1)} \left(\frac{n^2 p^2 - 1}{n^2 p^2 + 1} \right), \tag{13B.31}$$

where $C_n^{(\lambda)}(z)$ are the Gegenbauer polynomials defined in (8.102), for example

$$C_0^{(\lambda)}(z) = 1, \quad C_1^{(\lambda)}(z) = 2\lambda z, \quad C_2^{(\lambda)}(z) = 2\lambda(\lambda+1)z^2 - \lambda, \dots \tag{13B.32}$$

The lowest wave functions are

$$F_{10} = 4\sqrt{\frac{2}{\pi}} \frac{1}{(p^2 + 1)^2}, \quad F_{20} = \frac{32}{\sqrt{\pi}} \frac{4p^2 - 1}{(4p^2 + 1)^3}, \quad F_{21} = \frac{128}{\sqrt{3\pi}} \frac{p}{(4p^2 + 1)^3}. \quad (13B.33)$$

In two dimensions, the momentum space wave functions were listed in Ref. [21].

Solution of Further Path Integrals by Duru-Kleinert Method

The combination of a path-dependent time reparametrization and a compensating coordinate transformation, used by Duru and Kleinert to transform the Coulomb path integral into a harmonic-oscillator path integral, can be generalized to relate a variety of path integrals to each other. In this way, many unknown path integrals can be solved by their relation to known path integrals. In this chapter, the method is explained for a typical sample of one-dimensional path integrals as well as for a more involved three-dimensional system. The latter describes a generalization of the Coulomb system consisting of two particles which carry both electric and magnetic charges. It is commonly referred to as the *dionium* atom (by analogy with the positronium atom, the bound state between electron and positron). We also discuss further possible generalizations of the solution method.

14.1 One-Dimensional Systems

In one space dimension, the general relation to be established is the following: Let \hat{H} be a Hamiltonian operator

$$\hat{H} = \hat{T} + \hat{V}, \quad (14.1)$$

with the kinetic term $\hat{T} = \hat{p}^2/2M$, and define the auxiliary Hamiltonian operator

$$\hat{H}_E = \hat{H} - E, \quad (14.2)$$

with the associated time evolution amplitude

$$\langle x_b | \hat{U}_E(t) | x_a \rangle \equiv \langle x_b | e^{-it\hat{H}_E/\hbar} | x_a \rangle. \quad (14.3)$$

An integration of this amplitude over all $t > 0$ yields the fixed-energy amplitude

$$\langle x_b | x_a \rangle_E = \int_{t_a}^{\infty} dt_b \langle x_b | \hat{U}_E(t_b - t_a) | x_a \rangle \quad (14.4)$$

[recall (12.8)]. This can formally be written as a path integral

$$(x_b|x_a)_E = \int_{t_a}^{\infty} dt_b \int \mathcal{D}x(t) e^{i\mathcal{A}_E[x]/\hbar}, \quad (14.5)$$

with an action

$$\mathcal{A}_E[x] = \int_{t_a}^{t_b} dt \left[\frac{M}{2} \dot{x}^2(t) - V(x(t)) + E \right]. \quad (14.6)$$

As in the Coulomb system, another path integral representation is found for the amplitude (14.5) by making use of the more general representation (12.21) of the resolvent operator. By choosing two arbitrary regulating functions $f_l(x)$, $f_r(x)$ whose product is $f(x)$, we introduce the modified auxiliary Hamiltonian operator

$$\hat{\mathcal{H}}_E = f_l(x)(\hat{H} - E)f_r(x). \quad (14.7)$$

The associated pseudotime evolution amplitude

$$\langle x_b|\hat{\mathcal{U}}_E(S)|x_a\rangle \equiv f_r(x_b)f_l(x_a)\langle x_b|e^{-iS\hat{\mathcal{H}}_E/\hbar}|x_a\rangle \quad (14.8)$$

yields upon integration over all $S > 0$ the same fixed-energy amplitude as (14.4):

$$(x_b|x_a)_E = \int_0^{\infty} dS \langle x_b|\hat{\mathcal{U}}_E(S)|x_a\rangle \quad (14.9)$$

[recall (12.30)]. The amplitude can therefore be calculated from the path integral

$$(x_b|x_a)_E = \int_0^{\infty} dS \left[f_r(x_b)f_l(x_a) \int \mathcal{D}x(s) e^{i\mathcal{A}_E^f[x]/\hbar} \right], \quad (14.10)$$

with the modified action

$$\mathcal{A}_E^f[x] = \int_0^S ds \left\{ \frac{M}{2f(x(s))} \dot{x}^2(s) - f(x(s))[V(x(s)) - E] \right\}. \quad (14.11)$$

As observed in (12.37), this action is obtained from (14.6) by a path-dependent time reparametrization satisfying

$$dt = ds f(x(s)). \quad (14.12)$$

The introduction of $f(x)$ has brought the kinetic term to an inconvenient form containing a space-dependent mass $M/f(x)$. This space dependence is removed by a coordinate transformation

$$x = h(q). \quad (14.13)$$

Since the coordinate differentials are related by

$$dx = h'(q)dq, \quad (14.14)$$

we require the function $h(q)$ to satisfy

$$h'^2(q) = f(h(q)). \quad (14.15)$$

Then the action (14.11) reads, in terms of the new coordinate q ,

$$\mathcal{A}_E^{f,q} = \int_0^S ds \left\{ \frac{M}{2} q'^2(s) - f(q(s)) [V(q(s)) - E] \right\}, \quad (14.16)$$

with the obvious notation

$$f(q) \equiv f(h(q)), \quad V(q) \equiv V(h(q)). \quad (14.17)$$

In the transformed action (14.16), the kinetic term has the usual form.

The important fact to be proved and exploited in the sequel is the following: The initial fixed-energy amplitude (14.5) can be related to the fixed-pseudoenergy amplitude associated with the transformed action (14.16), if this action is extended by an effective potential

$$V_{\text{eff}}(q) = -\frac{\hbar^2}{4M} \left[\frac{h'''}{h'} - \frac{3}{2} \left(\frac{h''}{h'} \right)^2 \right]. \quad (14.18)$$

The quantity in brackets is known as the Schwartz derivative $\{h, q\}$ of Eq. (4.19) encountered in the semiclassical expansion coefficient $q_2(x)$. The effective potential is caused by time slicing effects and will be derived in the next section. Thus, instead of the naively transformed action (14.16), the fixed-pseudoenergy amplitude $(q_b|q_a)_\mathcal{E}$ is obtained from the extended action

$$\mathcal{A}_{E,\mathcal{E}}^{\text{DK}}[q] = \int_0^S ds \left\{ \frac{M}{2} q'^2(s) - f(q(s)) [V(q(s)) - E] - V_{\text{eff}}(q(s)) + \mathcal{E} \right\}, \quad (14.19)$$

by calculating the path integral

$$(q_b|q_a)_\mathcal{E} = \int_0^\infty dS \int \mathcal{D}q(s) e^{i\mathcal{A}_{E,\mathcal{E}}^{\text{DK}}[q]}. \quad (14.20)$$

The relation to be derived which leads to a solution of many nontrivial path integrals is

$$(x_b|x_a)_E = [f(x_b)f(x_a)]^{1/4} (q_b|q_a)_{\mathcal{E}=0}. \quad (14.21)$$

The procedure is an obvious generalization of the Duru-Kleinert transformation of the Coulomb path integral in Section 13.1, as indicated by the superscript DK on the transformed actions. Correspondingly, the actions $\mathcal{A}_E[x]$ and $\mathcal{A}_{E,\mathcal{E}}^{\text{DK}}[q]$, whose path integrals (14.5) and (14.20) producing the same fixed-energy amplitude $(x_b|x_a)_E$ via the relation (14.21), are called *DK-equivalent*.

The prefactor on the right-hand side has its origin in the normalization properties of the states. With $dx = dq h'(q) = dq f(h(q))^{1/2}$, the completeness relation

$$\int dx |x\rangle \langle x| = 1 \quad (14.22)$$

goes over into

$$\int dq \sqrt{f(q)} |h(q)\rangle \langle h(q)| = 1. \quad (14.23)$$

We want the transformed states $|q\rangle$ to satisfy the completeness relation

$$\int dq |q\rangle \langle q| \equiv 1. \quad (14.24)$$

This implies the relation between new and old states:

$$|x\rangle = f(q)^{-1/4} |q\rangle. \quad (14.25)$$

At first sight it appears as though the normalization factor in (14.21) should have the opposite power $-1/4$, but the sign is correct as it is. The reason lies, roughly speaking, in a factor $[f(x_b)f(x_a)]^{1/2}$ by which the pseudotimes dt and ds in the integrals (14.4) and (14.20) differ from each other. This causes the fixed-energy amplitude to be no longer proportional to the dimensions of the states, in which case Eq. (14.21) would have indeed carried a factor $[f(x_b)f(x_a)]^{-1/4}$. The extra factor $[f(x_b)f(x_a)]^{1/2}$ arising from the pseudotime integration *inverts* the naively expected prefactor.

In applications, the situation is usually as follows: There exists a solved path integral for a system with a singular potential. The time-sliced action is *not* the naively sliced classical action, but a more complicated regularized one which is free of path collapse problems. The most important example is the radial path integral (8.36) which involves a logarithm of a Bessel function rather than a centrifugal barrier. Further examples are the path integrals (8.174) and (8.207) of a particle near the surface of a sphere in $D = 3$ and $D = 4$ dimensions, where angular barriers are regulated by Bessel functions. In these examples, the explicit form of the time-sliced path integral without collapse as well as its solution are obtained from an angular momentum projection of a simple Euclidean path integral. In the first step of the solution procedure, the introduction of a path-dependent new time s via $dt = ds f(x(s))$ removes the dangerous singularities by an appropriate choice of the regulating function $f(x)$. The transformed system has a regular potential and possesses a time-sliced path integral, but it has an unconventional kinetic term. In the second step, the coordinate transformation brings the kinetic term to the conventional form. The final fixed-pseudoenergy amplitude $(q_b|q_a)_\mathcal{E}$ evaluated at $\mathcal{E} = 0$ coincides with the known amplitude of the initial system, apart from the above-discussed factor which is inversely related to the normalization of the states. Note that with (14.15), the relation (14.21) can also be written as

$$(x_b|x_a)_\mathcal{E} = [h'(q_b)h'(q_a)]^{1/2} (q_b|q_a)_{\mathcal{E}=0}. \quad (14.26)$$

This transformation formula will be used to find a number of path integrals. First, however, we shall derive the effective potential (14.18) as promised.

14.2 Derivation of the Effective Potential

In order to derive the effective potential (14.18), we consider the pseudotime-sliced path integral associated with the regularized pseudotime evolution operator (14.8):

$$\langle x_b | \hat{\mathcal{U}}_E(S) | x_a \rangle \approx \frac{f_r(x_b) f_l(x_a)}{\sqrt{2\pi i \epsilon_s \hbar f_l(x_b) f_r(x_a) / M}} \prod_{n=1}^N \left[\int \frac{dx_n}{\sqrt{2\pi i \epsilon_s \hbar f_n / M}} \right] \exp \left(\frac{i}{\hbar} \mathcal{A}^N \right), \tag{14.27}$$

where

$$\mathcal{A}^N = \sum_{n=1}^{N+1} \left\{ \frac{M}{2\epsilon_s} \frac{(\Delta x_n)^2}{f_l(x_n) f_r(x_{n-1})} + \epsilon_s [E - V(x_n)] f_l(x_n) f_r(x_{n-1}) \right\}. \tag{14.28}$$

In the measure, we have used the abbreviation $f_n \equiv f(x_n) = f_l(x_n) f_r(x_n)$. From now on, the potential $V(x)$ is omitted as being inessential to the discussion. By shifting the product index and the subscripts of f_n by one unit, and by compensating for this with a prefactor, the integration measure in (14.27) acquires the postpoint form

$$\frac{[f(x_b) f(x_a)]^{1/4}}{\sqrt{2\pi i \epsilon_s \hbar / M}} \left[\frac{f_r(x_a)}{f_r(x_b)} \right]^{-5/4} \left[\frac{f_l(x_a)}{f_l(x_b)} \right]^{1/4} \prod_{n=2}^{N+1} \int \frac{d\Delta x_n}{\sqrt{2\pi i \epsilon_s \hbar f_n / M}}, \tag{14.29}$$

where the integrals over $\Delta x_n = x_n - x_{n-1}$ are done successively from high to low n , each at a fixed postpoint position x_n .

We now go over to the new coordinate q with a transformation function $x = h(q)$ satisfying (14.15) which makes the leading kinetic term simple:

$$\mathcal{A}_0^N = \sum_{n=1}^{N+1} \frac{M}{2\epsilon_s} (\Delta q_n)^2. \tag{14.30}$$

The postpoint expansion of Δx_n reads at each n (omitting the subscripts)

$$\Delta x = x(q) - x(q - \Delta q) = e_1 \Delta q - \frac{1}{2} e_2 (\Delta q)^2 + \frac{1}{6} e_3 (\Delta q)^3 + \dots, \tag{14.31}$$

with the expansion coefficients

$$e_1 \equiv h' = f^{1/2}, \quad e_2 \equiv h'', \quad e_3 \equiv h''', \dots \tag{14.32}$$

evaluated at the postpoint q_n . The expansion (14.31) is the one-dimensional analog of the expansion (11.56), the coefficients corresponding to the basis triads e^i_μ in Eq. (10.12) and their derivatives ($e_1 \hat{=} e^i_\mu, e_2 \hat{=} e^i_{\mu,\nu}, \dots$). Let us also introduce the analog of the reciprocal triad e_i^μ defined in (10.12):

$$\bar{e} \equiv 1/e_1 = 1/h' = 1/f^{1/2}. \tag{14.33}$$

With it, we expand the kinetic term in (14.28) as

$$\frac{(\Delta x_n)^2}{2\epsilon_s f_l(x_n) f_r(x_{n-1})} = \frac{(\Delta q)^2}{2\epsilon_s} \left\{ 1 - \bar{e}e_2 \Delta q + \left[\frac{1}{3}\bar{e}e_3 + \frac{1}{4}(\bar{e}e_2)^2 \right] (\Delta q)^2 + \dots \right\} \times \left\{ 1 + \frac{f'_r}{f_r} \Delta q + \left[\left(\frac{f'_r}{f_r} \right)^2 - \frac{1}{2} \frac{f''_r}{f_r} \right] (\Delta q)^2 + \dots \right\}, \quad (14.34)$$

where $f'_r \equiv df_r/dq$. From Eq. (14.31) we see that the transformation of the measure has the Jacobian

$$J = \frac{\partial \Delta x}{\partial \Delta q} = f^{1/2} \left[1 - \bar{e}e_2 \Delta q + \frac{1}{2} \bar{e}e_3 (\Delta q)^2 + \dots \right] \quad (14.35)$$

[this being a special case of (11.59)]. Since the subsequent algebra is tedious, we restrict the regulating functions $f_l(x)$ and $f_r(x)$ somewhat as in Eq. (13.3) by assuming them to be different powers $f_l(x) = f(x)^{1-\lambda}$ and $f_r(x) = f(x)^\lambda$ of a single function $f(x)$, where λ is an arbitrary splitting parameter. Then the measure (14.29) becomes

$$\frac{f_b^{3\lambda/2} f_a^{(1-3\lambda)/2}}{\sqrt{2\pi i \epsilon_s \hbar / M}} \prod_{n=2}^{N+1} \int \frac{d\Delta x_n}{\sqrt{2\pi i \epsilon_s \hbar f_n / M}}, \quad (14.36)$$

with the obvious notation $f_b \equiv f(x_b)$, $f_a \equiv f(x_a)$. We now distribute the prefactor $f_b^{3\lambda/2} f_a^{(1-3\lambda)/2}$ evenly over the time interval by writing

$$f_b^{3\lambda/2} f_a^{(1-3\lambda)/2} = f_b^{1/4} f_a^{1/4} \prod_{n=1}^{N+1} \left(\frac{f_{n-1}}{f_n} \right)^{1/4-3\lambda/2}. \quad (14.37)$$

Then the path integral (14.27) becomes

$$\langle x_b | \hat{\mathcal{U}}_E(s) | x_a \rangle \approx \frac{f_b^{1/4} f_a^{1/4}}{\sqrt{2\pi i \epsilon_s \hbar / M}} \prod_{n=1}^N \left[\int \frac{d\Delta q_n}{\sqrt{2\pi i \epsilon_s \hbar / M}} \right] \times \exp \left\{ \frac{i}{\hbar} \left[\sum_{n=1}^{N+1} \frac{M}{2\epsilon_s} (\Delta q_n)^2 + \epsilon_s f(q_n) [E - V(q_n)] + \dots \right] \right\} [1 + C(q_n, \Delta q_n)], \quad (14.38)$$

where $1 + C$ is a correction factor arising from the three-step transformation

$$1 + C \equiv (1 + C_{\text{meas}})(1 + C_f)(1 + C_{\text{act}}). \quad (14.39)$$

Dropping irrelevant higher orders in Δq , the three contributions on the right-hand side have the following origins:

The transformation of the measure (14.35) gives rise to the time slicing correction

$$C_{\text{meas}} = -\bar{e}e_2 \Delta q + \frac{1}{2} \bar{e}e_3 (\Delta q)^2 + \dots \quad (14.40)$$

The rearrangement of the f -factors in (14.37) produces

$$C_f = \left(\frac{1}{4} - \frac{3\lambda}{2}\right) \left[-\frac{f'}{f} \Delta q + \frac{1}{2} \frac{f''}{f} (\Delta q)^2 \right] - \frac{1}{2} \left(\frac{3}{4} + \frac{3\lambda}{2}\right) \left(\frac{1}{4} - \frac{3\lambda}{2}\right) \left(\frac{f'}{f}\right)^2 (\Delta q)^2 + \dots \quad (14.41)$$

The transformation of the pseudotime-sliced kinetic term (14.34) yields

$$C_{\text{act}} = \frac{i}{\hbar} M \frac{(\Delta q)^2}{2\epsilon_s} \left\{ -\left(\bar{e}e_2 - \lambda \frac{f'}{f}\right) \Delta q + \left[\frac{1}{3} \bar{e}e_3 + \frac{1}{4} (\bar{e}e_2)^2 + \frac{1}{2} \left(-\lambda \frac{f''}{f} + \lambda(\lambda+1) \left(\frac{f'}{f}\right)^2 \right) - \lambda \bar{e}e_2 \frac{f'}{f} \right] (\Delta q)^2 \right\} - \frac{M^2 (\Delta q)^4}{2\hbar^2 4\epsilon_s^2} \left(\bar{e}e_2 - \lambda \frac{f'}{f}\right)^2 (\Delta q)^2 + \dots \quad (14.42)$$

We now calculate an equivalent kernel according to Section 11.2. The correction terms are evaluated perturbatively using the expectation values

$$\langle (\Delta q)^{2n} \rangle_0 = \left(\frac{i\hbar}{M}\right)^n (2n-1)!! \quad (14.43)$$

First we find the expectation value (11.70). Listing only the relevant terms of order ϵ_s , we obtain

$$\langle C\Delta q \rangle_0 = i\hbar\epsilon_s \left[-\bar{e}e_2 - \left(\frac{1}{4} - \frac{3\lambda}{2}\right) \frac{f'}{f} + \frac{3}{2} \left(\bar{e}e_2 - \lambda \frac{f'}{f}\right) \right] \quad (14.44)$$

The λ -terms cancel each other identically. The remainder vanishes upon using the relation (14.15), which reads in the present notation

$$e_1^2 = f, \quad (14.45)$$

implying that

$$2e_1e_2 = f', \quad 2\bar{e}e_2 = f'/f, \quad (14.46)$$

and yielding indeed $\langle C\Delta q \rangle_0 \equiv 0$.

We now turn to the expectation $\langle C \rangle_0$ which determines the effective potential via Eq. (11.47). By differentiating the second equation in (14.46), we see that

$$f''/f = 2 \left[(\bar{e}e_2)^2 + \bar{e}e_3 \right]. \quad (14.47)$$

By expressing f and f'' in Eqs. (14.41) and (14.42) in terms of the e -functions, we obtain

$$C_f = \left(\frac{1}{4} - \frac{3\lambda}{2}\right) \left\{ -2\bar{e}e_2 \Delta q + [(\bar{e}e_2)^2 + \bar{e}e_3] (\Delta q)^2 \right\} - 2 \left(\frac{3}{4} + \frac{3\lambda}{2}\right) \left(\frac{1}{4} - \frac{3\lambda}{2}\right) (\bar{e}e_2)^2 (\Delta q)^2 + \dots, \quad (14.48)$$

$$\begin{aligned}
 C_{\text{act}} = & i \frac{M (\Delta q)^2}{\hbar} \frac{1}{2\epsilon_s} \left\{ - (1 - 2\lambda) \bar{e}e_2 \Delta q \right. \\
 & + \left[\frac{1}{3} \bar{e}e_3 + \frac{1}{4} (\bar{e}e_2)^2 - \lambda (\bar{e}e_2 + \bar{e}e_3) + 2\lambda(\lambda + 1) (\bar{e}e_2)^2 - 2\lambda (\bar{e}e_2)^2 \right] (\Delta q)^2 \left. \right\} \\
 & - \frac{M^2 (\Delta q)^4}{2\hbar^2} \frac{1}{4\epsilon_s^2} (1 - 2\lambda)^2 (\bar{e}e_2)^2 (\Delta q)^2 + \dots \dots \quad (14.49)
 \end{aligned}$$

After forming the product (14.39), the total correction reads

$$\begin{aligned}
 C = & \bar{e}e_2 \left(\frac{1}{2} - \lambda \right) \Delta q \left[- \frac{iM}{\hbar\epsilon_s} (\Delta q)^2 - 3 \right] \\
 & + (\bar{e}e_2)^2 \left[\frac{9}{2} \left(\lambda - \frac{1}{6} \right) \left(\lambda - \frac{1}{2} \right) (\Delta q)^2 + i \left(4\lambda^2 - \frac{7}{2}\lambda + \frac{7}{8} \right) \frac{M}{\hbar\epsilon_s} (\Delta q)^4 \right. \\
 & \qquad \qquad \qquad \left. - \frac{1}{2} \left(\lambda - \frac{1}{2} \right)^2 \frac{M^2}{\hbar^2\epsilon_s^2} (\Delta q)^6 \right] \\
 & + \bar{e}e_3 \left[- \frac{3}{2} \left(\lambda - \frac{1}{2} \right) (\Delta q)^2 - \frac{1}{2} \left(\lambda - \frac{1}{3} \right) i \frac{M}{\hbar\epsilon_s} (\Delta q)^4 \right] + \dots \dots \quad (14.50)
 \end{aligned}$$

Using (14.43), we find the expectation to the relevant order ϵ_s :

$$\langle C \rangle_0 = - \frac{\epsilon_s \hbar}{M} \left[\frac{1}{4} \bar{e}e_3 - \frac{3}{8} (\bar{e}e_2)^2 \right]. \quad (14.51)$$

It amounts to an effective potential

$$V_{\text{eff}} = - \frac{i\hbar^2}{M} \left[\frac{1}{4} \bar{e}e_3 - \frac{3}{8} (\bar{e}e_2)^2 \right]. \quad (14.52)$$

By inserting (14.32) and (14.33), this turns into the expression (14.18) which we wanted to derive.

In summary we have shown that the kernel in (14.38)

$$K^{\epsilon_s}(\Delta q) = \frac{1}{\sqrt{2\pi i \epsilon_s \hbar / M}} \exp \left\{ \frac{i}{\hbar} \sum_{n=1}^{N+1} \left[\frac{M}{2\epsilon_s} (\Delta q_n)^2 + \epsilon_s E f(q_n) \right] \right\} [1 + C] \quad (14.53)$$

can be replaced by the simpler equivalent kernel

$$K^{\epsilon_s}(\Delta q) = \frac{1}{\sqrt{2\pi i \epsilon_s \hbar / M}} \exp \left\{ \frac{i}{\hbar} \sum_{n=1}^{N+1} \left[\frac{M}{2\epsilon_s} (\Delta q_n)^2 + \epsilon_s E f(q_n) - \epsilon_s V_{\text{eff}} \right] \right\}, \quad (14.54)$$

in which the correction factor $1 + C$ is accounted for by the effective potential V_{eff} of Eq. (14.18). This result is independent of the splitting parameter λ [1]. The same result emerges, after a lengthier algebra, for a completely general splitting of the regulating function $f(x)$ into a product $f_l(x)f_r(x)$.

14.3 Comparison with Schrödinger Quantum Mechanics

The DK transformation of the action (14.11) into the action (14.19) has of course a correspondence in Schrödinger quantum mechanics. In analogy with the introduction of the pseudotime evolution amplitude (14.8), we multiply the Schrödinger equation

$$\left[-\frac{\hbar^2}{2M} \partial_x^2 - E \right] \psi(x, t) = i\hbar \partial_t \psi(x, t) \quad (14.55)$$

from the left by an arbitrary regulating function $f_l(x)$, and obtain

$$\left[-\frac{\hbar^2}{2M} f_l(x) \partial_x^2 f_r(x) - E f(x) \right] \psi_f(x, t) = f(x) i\hbar \partial_t \psi_f(x, t), \quad (14.56)$$

with the transformed wave function $\psi_f(x, t) \equiv f_r(x)^{-1} \psi(x, t)$. After the coordinate transformation (14.14), we arrive at

$$\left[-\frac{\hbar}{2M} f_l(q) \left(\frac{1}{h'(q)} \partial_q \right)^2 f_r(q) - E f(q) \right] \psi_f(q, t) = f(q) i\hbar \partial_t \psi_f(q, t), \quad (14.57)$$

having used the notation $f(q) \equiv f(h(q))$ as in (14.17). Inserting $h'^2(q) = f(h(q)) = f_l(h(q)) f_r(h(q))$ from (14.15), the Schrödinger equation becomes

$$\left[-\frac{\hbar^2}{2M} f_r^{-1}(q) \left(\partial_q^2 - \frac{h''}{h'} \partial_q \right) f_r(q) - E f(q) \right] \psi_f(q, t) = f(q) i\hbar \partial_t \psi_f(q, t). \quad (14.58)$$

After going from $\psi_f(q, t)$ to a new wave function

$$\phi(q, t) = f_r^{3/4}(q) f_l^{-1/4}(q) \psi_f(q, t)$$

related to the initial one by $\psi(x, t) \equiv f_r(q) \psi_f(q, t) = f^{1/4}(q) \phi(q, t)$, the Schrödinger equation takes the form

$$\begin{aligned} & \left[-\frac{\hbar^2}{2M} h'(q)^{-1/2} \left(\partial_q^2 - \frac{h''}{h'} \partial_q \right) h'(q)^{1/2} - E f(q) \right] \phi(q, t) \\ & = \left[-\frac{1}{2M} \partial_q^2 + V_{\text{eff}} - E f(q) \right] \phi(q, t) = f(q) i\hbar \partial_t \phi(q, t), \end{aligned} \quad (14.59)$$

where V_{eff} is precisely the effective potential (14.18).

For the special coordinate transformation $r = h(q) = e^q$, we obtain

$$V_{\text{eff}} = -\frac{\hbar^2}{4M} \left[\frac{h'''}{h'} - \frac{3}{2} \left(\frac{h''}{h'} \right)^2 \right] = \frac{\hbar^2}{2M} \frac{1}{4}, \quad (14.60)$$

as first pointed out by Langer [2] when improving the WKB approximation of Schrödinger equations with a centrifugal barrier $\hbar^2 l(l+1)/2Mr^2$. This is too singular to allow for a semiclassical treatment. The transformation $r = h(q) = e^q$ leads to a smooth potential problem on the entire q -axis, in which the centrifugal barrier is replaced by $\hbar^2[l(l+1) + \frac{1}{4}]/2M$. Langer concluded from this that the original Schrödinger equation in r can be treated semiclassically if $l(l+1)$ is replaced by $l(l+1) + \frac{1}{4}$. The additional $\frac{1}{4}$ is known as the *Langer correction*.

The operator $f(q)\partial_t$ on the right-hand side of (14.59) plays the role of pseudotime derivative ∂_s .

14.4 Applications

We now present some typical solutions of path integrals via the DK method. The initial fixed-energy amplitudes will all have the generic action

$$\mathcal{A}_E = \int dt \left[\frac{M}{2} \dot{x}^2(t) - V(x) + E \right], \quad (14.61)$$

with different potentials $V(x)$ which usually do not allow for a naive time slicing. The associated path integrals are known from certain projections of Euclidean path integrals. In the sequel, we omit the subscript E for brevity (since we want to use its place for another subscript referring to the potential under consideration). The solution follows the general two-step procedure described in Section 14.4.

14.4.1 Radial Harmonic Oscillator and Morse System

Consider the action of a harmonic oscillator in D dimensions with an angular momentum $l_{\mathcal{O}}$ at a fixed energy $E_{\mathcal{O}}$:

$$\mathcal{A}_{\mathcal{O}} = \int dt \left[\frac{M}{2} \dot{r}^2 - \hbar^2 \frac{\mu_{\mathcal{O}}^2 - 1/4}{2Mr^2} - \frac{M}{2} \omega^2 r^2 + E_{\mathcal{O}} \right]. \quad (14.62)$$

Here $\mu_{\mathcal{O}}$ is an abbreviation for

$$\mu_{\mathcal{O}} = D_{\mathcal{O}}/2 - 1 + l_{\mathcal{O}} \quad (14.63)$$

[recall (8.138)], $D_{\mathcal{O}}$ denotes the dimension, and $l_{\mathcal{O}}$ the orbital angular momentum of the system. The subscript \mathcal{O} indicates that we are dealing with the harmonic oscillator. A free particle is described by the $\omega \rightarrow 0$ -limit of this action.

Due to the centrifugal barrier, the time evolution amplitude possesses only a complicated time-sliced path integral involving Bessel functions. According to the rule (8.140), the centrifugal barrier requires the regularization

$$\epsilon \hbar^2 \frac{\mu_{\mathcal{O}}^2 - 1/4}{2Mr_n^2} \longrightarrow i\hbar \log \tilde{I}_{\mu_{\mathcal{O}}} \left(\frac{M}{i\hbar\epsilon} r_n r_{n-1} \right). \quad (14.64)$$

This smoothens the small- r fluctuations and prevents a path collapse in the Euclidean path integral with $\mu_{\mathcal{O}} = 0$. The time-sliced path integral can then be solved using the formula (8.14). The final amplitude is obtained most simply, however, by solving the harmonic oscillator in $D_{\mathcal{O}}$ Cartesian coordinates, and by projecting the result into a state of fixed angular momentum $l_{\mathcal{O}}$. The result was given in Eq. (9.32), and reads for $r_b > r_a$

$$(r_b|r_a)_{E_{\mathcal{O}},l_{\mathcal{O}}} = -i \frac{1}{\omega} \frac{1}{\sqrt{r_b r_a}} \frac{\Gamma((1+\mu)/2-\nu)}{\Gamma(\mu+1)} W_{\nu,\mu/2} \left(\frac{M\omega}{\hbar} r_b^2 \right) M_{\nu,\mu/2} \left(\frac{M\omega}{\hbar} r_a^2 \right), \quad (14.65)$$

where the parameters on the right-hand side are

$$\nu = \nu_{\mathcal{O}} \equiv \frac{E_{\mathcal{O}}}{2\omega\hbar}, \quad \mu = \mu_{\mathcal{O}}. \quad (14.66)$$

The poles determining the energy eigenvalues lie at $\nu = n/2 + D/4 = n_r + l/2 + D/4$, where $n = 0, 1, 2, 3, \dots$.

A stable pseudotime evolution amplitude exists after a path-dependent time transformation with the regulating function

$$f(r) = r^2. \quad (14.67)$$

The time-transformed Hamiltonian

$$\mathcal{H}_{\mathcal{O}} = r^2 \frac{p^2}{M} + \hbar^2 \frac{\mu_{\mathcal{O}}^2 - 1/4}{2M} + \frac{M}{2} \omega^2 r^4 - E_{\mathcal{O}} r^2 \quad (14.68)$$

is free of the barrier singularity. Thus, when time-slicing the action

$$\mathcal{A}_{\mathcal{O}}^{f=r^2} = \int_0^S ds \left(\frac{M}{2} \frac{r'^2}{r^2} - \frac{\mu_{\mathcal{O}}^2 - 1/4}{2M} - \frac{M}{2} \omega^2 r^4 + E_{\mathcal{O}} r^2 \right) \quad (14.69)$$

associated with $\mathcal{H}_{\mathcal{O}}$, no Bessel functions are needed.

Note that the factor $1/r^2$ accompanying $r'^2 = [dr(s)/ds]^2$ does not produce additional problems. It merely diminishes the fluctuations at small r . However, the r -dependence of the kinetic term is undesirable for an evaluation of the time-sliced path integral. We therefore go over to a new coordinate x via the transformation

$$r = h(x) \equiv e^x, \quad (14.70)$$

the transformation function $h(x)$ being related to the regulating function $f(x)$ by (14.15):

$$h'^2 = e^{2x} = f(r) = r^2. \quad (14.71)$$

The resulting effective potential (14.18) happens to be a constant:

$$V_{\text{eff}} = -\frac{\hbar^2}{M} \left[\frac{1}{4} \frac{h'''}{h'} - \frac{3}{8} \left(\frac{h''}{h'} \right)^2 \right] = \frac{\hbar^2}{8M}. \quad (14.72)$$

Together with this constant, the DK-transformed radial oscillator action becomes

$$\mathcal{A}_{\mathcal{O}}^{\text{DK}} = \int_0^S ds \left[\frac{M}{2} x'^2 - \frac{\mu_{\mathcal{O}}^2}{2M} - \frac{M\omega^2}{2} e^{4x} + E_{\mathcal{O}} e^{2x} \right]. \quad (14.73)$$

The effective potential (14.72) has changed the initial centrifugal barrier term from $(\mu_{\mathcal{O}}^2 - 1/4)/2M$ to $\mu_{\mathcal{O}}^2/2M$. We have omitted the pseudoenergy \mathcal{E} since it is set equal to zero in the final DK relation (14.26). With the identifications

$$A = \frac{M}{2} \omega^2, \quad (14.74)$$

$$B = E_{\mathcal{O}}, \quad (14.75)$$

$$C = \frac{\hbar^2 \mu_{\mathcal{O}}^2}{2M} + E_{\mathcal{N}}, \quad (14.76)$$

the action (14.73) goes over into

$$\mathcal{A}_{\mathcal{N}} = \int_0^S ds \left[\frac{M}{2} x'^2 - (V_{\mathcal{N}} - E_{\mathcal{N}}) \right], \quad (14.77)$$

with the *Morse potential*

$$V_{\mathcal{N}}(x) = Ae^{4x} - Be^{2x} + C. \quad (14.78)$$

Its fixed-energy amplitude

$$(x_b|x_a)_{E_{\mathcal{N}}} = \int_0^{\infty} dS \int \mathcal{D}x(s) e^{i\mathcal{A}_{\mathcal{N}}/\hbar} \quad (14.79)$$

is therefore equivalent to the radial amplitude of the oscillator (14.65) via the DK relation (14.26), which now reads

$$(r_b|r_a)_{E_{\mathcal{C}},l} = e^{(x_b+x_a)/2} (x_b|x_a)_{E_{\mathcal{N}}}, \quad (14.80)$$

where $r = e^x$.

Let us use the relations (14.74)–(14.76) to extract the bound-state energy eigenvalues of the Morse potential. For this we use the relation (9.33) to rewrite B as

$$B = \hbar\omega(\mu_{\mathcal{O}} + n_r + 1/2), \quad n_r = 0, 1, 2, 3, \dots, \quad (14.81)$$

which becomes with (14.74)

$$B = \hbar\sqrt{2A/M}(\mu_{\mathcal{O}} + n_r + 1/2). \quad (14.82)$$

This is solved by $\mu_{\mathcal{O}} = B/\hbar\sqrt{2A/M} - (n_r + 1/2)$, and inserted into (14.76) to find

$$E_{\mathcal{N}} = C - \frac{B^2}{4A} \left[1 - \frac{\hbar}{B} \sqrt{\frac{2A}{M}} (n_r + 1/2) \right]^2, \quad (0 \leq n_r \leq \sqrt{MB^2/2A\hbar^2} - 1/2). \quad (14.83)$$

For studies of molecular vibrations one typically chooses the Morse potential $V_{\mathcal{N}} = V_0[e^{-4x} - 2e^{-2x}]$, in which case the energy spectrum becomes

$$E_{\mathcal{N}} = -V_0 \left[1 - \frac{\hbar}{\sqrt{MV_0/2}} (n_r + 1/2) \right]^2, \quad (0 \leq n_r \leq \sqrt{MV_0/2\hbar^2} - 1/2). \quad (14.84)$$

14.4.2 Radial Coulomb System and Morse System

By a similar argument, the completely different path integral of the radial Coulomb system can be shown to be DK-equivalent to the path integral of the Morse potential. The action is

$$\mathcal{A}_C = \int dt \left[\frac{M}{2} \dot{r}^2 - \hbar^2 \frac{\mu_C^2 - 1/4}{2Mr^2} + \frac{e^2}{r} + E_C \right], \quad (14.85)$$

where

$$\mu_C = D_C/2 - 1 + l_C. \quad (14.86)$$

For $e^2 = 0$, the action describes a free particle moving in a centrifugal barrier potential. As in the previous example, the action (14.85) does not lead to a time-sliced amplitude of the Feynman type, but involves Bessel functions. We must again remove the barrier via a path-dependent time transformation with

$$f(r) = r^2 \quad (14.87)$$

by introducing the pseudotime s satisfying $dt = ds r^2(s)$. This leads to the time-transformed action

$$\mathcal{A}_C^{f=r^2} = \int_0^S ds \left[\frac{M}{2} \frac{r'^2}{r^2} - \hbar^2 \frac{\mu_C^2 - 1/4}{2M} + e^2 r + E_C r^2 \right]. \quad (14.88)$$

To bring the kinetic term to the standard form, we change the variable r to x via

$$r = e^x. \quad (14.89)$$

This introduces the same effective potential as in (14.72),

$$V_{\text{eff}} = \frac{\hbar^2}{2M} \frac{1}{4}, \quad (14.90)$$

canceling the $1/4$ -term in the former centrifugal barrier [2]. Thus we arrive at the DK transform of the radial Coulomb action

$$\mathcal{A}_C^{\text{DK}} = \int_0^S ds \left[\frac{M}{2} x'^2 - \hbar^2 \frac{\mu_C^2}{2M} + e^2 e^x + E_C e^{2x} \right]. \quad (14.91)$$

A trivial change of variables

$$\begin{aligned} x &= 2\bar{x}, \\ M &= \bar{M}/4, \\ \mu_C &= 2\bar{\mu}, \end{aligned} \quad (14.92)$$

brings this to the form

$$\mathcal{A}_c^{\text{DK}} = \int_0^S ds \left[\frac{\bar{M}}{2} \bar{x}'^2 - \hbar^2 \frac{\bar{\mu}^2}{2\bar{M}} + e^2 e^{2\bar{x}} + E_c e^{4\bar{x}} \right], \quad (14.93)$$

and establishes contact with the Morse action (14.77). Upon replacing \bar{x} by x we see that

$$(r_b|r_a)_{E_c, l_c} = \frac{1}{2} e^{(x_b+x_a)} (x_b|x_a)_{E_\lambda}, \quad (14.94)$$

with $r = e^{2x}$. The factor $1/2$ accounts for the fact that the normalized states are related by $|x\rangle = |\bar{x}\rangle/2$. The identification of the parameters is now

$$A = -E_c, \quad (14.95)$$

$$B = e^2, \quad (14.96)$$

$$C = \hbar^2 \frac{\mu_c^2}{2M} + E_\lambda. \quad (14.97)$$

This can easily be checked inserting for E_λ the previous result (14.84), with A and B expressed by (14.74) and (14.75). This yields

$$E_c = -\frac{Me^4}{\hbar^2} \frac{1}{2(\mu_c + n_r + \frac{1}{2})^2} = -Mc^2 \frac{\alpha^2}{2n^2}, \quad (14.98)$$

with $n = n_r + l_c + (D_c - 1)/2$, $n_r = 0, 1, 2, \dots$. For $D_c = 3$, this agrees with (13.212).

14.4.3 Equivalence of Radial Coulomb System and Radial Oscillator

Since the radial oscillator and the radial Coulomb system are both DK-equivalent to a Morse system, they are DK-equivalent to each other. The relation between the parameters is

$$\begin{aligned} M_{\mathcal{O}} &= 4M_c, \\ \mu_{\mathcal{O}} &= 2\mu_c, \\ E_{\mathcal{O}} &= e^2, \\ -\frac{M_{\mathcal{O}}}{2}\omega^2 &= E_c, \\ r_{\mathcal{O}} &= \sqrt{r_c}. \end{aligned} \quad (14.99)$$

We have added subscripts \mathcal{O}, \mathcal{C} also to the masses M to emphasize the systems to which they belong. The relation $\mu_{\mathcal{O}} = 2\mu_c$ implies

$$D_{\mathcal{O}}/2 - 1 + l_{\mathcal{O}} = 2(D_c/2 - 1 + l_c) \quad (14.100)$$

for all dimensions and angular momenta of the two systems. Due to the square root relation $r_{\mathcal{O}} = \sqrt{r_{\mathcal{C}}}$, the orbital angular momenta satisfy

$$l_{\mathcal{O}} = 2l_{\mathcal{C}}. \quad (14.101)$$

For the dimensions, this implies

$$D_{\mathcal{O}} = 2D_{\mathcal{C}} - 2. \quad (14.102)$$

In the cases $D_{\mathcal{C}} = 2$ and 3 , there is complete agreement with Chapter 13 where the dimensions of the DK-equivalent oscillators were 2 and 4 , respectively.

To relate the amplitudes with each other we find it useful to keep the notation as close as possible to that of Chapter 13 and denote the radial coordinate of the radial oscillator by u . Then the DK relation for the pseudotime evolution amplitudes states that

$$(r_b|r_a)_{E_{\mathcal{C}},\mu_{\mathcal{C}}} = \frac{1}{2}\sqrt{u_b u_a}(u_b|u_a)_{E_{\mathcal{O}},\mu_{\mathcal{O}}}, \quad (14.103)$$

with the right-hand side given by (14.65) (after replacing r by u , $M_{\mathcal{O}}$ by $4M_{\mathcal{C}}$, and $M_{\mathcal{O}}\omega u^2/\hbar$ by $2\kappa r$).

Note once more that the prefactor on the right-hand side has a dimension opposite to what one might have expected from the quantum-mechanical completeness relation

$$\int_0^\infty dr |r\rangle\langle r| = 1, \quad (14.104)$$

whose u -space version reads

$$\int_0^\infty du 2u |r\rangle\langle r| = \int du |u\rangle\langle u| = 1. \quad (14.105)$$

As explained in Section 14.1, the reason lies in the different dimensions (by a factor r) of the pseudotimes over which the evolution amplitudes are integrated when going to the fixed-energy amplitudes. A further factor $1/4$ contained in (14.103) is due to the mass relation $M_{\mathcal{O}} = 4M_{\mathcal{C}}$.

Let us check the relation (14.103) for $D_{\mathcal{C}} = 3$. The fixed-energy amplitude of the Coulomb system has the partial-wave expansion

$$(\mathbf{x}_b|\mathbf{x}_a)_{E_{\mathcal{C}}} = \sum_{l_{\mathcal{C}}=0}^{\infty} \sum_{m=-l_{\mathcal{C}}}^{l_{\mathcal{C}}} \frac{1}{r_b r_a} (r_b|r_a)_{E_{\mathcal{C}},l_{\mathcal{C}}} Y_{l_{\mathcal{C}}m}(\theta_b, \varphi_b) Y_{l_{\mathcal{C}}m}^*(\theta_a, \varphi_a). \quad (14.106)$$

The four-dimensional oscillator, on the other hand, has

$$\begin{aligned} (\vec{u}_b|\vec{u}_a)_{E_{\mathcal{O}}} &= \sum_{l_{\mathcal{O}}=0}^{\infty} (u_b|u_a)_{E_{\mathcal{O}},l_{\mathcal{O}}} \\ &\times \frac{l_{\mathcal{O}}+1}{2\pi^2} \sum_{m_1, m_2=-l_{\mathcal{O}}/2}^{l_{\mathcal{O}}/2} \mathcal{D}_{m_1 m_2}^{l_{\mathcal{O}}/2}(\varphi_n, \theta_n, \gamma_n) \mathcal{D}_{m_1 m_2}^{l_{\mathcal{O}}/2*}(\varphi_{n-1}, \theta_{n-1}, \gamma_{n-1}). \end{aligned} \quad (14.107)$$

We now take Eq. (13.127),

$$(\mathbf{x}_b|\mathbf{x}_a)_{E_C} = \int_0^\infty dS e^{ie^2 S/\hbar} \frac{1}{16} \int_0^{4\pi} d\gamma_a (\vec{u}_b S | \vec{u}_a 0), \quad (14.108)$$

and observe that the integral $\int_0^{4\pi} d\gamma_a$ over the sum of angular wave functions

$$\frac{l_C + 1}{2\pi^2} \sum_{m_1, m_2 = -l_C/2}^{l_C/2} d_{m_1 m_2}^{l_C/2}(\theta_b) d_{m_1 m_2}^{l_C/2}(\theta_a) e^{im_1(\varphi_b - \varphi_a) + im_2(\gamma_b - \gamma_a)} \quad (14.109)$$

produces a sum

$$8 \sum_m^{l_C/2} Y_{l_C/2, m, 0}(\theta_b, \phi_b) Y_{l_C/2, m, 0}^*(\theta_a, \phi_a), \quad (14.110)$$

with the spherical harmonics

$$Y_{l_C/2, m}(\theta, \phi) = \sqrt{\frac{l_C + 1}{4\pi}} e^{im\phi} d_{m, 0}^{l_C/2}(\theta). \quad (14.111)$$

Only even l_C -values survive the integration, and we identify $l_C = l_O/2$

Recalling the radial amplitude of the harmonic oscillator (9.32), we find from (14.103) the radial amplitude of the Coulomb system in any dimension D_C for $r_b > r_a$:

$$(r_b|r_a)_{E_C, l_C} = -i \frac{M_C \Gamma(-\nu + l_C + (D_C - 1)/2)}{\hbar \kappa (2l_C + D_C - 2)!} W_{\nu, l_C + D_C/2 - 1}(2\kappa r_b) M_{\nu, l_C + D_C/2 - 1}(2\kappa r_a), \quad (14.112)$$

where $\kappa = \sqrt{-2ME/\hbar^2}$ and $\nu = \sqrt{-e^4 M_C/2\hbar^2 E_C}$ as in (13.39) and (13.40). For $D_C = 3$, this agrees with (13.211).

The full D_C -dimensional amplitude is given by the sum over partial waves

$$(\mathbf{x}_b|\mathbf{x}_a)_{E_C, l_C} = \frac{1}{(r_b r_a)^{(D_C - 1)/2}} \sum_{l=0}^{\infty} (r_b|r_a)_{E_C, l_C} \sum_{\mathbf{n}} Y_{l\mathbf{n}}(\hat{\mathbf{x}}_b) Y_{l\mathbf{n}}^*(\hat{\mathbf{x}}_a),$$

which becomes with (8.126)

$$(\mathbf{x}_b|\mathbf{x}_a)_{E_C, l_C} = \frac{1}{(r_b r_a)^{(D_C - 1)/2}} \sum_{l_C=0}^{\infty} (r_b|r_a)_{E_C, l_C} \frac{2l_C + D_C - 2}{D_C - 2} \frac{1}{S_{D_C}} C_{l_C}^{(D_C/2 - 1)}(\cos \Delta\vartheta_n). \quad (14.113)$$

It is easy to perform the sum if we make use of an integral representation of the radial amplitude obtained by DK-transforming the integral representation (9.25) of the radial oscillator amplitude. Replacing the imaginary time by the new variable of integration $\varrho = e^{-2\omega(\tau_b - \tau_a)}$, the radial variables r by u , and the oscillator mass M

by $M_{\mathcal{O}}$ to match the notation of Chapter 13, the amplitude (9.25) can be rewritten as

$$(u_b|u_a)_{E_{\mathcal{O}},l_{\mathcal{O}}} = -i \frac{M_{\mathcal{O}}}{\hbar} \sqrt{u_b u_a} \int_0^1 \frac{d\rho}{2\rho} \rho^{-\nu} e^{-\kappa(u_b^2 + u_a^2) \frac{1+\rho}{1-\rho}} I_{l_{\mathcal{O}} + D_{\mathcal{O}}/2 - 1} \left(2\kappa u_b u_a \frac{2\sqrt{\rho}}{1-\rho} \right), \quad (14.114)$$

with

$$\kappa \equiv \frac{M_{\mathcal{O}}\omega}{2\hbar}, \quad \nu \equiv E_{\mathcal{O}}/2\hbar\omega. \quad (14.115)$$

Recalling (9.35), the poles of this amplitude lie at $\nu = n/2 + D_{\mathcal{O}}/4 = n_r + l_{\mathcal{O}}/2 + D_{\mathcal{O}}/4$, where $n = 0, 1, 2, 3, \dots$, so that the energy eigenvalues are

$$E_{\mathcal{O}n} = 2\hbar\omega \left(\frac{n}{2} + \frac{D_{\mathcal{O}}}{4} \right) = \hbar\omega \left(2n_r + l + \frac{D_{\mathcal{O}}}{2} \right). \quad (14.116)$$

From the DK relation (14.103) we obtain $(r_b|r_a)_{l_{\mathcal{O}},E_{\mathcal{O}}}$ and insert it into (14.113). Then we recall the summation formula

$$\begin{aligned} \left(\frac{1}{2}kz \right)^{D_{\mathcal{C}}/2 - 1/2} I_{D_{\mathcal{C}}/2 - 3/2}(kz) &= k^{D_{\mathcal{C}} - 2} \sum_{l=0}^{\infty} \frac{1}{l!} \frac{\Gamma(l + D_{\mathcal{C}} - 2)}{\Gamma(D_{\mathcal{C}}/2 - 1/2)} (2l + D_{\mathcal{C}} - 2) \\ &\times F(-l, l + D_{\mathcal{C}} - 2; D_{\mathcal{C}}/2 - 1/2; (1 + k^2)/2) (-)^l I_{2l + D_{\mathcal{C}} - 2}(z), \end{aligned} \quad (14.117)$$

which follows from Eq. (13.205) for $\nu = D_{\mathcal{C}}/2 - 3/2$ and $\mu = D_{\mathcal{C}} - 2$. After expressing the right-hand side in terms of the Gegenbauer polynomial $C_l^{D_{\mathcal{C}}/2 - 1}$ with the help of (8.106), this becomes

$$\begin{aligned} \frac{1}{2} \frac{1}{(2\pi)^{D_{\mathcal{C}}/2 - 1/2}} \left(\frac{z}{2} \right)^{D_{\mathcal{C}} - 2} I_{D_{\mathcal{C}}/2 - 3/2}(kz) / (kz)^{D_{\mathcal{C}}/2 - 3/2} \\ = \sum_{l_{\mathcal{C}}=0}^{\infty} \frac{2l_{\mathcal{C}} + D_{\mathcal{C}} - 2}{D_{\mathcal{C}} - 2} \frac{1}{S_{D_{\mathcal{C}}}} C_{l_{\mathcal{C}}}^{(D_{\mathcal{C}}/2 - 1)} ((1 + k^2)/2) I_{2l_{\mathcal{C}} + D_{\mathcal{C}} - 2}(z). \end{aligned} \quad (14.118)$$

Setting

$$z \equiv 2\kappa u_b u_a \frac{2\sqrt{\rho}}{1-\rho}, \quad k \equiv \cos(\vartheta/2), \quad (14.119)$$

the sum over the partial waves in (14.113) is easily performed, and we obtain for the fixed-energy amplitude of the Coulomb system in $D_{\mathcal{C}}$ dimensions the generalization of the integral representations (13.43) and (13.133) in two and three dimensions:

$$\begin{aligned} (\mathbf{x}_b|\mathbf{x}_a)_E &= -i \frac{M}{\hbar} \frac{\kappa^{D_{\mathcal{C}} - 2}}{(2\pi)^{(D_{\mathcal{C}} - 1)/2}} \int_0^1 \frac{d\rho}{(1-\rho)^2} \rho^{-\nu} \\ &\times \left(\frac{2\sqrt{\rho}}{1-\rho} \right)^{(D_{\mathcal{C}} - 3)/2} e^{-\kappa \frac{1+\rho}{1-\rho} (r_b + r_a)} I_{D_{\mathcal{C}}/2 - 3/2}(kz) / (kz)^{D_{\mathcal{C}}/2 - 3/2}, \end{aligned} \quad (14.120)$$

ref(13.43)
lab(13.30)
est(13.41)

where

$$kz = 2\kappa \frac{2\sqrt{\varrho}}{1-\varrho} \sqrt{(r_b r_a + \mathbf{x}_b \mathbf{x}_a)/2}, \quad (14.121)$$

and κ, ν are the Coulomb parameters (13.40).

By changing the integration variable to $\zeta = (1 + \varrho)/(1 - \varrho)$ as in (13.49), the integral in (14.120) is transformed into a contour integral encircling the cut from $\zeta = 1$ to ∞ in the clockwise sense. Then the amplitude reads [3]

$$\begin{aligned} (\mathbf{x}_b | \mathbf{x}_a)_E &= -i \frac{M}{2\hbar} \frac{\kappa^{D_C-2}}{(2\pi)^{(D_C-1)/2}} \frac{\pi e^{i\pi(\nu-D_C/2+3/2)}}{\sin[\pi(\nu-D_C/2+3/2)]} \\ &\times \int_C \frac{d\zeta}{2\pi i} (\zeta-1)^{-\nu+D_C/2-3/2} (\zeta+1)^{\nu+D_C/2-3/2} e^{-\kappa\zeta(r_b+r_a)} I_{D_C/2-3/2}(z) / z^{D_C/2-3/2}. \end{aligned} \quad (14.122)$$

This expression generalizes the integral representations (13.53) and (13.135) for $D_C = 2$ and $D_C = 3$, respectively. The poles of this amplitude lie at all integer $\nu = n_r + l_C + (D_C - 1)/2$, corresponding to the energies

$$E_C = -\frac{Me^4}{\hbar^2} \frac{1}{2n^2}, \quad \text{with } n = n_r + l_C + (D_C - 1)/2, \quad n_r = 0, 1, 2, \dots, \quad (14.123)$$

in agreement with (14.98) and, for $D_C = 3$, with (13.212).

As a final remark let us emphasize that at the time-sliced level there is no way of going directly from the radial Coulomb problem to the radial oscillator via the DK relation, due to the catastrophic centrifugal barriers. This has been attempted in the literature [4]. An intermediate Morse potential is necessary to do this properly. See Appendix 14A.

14.4.4 Angular Barrier near Sphere, and Rosen-Morse Potential

For another application of the solution method, consider the path integral for a mass point near the surface of a sphere in three dimensions, projected into a state of fixed azimuthal angular momentum $m = 0, \pm 1, \pm 2, \dots$. The projection generates an angular barrier $\propto (m^2 - 1/4)/\sin^2 \theta$ which is a potential of the Pöschl-Teller type. With $\mu = Mr^2$, the real-time action is

$$\mathcal{A}_{\mathcal{PT}} = \int dt \left[\frac{\mu}{2} \dot{\theta}^2 + \frac{\hbar^2}{8\mu} - \frac{\hbar^2}{2\mu} \frac{m^2 - 1/4}{\sin^2 \theta} + E_{\mathcal{PT}} \right]. \quad (14.124)$$

The quotation marks are defined in analogy with those of the centrifugal barrier in Eq. (8.140). The precise meaning is given by the proper time-sliced expression in Eq. (8.175) whose limiting form for narrow time slices is (8.177). After an analytic continuation of the parameter m to arbitrary real numbers μ , the resulting amplitude was given in (8.187). In the sequel we refrain from using the symbol μ for the noninteger m -values to avoid confusion with the mass parameter μ .

The spectral representation of the associated fixed-energy amplitude is easily written down; it arises by simply integrating (8.187) over $-id\tau_b$ and reads

$$(\theta_b|\theta_a)_{m,E_{\mathcal{PT}}} = \sqrt{\sin\theta_b \sin\theta_a} \sum_{n=0}^{\infty} \frac{i\hbar}{E_{\mathcal{PT}} - \hbar^2 L_2/2\mu} \quad (14.125)$$

$$\times \frac{2n+2m+1}{2} \frac{(n+2m)!}{n!} P_{n+m}^{-m}(\cos\theta_b) P_{n+m}^{-m}(\cos\theta_a),$$

where $L_2 = l(l+1)$ with $l = n+m$ [recall (8.225) for $D=3$]. The sum over n can be done using the so-called Sommerfeld-Watson transformation [5]. The sum is re-expressed as a contour integral in the complex n -plane and deformed in such a way that only the Regge poles at

$$n+m = l = l(E_{\mathcal{PT}}) \equiv -\frac{1}{2} + \sqrt{\frac{1}{4} + \frac{2\mu E_{\mathcal{PT}}}{\hbar^2}} \quad (14.126)$$

contribute, with both signs of the square root. The result for $\theta_b > \theta_a$ is [6]

$$(\theta_b|\theta_a)_{m,E_{\mathcal{PT}}} = \sqrt{\sin\theta_b \sin\theta_a} \frac{-i\mu}{\hbar} \Gamma(m - l(E_{\mathcal{PT}})) \Gamma(l(E_{\mathcal{PT}}) + m + 1)$$

$$\times P_{l(E_{\mathcal{PT}})}^{-m}(-\cos\theta_b) P_{l(E_{\mathcal{PT}})}^{-m}(\cos\theta_a). \quad (14.127)$$

Here we shall consider m as a free parameter characterizing the interaction strength of the Pöschl-Teller potential [7]

$$V_{\mathcal{PT}}(\theta) = \frac{\hbar^2}{2\mu} \frac{m^2}{\sin^2\theta}. \quad (14.128)$$

The regulating function removing the angular barrier is

$$f(\theta) = \sin^2\theta, \quad (14.129)$$

and the time-transformed action reads with $dt = ds \sin^2\theta(s)$

$$\mathcal{A}_{\mathcal{PT}}^{f=\sin^2\theta} = \int_0^S ds \left[\frac{\mu}{2\sin^2\theta} \theta'^2 + \frac{\hbar^2}{8\mu} \sin^2\theta - \frac{\hbar^2}{2\mu} (m^2 - 1/4) + E_{\mathcal{PT}} \sin^2\theta \right]. \quad (14.130)$$

We now bring the kinetic term to the conventional form by the variable change

$$\sin\theta = \frac{1}{\cosh x}, \quad \cos\theta = -\tanh x, \quad (14.131)$$

which maps the interval $\theta \in (0, \pi)$ into $x \in (-\infty, \infty)$. Then we have

$$h'(x) = \sin\theta = \frac{1}{\cosh x}. \quad (14.132)$$

Forming the higher derivatives

$$h''(x) = -\frac{\tanh x}{\cosh x}, \quad h'''(x) = -\frac{1}{\cosh x} (1 - 2 \tanh^2 x), \quad (14.133)$$

the effective potential is found to be

$$V_{\text{eff}} = \frac{\hbar^2}{8\mu} \left(1 + \frac{1}{\cosh^2 x} \right). \quad (14.134)$$

The DK-transformed action is therefore

$$\mathcal{A}_{\mathcal{PT}}^{\text{DK}} = \int_0^S ds \left[\frac{\mu}{2} x'^2 - \frac{\hbar^2 m^2}{2\mu} + E_{\mathcal{PT}} \frac{1}{\cosh^2 x} \right]. \quad (14.135)$$

It describes the motion of a mass point in a smooth potential well known as the *Rosen-Morse potential* (also called the *modified Pöschl-Teller potential*) [8]. The standard parametrization is¹

$$V_{\mathcal{RL}}(x) = -\frac{\hbar^2 s(s+1)}{2\mu \cosh^2 x}, \quad (14.136)$$

This corresponds to $l(E_{\mathcal{PT}})$ in (14.126) having the value s . The energy of the Rosen-Morse potential determines the parameter m in the action (14.135), and we identify

$$m = m(E_{\mathcal{RL}}) = \sqrt{-2\mu E_{\mathcal{RL}} / \hbar^2}. \quad (14.137)$$

It is obvious that the time-sliced amplitude of the Rosen-Morse potential has no path collapse problems. Its fixed-energy amplitude is thus DK-equivalent to the Pöschl-Teller amplitude (14.127), with the precise relation being

$$(\theta_b | \theta_a)_{m, E_{\mathcal{PT}}} = \sqrt{\sin \theta_b \sin \theta_a} (x_b | x_a)_{m, E_{\mathcal{RL}}}, \quad (14.138)$$

where $\tanh x = -\cos \theta$, $\theta \in (0, \pi)$, $x \in (-\infty, \infty)$. Inserting (14.127), the amplitude of the Rosen-Morse system reads explicitly

$$\begin{aligned} (x_b | x_a)_{m(E_{\mathcal{RL}})} &= \frac{-i\mu}{\hbar} \Gamma(m(E_{\mathcal{RL}}) - s) \Gamma(s + m(E_{\mathcal{RL}}) + 1) \\ &\times P_s^{-m(E_{\mathcal{RL}})}(\tanh x_b) P_s^{-m(E_{\mathcal{RL}})}(-\tanh x_a). \end{aligned} \quad (14.139)$$

The bound states lie at the poles of the first Gamma function where

$$m(E_{\mathcal{RL}}) = s - n, \quad n = 0, 1, 2, \dots, [s], \quad (14.140)$$

with $[s]$ denoting the largest integer number $\leq s$. From the residues we extract the normalized wave functions [6]

$$\psi_n(x) = \sqrt{\Gamma(2s - n + 1)(s - n)/n} P_s^{n-s}(\tanh x). \quad (14.141)$$

For noninteger values of s , these are not polynomials. However, the identity between hypergeometric functions (1.453)

$$F(a, b; c; z) = (1 - z)^{c-a-b} F(c - a, c - b; c; z) \quad (14.142)$$

¹There is no danger of confusing this parameter s with the pseudotime s .

permits relating them to polynomials:

$$P_s^{n-s}(\tanh x) = \frac{2^{n-s}}{\Gamma(s-n+1)} \frac{1}{\cosh^{s-n} x} F(-n, 1+2s-n; s-n+1; (1-\tanh x)/2). \tag{14.143}$$

The continuum wave functions are obtained from (14.141) by an appropriate analytic continuation of m to $-ik$. This amounts to replacing n by $s+ik$.

14.4.5 Angular Barrier near Four-Dimensional Sphere and General Rosen-Morse Potential

Let us extend the previous path integral of a mass point moving near the surface of a sphere from $D=3$ to $D=4$ dimensions. By projecting the amplitude into a state of fixed azimuthal angular momenta m_1 and m_2 , an angular barrier is generated in the Euler angle θ proportional to $(m_1^2 + m_2^2 - 1/4 - 2m_1m_2 \cos \theta)/\sin^2 \theta$. This is again a potential of the Pöschl-Teller type, although of a more general form to be denoted by \mathcal{PT}' . The action (8.212) is, with $\mu = Mr^2/4$,

$$\mathcal{A}_{\mathcal{PT}'} = \int dt \left[\frac{\mu}{2} \dot{\theta}^2 + \frac{\hbar^2}{32\mu} - \frac{\hbar^2}{2\mu} \frac{m_1^2 + m_2^2 - 2m_1m_2 \cos \theta - 1/4}{\sin^2 \theta} + E_{\mathcal{PT}'} \right], \tag{14.144}$$

ref(8.212)
lab(8.177b)
est(8.213)

where the quotation marks indicate the need to regularize the angular barrier via Bessel functions as specified in (8.208). The projected amplitude was given in Eq. (8.203) and continued to arbitrary real values of $m_1 = \mu_1$, $m_2 = \mu_2$ with $\mu_1 \geq \mu_2 \geq 0$ in (8.213). As in subsection 14.4.4, we shall also use the parameters m_1, m_2 when they have noninteger values.

ref(8.213)
lab(8.152f)
est(8.214)

The most general Pöschl-Teller potential

$$V_{\mathcal{PT}'}(\theta) = \frac{\hbar^2}{2\mu} \left[\frac{s_1(s_1+1)}{\sin^2(\theta/2)} + \frac{s_2(s_2+1)}{\cos^2(\theta/2)} \right] \tag{14.145}$$

can easily be mapped onto the above angular barrier, where $s_1(s_1+1) = \frac{(m_1+m_2)^2}{4} - \frac{1}{16}$, $s_2(s_2+1) = \frac{(m_1-m_2)^2}{4} - \frac{1}{16}$ or $s_1 = -\frac{1}{2} \left(1 - \sqrt{\frac{3}{4} + (m_1+m_2)^2} \right)$, $s_2 = -\frac{1}{2} \left(1 - \sqrt{\frac{3}{4} + (m_1-m_2)^2} \right)$.

The fixed-energy amplitude is obtained directly from Eq. (8.213) by an integration over $-id\tau_b$. It reads for $m_1 \geq m_2$

$$(\theta_b|\theta_a)_{m_1, m_2, E_{\mathcal{PT}'}} = \sqrt{\sin \theta_b \sin \theta_a} \times \sum_{n=0}^{\infty} \frac{i\hbar}{E_{\mathcal{PT}'} - \hbar^2 L_2/8\mu} \frac{2n+2m_1+1}{2} d_{m_1, m_2}^{n+m_1}(\theta_b) d_{m_1, m_2}^{n+m_1}(\theta_a), \tag{14.146}$$

where L_2 is given by $L_2 = (l+1)^2 - 1/4$ with $l = 2n + 2m_1$ [recall (8.220) with (8.225)].

ref(8.225)
lab(x8.226)
est(8.226)

As in Eq. (14.125), the sum over n can be performed with the help of a Sommerfeld-Watson transformation by rewriting the sum as a contour integral in the complex n -plane. After deforming the contour in such a way that only the Regge poles at

$$2n + 2m_1 = l = l(E_{\mathcal{PT}'}) \equiv -1 + 2\sqrt{\frac{1}{16} + \frac{2\mu E_{\mathcal{PT}'}}{\hbar^2}} \quad (14.147)$$

contribute, with both signs of the square root, we find for $\theta_b > \theta_a$:

$$\begin{aligned} (\theta_b|\theta_a)_{m_1, m_2, E_{\mathcal{PT}'}} &= \sqrt{\sin \theta_b \sin \theta_a} \frac{-2i\mu}{\hbar} \\ &\times \Gamma(m_1 - l(E_{\mathcal{PT}'})/2) \Gamma(l(E_{\mathcal{PT}'})/2 - m_1 + 1) \frac{1}{2} d_{m_1, -m_2}^{l(E_{\mathcal{PT}'})/2}(\theta_b - \pi) d_{m_1, m_2}^{l(E_{\mathcal{PT}'})/2}(\theta_a), \end{aligned} \quad (14.148)$$

with arbitrary real parameters m_1, m_2 characterizing the interaction strength. The eigenvalues of the discrete energies are given by the poles of the first Gamma function:

$$E_{\mathcal{PT}'} = \frac{\hbar^2}{2\mu} \left[(m_1 + n + \frac{1}{2})^2 - \frac{1}{16} \right], \quad n = 0, 1, 2, \dots \quad (14.149)$$

The regulating function which removes the angular barrier is

$$f(\theta) = \sin^2 \theta, \quad (14.150)$$

and the time-transformed action reads, with $dt = ds \sin^2 \theta(s)$,

$$\begin{aligned} \mathcal{A}_{\mathcal{PT}'}^{f=\sin^2 \theta} &= \int_0^S ds \left[\frac{\mu}{2 \sin^2 \theta} \theta'^2 + \frac{\hbar^2}{32\mu} \sin^2 \theta \right. \\ &\quad \left. - \frac{\hbar^2}{2\mu} (m_1^2 + m_2^2 - 1/4 - 2m_1 m_2 \cos \theta) + E_{\mathcal{PT}'} \sin^2 \theta \right]. \end{aligned} \quad (14.151)$$

We now bring the kinetic term to the conventional form by the variable change

$$\sin \theta = \pm \frac{1}{\cosh x}, \quad \cos \theta = -\tanh x. \quad (14.152)$$

As in the previous case, this leads to the effective potential

$$V_{\text{eff}} = \frac{\hbar^2}{8\mu} \left(1 + \frac{1}{\cosh^2 x} \right). \quad (14.153)$$

The DK-transformed action is then

$$\mathcal{A}_{\mathcal{PT}'}^{\text{DK}} = \int_0^S ds \left[\frac{\mu}{2} x'^2 - \frac{\hbar^2}{2\mu} (m_1^2 + m_2^2 + 2m_1 m_2 \tanh x) + \left(E_{\mathcal{PT}'} - \frac{3\hbar^2}{32\mu} \right) \frac{1}{\cosh^2 x} \right]. \quad (14.154)$$

It contains a smooth potential well near the origin known as the *general Rosen-Morse potential* [8]:

$$V_{\mathcal{R}\mathcal{N}'}(x) = - \left(E_{\mathcal{P}\mathcal{T}'} - \frac{3\hbar^2}{32\mu} \right) \frac{1}{\cosh^2 x} + \frac{\hbar^2}{2\mu} 2m_1 m_2 \tanh x. \quad (14.155)$$

The standard parametrization for this is²

$$V_{\mathcal{R}\mathcal{N}'}(x) = \frac{\hbar^2}{2\mu} \left[-\frac{s(s+1)}{\cosh^2 x} + 2c \tanh x \right], \quad (14.156)$$

which amounts to choosing

$$E_{\mathcal{P}\mathcal{T}'} = \frac{\hbar^2}{2\mu} \left[s(s+1) + \frac{3}{16} \right], \quad m_1 m_2 = c, \quad (14.157)$$

in (14.154). Inserting this into (14.147) makes $l(E_{\mathcal{P}\mathcal{T}'})/2$ equal to s .

The energy of the general Rosen-Morse potential is defined by the action in the fixed-energy path integral [compare (14.77)]

$$\mathcal{A}_{\mathcal{R}\mathcal{N}'} = \int_0^S ds \left[\frac{\mu}{2} x'^2 - (V_{\mathcal{R}\mathcal{N}'} - E_{\mathcal{R}\mathcal{N}'}) \right]. \quad (14.158)$$

Comparison with (14.154) shows that the bound-state energies have the eigenvalues

$$E_{\mathcal{R}\mathcal{N}'} = -\frac{\hbar^2}{2\mu} (m_1^2 + m_2^2) = -\frac{\hbar^2}{2\mu} (m_1^2 + c^2/m_1^2). \quad (14.159)$$

The solution of this equation will be a function $m_1(E_{\mathcal{R}\mathcal{N}'})$. Correspondingly, we may define $m_2(E_{\mathcal{R}\mathcal{N}'}) \equiv c/m_1(E_{\mathcal{R}\mathcal{N}'})$.

Feynman's time-sliced amplitude certainly exists for this potential, and the fixed-energy amplitude is determined in terms of the angular-projected amplitude (14.148) of a mass point near the surface of a sphere which describes the motion in a general Pöschl-Teller potential. The relation is [9]

$$(\theta_b | \theta_a)_{m_1, m_2, E_{\mathcal{P}\mathcal{T}'}} = \sqrt{\sin \theta_b \sin \theta_a} (x_b | x_a)_{m_1, m_2, E_{\mathcal{R}\mathcal{N}'}} , \quad (14.160)$$

with $\tanh x = -\cos \theta$, $\theta \in (0, \pi)$, $x \in (-\infty, \infty)$. Explicitly we have

$$\begin{aligned} (x_b | x_a)_{m_1, m_2, E_{\mathcal{R}\mathcal{N}'}} &= \frac{-2i\mu}{\hbar} \Gamma(m_1(E_{\mathcal{R}\mathcal{N}'}) - s) \Gamma(s - m_1(E_{\mathcal{R}\mathcal{N}'})) + 1) \\ &\times \frac{1}{2} d_{m_1(E_{\mathcal{R}\mathcal{N}'})}^s, -m_2(E_{\mathcal{R}\mathcal{N}'})}(\theta_b(x_b) - \pi) d_{m_1(E_{\mathcal{R}\mathcal{N}'})}^s, m_2(E_{\mathcal{R}\mathcal{N}'})}(\theta_a(x_a)). \end{aligned} \quad (14.161)$$

Since $s - m_1 \geq 0$, the bound states lie at the poles of the first Gamma function. With the energy-dependent function $m_1(E_{\mathcal{R}\mathcal{N}'})$ defined by (14.159), they are given by the solutions of the equation

$$m_1(E_{\mathcal{R}\mathcal{N}'}) = s - n, \quad n = 0, 1, \dots, [s]. \quad (14.162)$$

²There is no danger of confusing this parameter s with the pseudotime s .

The residues in (14.161) render the normalized wave functions

$$\begin{aligned} \Psi_n(x) = & \sqrt{\frac{m_1^2 - m_2^2}{m_1} \frac{\Gamma(s+1-m_1)n!}{\Gamma(s+1-m_2)\Gamma(s+1+m_2)}} \\ & \times [\tfrac{1}{2}(1+\tanh x)]^{(m_1-m_2)/2} [\tfrac{1}{2}(1-\tanh x)]^{(m_1+m_2)/2} P_n^{(m_1-m_2, m_1+m_2)}(-\tanh x), \end{aligned} \quad (14.163)$$

or, expressed in terms of hypergeometric functions,

$$\begin{aligned} \Psi_n(x) = & \sqrt{\frac{m_1^2 - m_2^2}{m_1} \frac{\Gamma(s+1+m_1)\Gamma(s+1-m_2)}{n!\Gamma(1+m_1-m_2)^2\Gamma(s+1+m_2)}} \\ & \times [\tfrac{1}{2}(1+\tanh x)]^{(m_1-m_2)/2} [\tfrac{1}{2}(1-\tanh x)]^{(m_1+m_2)/2} \\ & \times F(2s-n+1, -n; 1+m_1-m_2; \tfrac{1}{2}(1+\tanh x)), \end{aligned} \quad (14.164)$$

with $m_1 = s - n$ and $m_2 = c/m_1$ [10]. The continuum wave functions are obtained from these by an appropriate analytic continuation of m_1 to complex values $-ik$ satisfying the relation $k^2 = (m_1^2 + c^2/m_1^2)$ [compare (14.159)].

When inserting (14.161) into (14.160), we have to make sure to use for s the $E_{\mathcal{PT}'}$ -dependent expression $s(E_{\mathcal{PT}'})$ obtained from solving (14.157).

14.4.6 Hulthén Potential and General Rosen-Morse Potential

For a further application of the solution method, consider the path integral of a particle moving along the positive r -axis with the singular Hulthén potential

$$V_{\mathcal{H}}(r) = g \frac{1}{e^{r/a} - 1}, \quad (14.165)$$

where g and a are energy and length parameters. Note that this potential contains the Coulomb system in the limit $a \rightarrow \infty$ at $ag = e^2 = \text{fixed}$.

The fixed-energy amplitude is controlled by the action

$$\mathcal{A}_{\mathcal{H}} = \int dt \left[\frac{M}{2} \dot{r}^2 - V_{\mathcal{H}}(r) + E_{\mathcal{H}} \right]. \quad (14.166)$$

The potential is singular at $r = 0$, and for $g < 0$, the Euclidean time-sliced amplitude does not exist due to path collapse. A regulating function which stabilizes the fluctuations is

$$f(r) = 4(1 - e^{-r/a})^2. \quad (14.167)$$

The time-transformed action is therefore

$$\mathcal{A}_{\mathcal{H}}^f = \int_0^\infty ds \left[\frac{M}{2} \frac{r'^2}{4(1-e^{-r/a})^2} - g 4e^{-r/a}(1 - e^{-r/a}) + E_{\mathcal{H}} 4(1 - e^{-r/a})^2 \right]. \quad (14.168)$$

The coordinate transformation leading to a conventional kinetic energy in terms of the new variable x is found by solving the differential equation

$$\frac{dr}{dx} = h'(x), \quad (14.169)$$

with

$$h' = \sqrt{f} = 2(1 - e^{-r/a}). \quad (14.170)$$

The solution is

$$\frac{r}{a} = x + a \log[2 \cosh(x/a)] = \log(e^{2x/a} + 1), \quad (14.171)$$

so that

$$h'(x) = 2 \frac{e^{2x/a}}{e^{2x/a} + 1} = \frac{e^{x/a}}{\cosh(x/a)}. \quad (14.172)$$

The semi-axis $r \in (0, \infty)$ is mapped into the entire x -axis.

To find the effective potential we calculate the derivatives

$$\begin{aligned} h''(x) &= \frac{1}{a} \frac{1}{\cosh^2(x/a)} = \frac{1}{a} \frac{e^{x/a}}{\cosh(x/a)} [1 - \tanh(x/a)], \\ h'''(x) &= -\frac{2}{a^2} \frac{\sinh x}{\cosh^3 x} = -\frac{2}{a^2} \frac{e^{x/a}}{\cosh(x/a)} [\tanh(x/a) - \tanh^2(x/a)], \end{aligned} \quad (14.173)$$

and obtain

$$\begin{aligned} \frac{h''}{h'} &= \frac{1}{a} \frac{e^{-x/a}}{\cosh(x/a)} = \frac{1}{a} [1 - \tanh(x/a)], \\ \frac{h'''}{h'} &= -\frac{2}{a^2} \frac{e^{-x/a} \sinh(x/a)}{\cosh^2(x/a)} = -\frac{2}{a^2} \tanh(x/a) [1 - \tanh(x/a)], \end{aligned} \quad (14.174)$$

so that the effective potential becomes

$$V_{\text{eff}} = \frac{\hbar^2}{8Ma^2} \left[2 - 2 \tanh(x/a) - \frac{4}{\cosh^2(x/a)} \right]. \quad (14.175)$$

After adding this to the time-transformed potential, the DK-transformed action is found to be

$$\begin{aligned} \mathcal{A}_{\mathcal{H}}^{\text{DK}} &= \int_0^S ds \left\{ \frac{M}{2} x'^2 - \left(g + E_{\mathcal{H}} - \frac{\hbar^2}{2Ma^2} \right) \frac{1}{\cosh^2(x/a)} \right. \\ &\quad \left. + \left(2E_{\mathcal{H}} + \frac{\hbar^2}{4Ma^2} \right) \tanh(x/a) + \left(2E_{\mathcal{H}} - \frac{\hbar^2}{4Ma^2} \right) \right\}. \end{aligned} \quad (14.176)$$

This is the action governing the fixed-energy amplitude of the general Rosen-Morse potential (14.156)

$$V_{\mathcal{R}\mathcal{M}}(x/a) = \frac{\hbar^2}{2Ma^2} \left[-\frac{s(s+1)}{\cosh^2(x/a)} + c \tanh(x/a) \right]. \quad (14.177)$$

Since this potential is smooth, there exists a time-sliced path integral of the Feynman type. The relation between the fixed-energy amplitudes is

$$(r_b|r_a)_{E_{\mathcal{H}}} = e^{(x_b+x_a)/2a} [\cosh(x_b/a) \cosh(x_a/a)]^{-1/2} (x_b|x_a)_{E_{\mathcal{R}\mathcal{M}}}, \quad (14.178)$$

with $r/a = \log(e^{2x/a} + 1) \in (0, \infty)$, $x \in (-\infty, \infty)$. The amplitude on the right-hand side is known from the last section; it is related to the amplitude for the motion of a mass point on the surface of a sphere in four dimensions, projected into a state of fixed azimuthal angular momenta m_1 and m_2 . Only a simple rescaling of x/a to x is necessary to make the relation explicit.

From the energy spectrum (14.159), with (14.162), of the generalized Rosen-Morse potential and the above DK we derive the discrete spectrum of the Hulthén potential for $g < 0$ [7]:

$$E_{\mathcal{H}n} = g \left(\frac{n_g^2 - n^2}{2n_g n} \right)^2 = -\frac{\hbar^2}{2Ma^2} \frac{1}{4n^2} (n_g^2 - n^2)^2, \quad 1 \leq n < n_g, \quad (14.179)$$

where $n_g^2 = -2Mga^2/\hbar^2$.

In the literature, a solution of the time-sliced path integral with the action (14.166) has been attempted using a regulating function [11]

$$f = a^2(e^{r/a} - 1). \quad (14.180)$$

This implies going to the new variables

$$\frac{r}{a} = -2 \log \cos(\theta/2), \quad (14.181)$$

so that

$$f = a^2 \tan^2(\theta/2) = a^2 \left[\frac{1}{\cos^2(\theta/2)} - 1 \right]. \quad (14.182)$$

Note that this does not lead to a solution of the time-sliced path integral, since the transformed potential is still singular. Indeed, with $h' = a \tan(\theta/2)$, $h'' = a/2 \cos^2(\theta/2)$, $h''' = a \sin(\theta/2)/2 \cos^3(\theta/2)$, we would find the effective potential

$$V_{\text{eff}}(\theta) = \frac{\hbar^2}{8Ma^2} \frac{1}{\sin^2 \theta} (1 + 2 \cos \theta) = \frac{\hbar^2}{32Ma^2} \left[\frac{3}{\sin^2(\theta/2)} - \frac{1}{\cos^2(\theta/2)} \right], \quad (14.183)$$

and a transformed action

$$\tilde{\mathcal{A}}_{\mathcal{H}}^{\text{DK}} = \int_0^S (ds/a^2) \left\{ \frac{Ma^4}{2} \theta'^2 - g + E_{\mathcal{H}} \left[\frac{1}{\cos^2(\theta/2)} - 1 \right] + V_{\text{eff}}(\theta) \right\}, \quad (14.184)$$

which is of the general Pöschl-Teller type (14.145). Due to the presence of the $1/\cos^2(\theta/2)$ -term, the Euclidean time evolution amplitude cannot be time-sliced. Only by starting from the particle near the surface of a sphere with the particular Bessel function regularization of (8.208), can a well-defined time-sliced amplitude be written down whose action looks like (14.184) in the continuum limit. It would be impossible, however, to invent this regularization when starting from the continuum action (14.184).

14.4.7 Extended Hulthén Potential and General Rosen-Morse Potential

The alert reader will have noticed that the regulating function (14.165) overkills the ga/r singularity of the Hulthén potential (14.165). In fact, we may add to the potential a term

$$\Delta V_{\mathcal{H}} = \frac{g'}{(e^{r/a} - 1)^2} \quad (14.185)$$

without loosing the stability of the path integral. In the limit $a \rightarrow \infty$, the extended potential contains the radial Coulomb system plus a centrifugal barrier, if we set $ga = -e^2 = \text{const}$ and $g'a^2 = \hbar^2 l(l+1)/2M$. The potential (14.185) adds to the time-transformed action (14.168) a term

$$\Delta \mathcal{A}_{\mathcal{H}}^f = - \int_0^S ds g' 4e^{-2r/a}, \quad (14.186)$$

which winds up in the final DK-transformed action as

$$\Delta \mathcal{A}_{\mathcal{H}}^{\text{DK}} = - \int_0^S ds g' \left[2 - 2 \tanh(x/a) - \frac{1}{\cosh^2(x/a)} \right]. \quad (14.187)$$

Therefore, the extended Hulthén potential is again DK-equivalent to the general Rosen-Morse potential with the same relation (14.178) between the amplitudes, but with different relations between the constants.

The discrete energy spectrum of the extended Hulthén potential is

$$E_{\mathcal{H}'n} = - \frac{\hbar^2}{2Ma^2} \left[\frac{n(n-1) + n_g^2}{2(n-s_2)} - n + \frac{1}{2} \right]^2, \quad 1 \leq n < \bar{n}, \quad (14.188)$$

where $n_g^2 \equiv 2Mg'a^2/\hbar^2$, and $s_2 \equiv -\frac{1}{2} \left(1 - \sqrt{1 + 4n_g^2} \right)$ solves $s_2(s_2 + 1) = n_g^2$. For $g' = 0$, this reduces to (14.179).

14.5 *L-Dimensional Systems*

Let us now perform the path-dependent time transformation in D dimensions. The fixed-energy amplitude is given by the integral

$$\langle \mathbf{x}_b | \mathbf{x}_a \rangle_E = \int_0^\infty dS \langle \mathbf{x}_b | \hat{\mathcal{U}}_E(S) | \mathbf{x}_a \rangle, \quad (14.189)$$

with the pseudotime evolution amplitude

$$\langle \mathbf{x}_b | \hat{\mathcal{U}}_E(S) | \mathbf{x}_a \rangle = f_r(\mathbf{x}_b) f_l(\mathbf{x}_a) \langle \mathbf{x}_b | \exp \left[-\frac{i}{\hbar} S f_l(\mathbf{x}) (\hat{H} - E) f_r(\mathbf{x}) \right] | \mathbf{x}_a \rangle. \quad (14.190)$$

It has the time-sliced path integral

$$\langle \mathbf{x}_b | \hat{\mathcal{U}}_E(S) | \mathbf{x}_a \rangle \approx \frac{f_r(\mathbf{x}_b) f_l(\mathbf{x}_a)}{\sqrt{2\pi i \epsilon_s \hbar f_l(\mathbf{x}_b) f_r(\mathbf{x}_a) / M}^D} \prod_{n=1}^N \left[\int \frac{dx_n}{\sqrt{2\pi i \epsilon_s \hbar f_n / M}} \right] \exp \left\{ \frac{i}{\hbar} \mathcal{A}^N \right\}, \quad (14.191)$$

with the action

$$\mathcal{A}^N = \sum_{n=1}^{N+1} \left\{ \frac{M}{2\epsilon_s} \frac{(\Delta \mathbf{x}_n)^2}{f_l(\mathbf{x}_n) f_r(\mathbf{x}_{n-1})} + \epsilon_s [E - V(\mathbf{x}_n)] f_l(\mathbf{x}_n) f_r(\mathbf{x}_{n-1}) \right\}, \quad (14.192)$$

where the integration measure contains the abbreviation $f_n \equiv f(r_n) = f_l(\mathbf{x}_n) f_r(\mathbf{x}_n)$. The time-transformed measure of path integration reads

$$\frac{f_r(\mathbf{x}_b) f_l(\mathbf{x}_a)}{\sqrt{2\pi i \epsilon_s \hbar f_l(\mathbf{x}_b) f_r(\mathbf{x}_a) / M}^D} \prod_{n=1}^N \int \frac{d^D x_n}{\sqrt{2\pi i \epsilon_s \hbar f_n / M}^D}. \quad (14.193)$$

By shifting the product index and the subscripts of f_n by one unit, and by compensating for this with a prefactor, the integration measure in (14.27) acquires the postpoint form

$$\frac{f_r(\mathbf{x}_b) f_l(\mathbf{x}_a)}{\sqrt{2\pi i \epsilon_s \hbar f_l(\mathbf{x}_b) f_r(\mathbf{x}_a) / M}^D} \sqrt{\frac{f(\mathbf{x}_b)}{f(\mathbf{x}_a)}}^D \prod_{n=2}^{N+1} \int \frac{d^D \Delta x_n}{\sqrt{2\pi i \epsilon_s \hbar f_n / M}^D}. \quad (14.194)$$

The integrals over each coordinate difference $\Delta \mathbf{x}_n = \mathbf{x}_n - \mathbf{x}_{n-1}$ are done at fixed postpoint positions \mathbf{x}_n .

To simplify the subsequent discussion, it is preferable to work only with the postpoint regularization in which $f_l(\mathbf{x}) = f(\mathbf{x})$ and $f_r(\mathbf{x}) \equiv 1$. Then the measure becomes simply

$$\frac{f(\mathbf{x}_a)}{\sqrt{2\pi i \epsilon_s f(\mathbf{x}_a) \hbar / M}^D} \prod_{n=2}^{N+1} \int \frac{d^D \Delta x_n}{\sqrt{2\pi i \epsilon_s \hbar f_n / M}^D}. \quad (14.195)$$

We now introduce the coordinate transformation. In D dimensions it is given by

$$x^i = h^i(q). \quad (14.196)$$

The differential mapping may be written as in Chapter 10 as

$$dx^i = \partial_\mu h^i(q) = e^i_\mu(q) dq^\mu. \quad (14.197)$$

The transformation of a single time slice in the path integral can be done following the discussion in Sections 10.3 and 10.4. This leads to the path integral

$$(\mathbf{x}_b|\mathbf{x}_a)_E \approx \frac{f(q_a)}{\sqrt{2\pi i \epsilon_s f(q_a) \hbar / M}} \int_0^\infty dS \prod_{n=2}^{N+1} \left[\int \frac{d^D \Delta q_n g^{1/2}(q_n)}{\sqrt{2\pi i \epsilon_s \hbar f_n / M}} \right] e^{i\mathcal{A}_{\text{tot}}/\hbar}, \quad (14.198)$$

with the total time-sliced action

$$\mathcal{A}_{\text{tot}} = \sum_{n=1}^{N+1} \mathcal{A}_{\text{tot}}^\epsilon. \quad (14.199)$$

Each slice contains three terms

$$\mathcal{A}_{\text{tot}}^\epsilon = \mathcal{A}^\epsilon + \mathcal{A}_J^\epsilon + \mathcal{A}_{\text{pot}}^\epsilon. \quad (14.200)$$

In the postpoint form, the first two terms were given in (13.163) and (13.164). They are equal to

$$\mathcal{A}^\epsilon + \mathcal{A}_J^\epsilon = \frac{M}{2\epsilon f} g_{\mu\nu}(q) \Delta q^\mu \Delta q^\nu - i \frac{\hbar}{2} \Gamma_\mu{}^\mu{}_\nu \Delta q^\nu - \epsilon_s f \frac{\hbar^2}{8M} (\Gamma_\mu{}^\mu{}_\nu)^2. \quad (14.201)$$

The third term contains the effect of a potential and a vector potential as derived in (10.183). After the DK transformation, it reads

$$\mathcal{A}_{\text{pot}}^\epsilon = A_\mu \Delta q^\mu - i \epsilon_s f \frac{\hbar}{2M} (A_\nu \Gamma_\mu{}^{\mu\nu} + D_\mu A^\mu) - \epsilon_s f V(q). \quad (14.202)$$

14.6 Path Integral of the Dionium Atom

We now apply the generalized D -dimensional Duru-Kleinert transformation to the path integral of a dionium atom in three dimensions. This is a system of two particles with both electric and magnetic charges (e_1, g_1) and (e_2, g_2) [12]. Its Lagrangian for the relative motion reads

$$L = \frac{M}{2} \dot{\mathbf{x}}^2 + \mathbf{A}(\mathbf{x}) \dot{\mathbf{x}} - V(\mathbf{x}), \quad (14.203)$$

where \mathbf{x} is the distance vector pointing from the first to the second article, M the reduced mass, $V(\mathbf{x})$ a Coulomb potential

$$V(\mathbf{x}) = -\frac{e^2}{r}, \quad (14.204)$$

and $\mathbf{A}(\mathbf{x})$ the vector potential

$$\mathbf{A}(\mathbf{x}) = \hbar q \frac{\hat{\mathbf{z}} \times \mathbf{x}}{r} \left(\frac{1}{r-z} - \frac{1}{r+z} \right) = \hbar q \frac{(x\hat{\mathbf{y}} - y\hat{\mathbf{x}})z}{r(x^2 + y^2)}. \quad (14.205)$$

The coupling constants are $q \equiv -(e_1 g_2 - e_2 g_1)/\hbar c$ and $e^2 \equiv -(e_1 e_2 + g_1 g_2)$. The vector potential (14.205) is a generalization of the magnetic monopole interaction (8.300) with an electric charge. If we take the coupling as and $e^2 \equiv -e_1 e_2 - g_1 g_2$ in (14.205) we allow for the two particles to carry both electric and magnetic charges of the two particles, if we take for $V(\mathbf{x})$ the potential

$$V(\mathbf{x}) = -\frac{e^2}{r}. \quad (14.206)$$

The hydrogen atom is a special case of the dionium atom with $e_1 = -e_2 = e$ and $g = 0, l_0 = 0$. An electron around a pure magnetic monopole has $e_1 = e, g_2 = g, e_2 = g_1 = 0$.

In the vector potential (14.205) we have made use of the gauge freedom $\mathbf{A} \rightarrow \mathbf{A}(\mathbf{x}) + \nabla\Lambda(\mathbf{x})$ to enforce the transverse gauge $\nabla\mathbf{A}(\mathbf{x}) = 0$. In addition, we have taken advantage of the extra *monopole gauge invariance* which allows us to choose the shape of the Dirac string that imports the magnetic flux to the monopoles. The field $\mathbf{A}(\mathbf{x})$ in (14.205) has two strings of equal strength importing the flux, one along the positive x^3 -axis from minus infinity to the origin, the other along the negative x^3 -axis from plus infinity to the origin. It is the average of the vector potentials (10A.59) and (10A.60).

For the sake of generality, we shall assume the potential $V(\mathbf{x})$ to contain an extra $1/r^2$ -potential:

$$V(\mathbf{x}) = -\frac{e^2}{r} + \frac{\hbar^2 l_0^2}{2Mr^2}. \quad (14.207)$$

The extra potential is parametrized as a centrifugal barrier with an effective angular momentum $\hbar l_0$.

At the formal level, i.e., without worrying about path collapse and time slicing corrections, the amplitude has been derived in Ref. [13]. Here we reproduce the derivation and demonstrate, in addition, that the time slicing produces no corrections.

14.6.1 Formal Solution

We extend the action of the type (14.11) by a dummy fourth coordinate as in the Coulomb system and go over to \vec{u} -coordinates depending on the radial coordinate $u = \sqrt{r}$ and the Euler angles θ, φ, γ as given in Eq. (13.102). Then the action reads

$$\mathcal{A} = \int dt \left\{ \frac{M}{2} 4u^2 \dot{u}^2 + \frac{M}{2} u^4 \left[\dot{\theta}^2 + \dot{\varphi}^2 + \dot{\gamma}^2 + 2 \left(\dot{\gamma} + \frac{\hbar q}{Mu^4} \right) \dot{\varphi} \cos \theta \right] - \frac{e^2}{u^2} - \frac{\hbar^2 l_0^2}{2Mu^4} + E \right\}. \quad (14.208)$$

By performing the Duru-Kleinert time reparametrization $dt = ds r(s)$ and changing the mass to $\mu = 4M$, the action takes the form

$$\mathcal{A}^{\text{DK}} = \int_0^S ds \frac{\mu}{2} \left\{ u'^2 + \frac{u^2}{4} \left[\theta'^2 + \varphi'^2 + \gamma'^2 + 2 \left(\gamma' + \frac{4\hbar q}{\mu u^2} \right) \varphi' \cos \theta \right] - \frac{4\hbar^2 l_0^2}{2\mu u^2} + Eu^2 \right\}. \quad (14.209)$$

This can be rewritten in a canonical form

$$\mathcal{A} = \int_0^S ds (p_u u' + p_\theta \theta' + p_\varphi \varphi' + p_\gamma \gamma' - H), \quad (14.210)$$

with the Hamiltonian

$$\begin{aligned} H &= \frac{1}{2\mu} \left\{ p_u^2 + \frac{4}{u^2} \left[p_\theta^2 + \frac{1}{\sin^2 \theta} \left(p_\varphi^2 + (p_\gamma + \hbar q)^2 - 2(p_\gamma + \hbar q)p_\varphi \cos \theta \right) \right] \right\} \\ &+ \frac{4}{2\mu u^2} \left[-2\hbar q p_\gamma + \hbar^2 (l_0^2 - q^2) \right]. \end{aligned} \quad (14.211)$$

In the canonical path integral, the momenta are dummy integration variables so that we can replace $p_\gamma + \hbar q$ by p_γ . Then the action becomes

$$\mathcal{A} = \int_0^S ds [p_u u' + p_\theta \theta' + p_\varphi \varphi' + (p_\gamma - \hbar q) \gamma' - \bar{H}], \quad (14.212)$$

with the Hamiltonian

$$\begin{aligned} \bar{H} &= \frac{1}{2\mu} \left\{ p_u^2 + \frac{4}{u^2} \left[p_\theta^2 + \frac{1}{\sin^2 \theta} \left(p_\varphi^2 + p_\gamma^2 - 2p_\gamma p_\varphi \cos \theta \right) \right] \right\} \\ &+ \frac{4}{2\mu u^2} \left[-2\hbar q (p_\gamma - \hbar q) + \hbar^2 (l_0^2 - q^2) \right]. \end{aligned} \quad (14.213)$$

This differs from the pure Coulomb case in three ways:

First, the Hamiltonian has an extra centrifugal barrier proportional to the charge parameter $4q$:

$$V(r) = \frac{-8\hbar q (p_\gamma - \hbar q)}{2\mu u^2}. \quad (14.214)$$

Second, there is an extra centrifugal barrier

$$V(r) = \frac{\hbar^2 l_{\text{extra}}^2}{2\mu u^2}, \quad (14.215)$$

whose effective quantum number of angular momentum is given by

$$l_{\text{extra}}^2 \equiv 4(l_0^2 - q^2). \quad (14.216)$$

Third, the action (14.212) contains an additional term

$$\Delta\mathcal{A} = -\hbar q \int_0^S ds \gamma'. \quad (14.217)$$

Fortunately, this is a pure surface term

$$\Delta\mathcal{A} = -\hbar q(\gamma_b - \gamma_a). \quad (14.218)$$

In the case $q^2 = l_0^2$, the extra centrifugal barrier vanishes, making it straightforward to write down the fixed-energy amplitude $(\mathbf{x}_b|\mathbf{x}_a)_E$ of the system. It is given by a simple modification of the relation (13.127) that expresses the fixed-energy amplitude of the Coulomb system $(\mathbf{x}_b|\mathbf{x}_a)_E$ in terms of the four-dimensional harmonic oscillator amplitude $(\vec{u}_b S|\vec{u}_a 0)$. Due to (14.217), the modification consists of a simple extra phase factor $e^{-iq(\gamma_b - \gamma_a)}$ in the integral over γ_a so that

$$(\mathbf{x}_b|\mathbf{x}_a)_E = \int_0^\infty dS e^{ie^2 S/\hbar} \frac{1}{16} \int_0^{4\pi} d\gamma_a e^{-iq(\gamma_a - \gamma_b)} (\vec{u}_b S|\vec{u}_a 0). \quad (14.219)$$

The integral over γ_a forces the momentum p_γ in the canonical action (14.212) to take the value $\hbar q$. This eliminates the term proportional to $p_\gamma - \hbar$ in (14.213).

In the general case $l_0 \neq q$, the amplitude becomes

$$(\mathbf{x}_b|\mathbf{x}_a)_E = \int_0^\infty dS e^{ie^2 S/\hbar} \frac{1}{16} \int_0^{4\pi} d\gamma_a e^{-iq(\gamma_a - \gamma_b)} (\vec{u}_b S|\vec{u}_a 0)_{l_{\text{extra}}}, \quad (14.220)$$

where the subscript l_{extra} indicates the presence of the extra centrifugal barrier potential in the harmonic oscillator amplitude. This amplitude was given for any dimension D in Eqs. (8.133) with (8.144). In the present case of $D = 4$, it has the partial-wave expansion [compare (8.162)]

$$\begin{aligned} (\vec{u}_b S|\vec{u}_a 0)_{l_{\text{extra}}} &= \frac{1}{(u_b u_a)^{3/2}} \sum_{l_{\mathcal{C}}=0}^{\infty} (u_b S|u_a 0)_{\tilde{l}_{\mathcal{C}}} \frac{l_{\mathcal{C}} + 1}{2\pi^2} \\ &\times \sum_{m_1, m_2 = -l_{\mathcal{C}}/2}^{l_{\mathcal{C}}/2} d_{m_1 m_2}^{l_{\mathcal{C}}/2}(\theta_b) d_{m_1 m_2}^{l_{\mathcal{C}}/2}(\theta_a) e^{im_1(\varphi_b - \varphi_a) + im_2(\gamma_b - \gamma_a)}, \end{aligned} \quad (14.221)$$

with the radial amplitude

$$(u_b S|u_a 0)_{\tilde{l}_{\mathcal{C}}} = \frac{M_{\mathcal{O}} \omega \sqrt{u_b u_a}}{i\hbar \sin \omega S} e^{i(M_{\mathcal{O}} \omega / 2\hbar)(u_b^2 + u_a^2) \cot \omega S} I_{\tilde{l}_{\mathcal{C}}+1} \left(\frac{M_{\mathcal{O}} \omega u_b u_a}{i\hbar \sin \omega S} \right). \quad (14.222)$$

This differs from the pure oscillator amplitude [compare (8.142) for $D = 4$] by having the index $l_{\mathcal{C}} + 1$ of the Bessel function replaced by the square root of the “shifted square” as in (8.146):

ref(8.146)

lab(x8.146)

est(8.146)

$$\tilde{l}_{\mathcal{C}} + 1 \equiv \sqrt{(l_{\mathcal{C}} + 1)^2 + l_{\text{extra}}^2} = \sqrt{(l_{\mathcal{C}} + 1)^2 + 4(l_0^2 - q^2)} = 2\sqrt{(j_{\mathcal{D}} + 1/2)^2 + l_0^2 - q^2}. \quad (14.223)$$

The expansion (14.221) is inserted into (14.220) with the variables u_b, u_a replaced by $\sqrt{r_b}, \sqrt{r_a}$. Just as in the Coulomb case in (14.110) and (14.111), the integral $\int_0^{4\pi} d\gamma_a e^{-iq(\gamma_b - \gamma_a)}$ over the sum of angular wave functions

$$\frac{l_{\mathcal{O}} + 1}{2\pi^2} \sum_{m_1, m_2 = -l/2}^{l_{\mathcal{O}}/2} d_{m_1 m_2}^{l_{\mathcal{O}}/2}(\theta_b) d_{m_1 m_2}^{l_{\mathcal{O}}/2}(\theta_a) e^{im_1(\varphi_b - \varphi_a) + im_2(\gamma_b - \gamma_a)} \quad (14.224)$$

can immediately be done, resulting in

$$8 \sum_m^{l_{\mathcal{O}}/2} Y_{m,q}^{l_{\mathcal{O}}/2}(\theta_b, \varphi_b) Y_{m,q}^{l_{\mathcal{O}}/2*}(\theta_a, \varphi_a), \quad (14.225)$$

where $Y_{m,q}^{l_{\mathcal{O}}/2}(\theta, \varphi)$ are the monopole spherical harmonics (8.278). They coincide with the wave functions of a spinning symmetric top which possesses a spin q along the body axis. Physically, this spin is caused by the field's momentum density $\boldsymbol{\pi} = (\mathbf{E} \times \mathbf{B})/4\pi c$ encircling the radial distance vector \mathbf{x} . The *Poynting* vector yielding the energy density is $\mathbf{S} = \mathbf{E} \times \mathbf{B}/4\pi$. If a magnetically charged particle lies at the origin and electrically charged particle orbits around it at \mathbf{x} , the total angular momentum carried by the fields is [14]

$$\mathbf{J} = \int d^3x' \mathbf{x}' \times \boldsymbol{\pi}(\mathbf{x}') = \frac{1}{4\pi c} \int d^3x' \mathbf{x}' \times \left[\frac{g \mathbf{x}'}{|\mathbf{x}'|^3} \times \frac{e(\mathbf{x}' - \mathbf{x})}{|\mathbf{x}' - \mathbf{x}|^3} \right] = \frac{eg}{c} \hat{\mathbf{x}}. \quad (14.226)$$

The quantization of the angular momentum

$$\frac{eg}{c} = n \frac{\hbar}{2}, \quad n = \text{integer} \quad (14.227)$$

is Dirac's famous charge quantization condition [16] [see also Eq. (8.304)].

Thus we arrive at the fixed-energy amplitude of the dionium atom, labeled by the subscript \mathcal{D} ,

$$(\mathbf{x}_b | \mathbf{x}_a)_{E_{\mathcal{D}}} = \frac{1}{r_b r_a} \sum_{j_{\mathcal{D}}} (r_b | r_a)_{E_{\mathcal{D}}, j_{\mathcal{D}}} \sum_{m=-j_{\mathcal{D}}}^{j_{\mathcal{D}}} Y_{m,q}^{j_{\mathcal{D}}}(\theta_b, \varphi_b) Y_{m,q}^{j_{\mathcal{D}}*}(\theta_a, \varphi_a), \quad (14.228)$$

where the sum over $j_{\mathcal{D}} = l_{\mathcal{O}}/2$ runs over integer or half-integer values depending on q , and with the radial amplitude given by the pseudotime integral over the radial oscillator amplitude of mass $M_{\mathcal{O}} = 4M$ and frequency $\omega = \sqrt{-E/2M_{\mathcal{O}}}$ [recall (13.123)]:

$$(r_b | r_a)_{E_{\mathcal{D}}, j_{\mathcal{D}}} = \frac{1}{2} \int_0^{\infty} dS e^{ie^2 S/\hbar} \frac{M_{\mathcal{O}} \omega \sqrt{r_b r_a}}{i\hbar \sin \omega S} I_{l_{\mathcal{O}}+1} \left(\frac{M_{\mathcal{O}} \omega \sqrt{r_b r_a}}{i\hbar \sin \omega S} \right) \times \exp \left[\frac{iM_{\mathcal{O}} \omega}{2\hbar} (r_b + r_a) \cot \omega S \right], \quad (14.229)$$

where $\kappa = \sqrt{-2ME_{\mathcal{D}}/\hbar^2}$ and $\nu = \sqrt{-e^4 M/2\hbar^2 E_{\mathcal{D}}}$ as in (13.39) and (13.40). Note that the dionium atom can be a fermion, even if the constituent particles are both bosons (or both fermions).

After the variable changes $e^2/\hbar = 2\omega\nu$, $\omega S = -iy$, we do the S -integral as in (9.29) and find for $r_b > r_a$ the radial amplitude of the dionium atom

$$(r_b|r_a)_{E_{\mathcal{D}},j_{\mathcal{D}}} = -i \frac{M \Gamma(-\nu + \tilde{j}_{\mathcal{D}} + 1)}{\hbar \kappa (2\tilde{j}_{\mathcal{D}} + 1)!} W_{\nu, \tilde{j}_{\mathcal{D}}+1/2}(2\kappa r_b) M_{\nu, \tilde{j}_{\mathcal{D}}+1/2}(2\kappa r_a), \quad (14.230)$$

where $\tilde{j}_{\mathcal{D}} = \tilde{l}_{\mathcal{O}}/2 = \sqrt{(j_{\mathcal{D}} + \frac{1}{2})^2 + l_0^2 - q^2} - \frac{1}{2}$. For $q = 0$ and $l_0 = 0$, this reduces properly to the $D_{\mathcal{C}}$ -dimensional Coulomb amplitude (14.112).

The energy eigenvalues are obtained from the poles of the Gamma function at

$$\nu = \nu_{n_r} \equiv \tilde{j}_{\mathcal{D}} + n_r + 1, \quad n_r = 0, 1, 2, 3, \dots, \quad (14.231)$$

which yield

$$E_n = -M\hbar^2 e^4 \frac{1}{2 \left[n_r + \frac{1}{2} + \sqrt{(j_{\mathcal{D}} + \frac{1}{2})^2 + l_0^2 - q^2} \right]^2}. \quad (14.232)$$

From the residues at the poles and the discontinuity across the cut at $E_{\mathcal{D}} > 0$ in (14.230), we can extract the bound and continuum radial wave functions by the same method as in Section 13.8 from Eqs. (13.217)–(13.229).

14.6.2 Absence of Time Slicing Corrections

Let us now show that the above formal manipulations receive no correction in a proper time-sliced treatment [15]. Due to the presence of centrifugal and angular barriers, a path collapse can be avoided only after an appropriate regularization of both singularities. This is achieved by the path-dependent time transformation $dt = ds f(\mathbf{x}(s))$ with the postpoint regulating functions

$$f_l(\mathbf{x}) = f(\mathbf{x}) = r^2 \sin^2 \theta, \quad f_r(\mathbf{x}) \equiv 1. \quad (14.233)$$

After the extension of the path integral by an extra dummy dimension x^4 , the time-sliced time-transformed fixed-energy amplitude to be studied is [see (14.189)–(14.195)]

$$\begin{aligned} (\mathbf{x}_b|\mathbf{x}_a)_E &\approx \int dx_a^4 \frac{1}{r_a^2 \sin^2 \theta_a} \int_0^\infty dS \frac{1}{(2\pi i \hbar \epsilon_s / M)^2} \\ &\times \prod_{n=2}^{N+1} \left[\int \frac{d^4 \Delta x_n}{(2\pi i \hbar \epsilon_s / M)^2 r_n^4 \sin^4 \theta_n} \right] e^{i\mathcal{A}^N / \hbar}, \end{aligned} \quad (14.234)$$

with the sliced postpoint action

$$\mathcal{A}^N = \sum_{n=1}^{N+1} \left\{ \frac{M}{2\epsilon_s} \frac{(\Delta x_n^i)^2}{r_n^2 \sin^2 \theta_n} - \epsilon_s r_n^2 \sin^2 \theta_n [V(\mathbf{x}_n) - E] + A_i(\mathbf{x}_n) \Delta x^i - \epsilon_s \frac{\hbar}{2M} A_{i,i}(\mathbf{x}_n) \right\}. \quad (14.235)$$

On this action, we now perform the coordinate transformation in two steps. First we go through the nonholonomic Kustaanheimo-Stiefel transformation as in Section 13.4 and express the four-dimensional \vec{u} -space in terms of $r = |\mathbf{x}|$ and the Euler angles θ, φ, γ . Explicitly,

$$\begin{aligned} x^1 &= r \sin \theta \cos \varphi, \\ x^2 &= r \sin \theta \sin \varphi, \\ x^3 &= r \cos \theta, \\ dx^4 &= r \cos \theta d\varphi + rd\gamma. \end{aligned} \quad (14.236)$$

Only the last equation is nonholonomic. If $q^\mu = 1, 2, 3, 4$ denotes the components $r, \beta, \varphi, \gamma$, the transformation matrix reads

$$e^i{}_\mu = \frac{\partial x^i}{\partial q^\mu} = \begin{pmatrix} \sin \theta \cos \varphi & r \cos \theta \cos \varphi & -r \sin \theta \sin \varphi & 0 \\ \sin \theta \sin \varphi & r \cos \theta \sin \varphi & r \sin \theta \cos \varphi & 0 \\ \cos \theta & -r \sin \theta & 0 & 0 \\ 0 & 0 & r \cos \theta & r \end{pmatrix}.$$

It has the metric

$$g_{\mu\nu} = e^i{}_\mu e_{i\nu} = \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & r^2 & 0 & 0 \\ 0 & 0 & r^2 & r^2 \cos \theta \\ 0 & 0 & r^2 \cos \theta & r^2 \end{pmatrix}, \quad (14.237)$$

with an inverse

$$g^{\mu\nu} = \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & 1/r^2 & 0 & 0 \\ 0 & 0 & 1/r^2 \sin^2 \theta & -\cos \theta / r^2 \sin^2 \theta \\ 0 & 0 & -\cos \theta / r^2 \sin^2 \theta & 1/r^2 \sin^2 \theta \end{pmatrix}. \quad (14.238)$$

The regulating function $f(\mathbf{x}) = r^2 \sin^2 \theta$ removes the singularities in $g^{\mu\nu}$ and thus in the free part of the Hamiltonian $(1/2M)g^{\mu\nu}p_\mu p_\nu$; there is no more danger of path collapse in the Euclidean amplitude.

In a second step we go to new coordinates

$$r = e^\xi, \quad \sin \theta = 1/\cosh \beta, \quad \cos \theta = -\tanh \beta, \quad (14.239)$$

as in the treatment of the angular barriers for $D = 3$ and $D = 4$ in Section 14.4. With $q^\mu = 1, 2, 3, 4$ denoting the coordinates $\xi, \beta, \varphi, \gamma$, respectively, the combined transformation matrix reads

$$e^i{}_\mu = \begin{pmatrix} e^\xi \cosh^{-1} \beta \cos \varphi & -e^\xi \frac{\sinh \beta}{\cosh^2 \beta} \cos \varphi & -e^\xi \cosh^{-1} \beta \sin \varphi & 0 \\ e^\xi \cosh^{-1} \beta \sin \varphi & -e^\xi \frac{\sinh \beta}{\cosh^2 \beta} \sin \varphi & e^\xi \cosh^{-1} \beta \cos \varphi & 0 \\ -e^\xi \tanh \beta & -e^\xi \cosh^{-2} \beta & 0 & 0 \\ 0 & 0 & -e^\xi \tanh \beta & e^\xi \end{pmatrix}, \quad (14.240)$$

with the metric

$$g_{\mu\nu} = \begin{pmatrix} e^{2\xi} & 0 & 0 & 0 \\ 0 & e^{2\xi} \cosh^{-2} \beta & 0 & 0 \\ 0 & 0 & e^{2\xi} & -e^{2\xi} \tanh \beta \\ 0 & 0 & -e^{2\xi} \tanh \beta & e^{2\xi} \end{pmatrix}, \quad (14.241)$$

and the determinant

$$g = e^{8\xi} / \cosh^4 \beta. \quad (14.242)$$

The inverse metric is completely regular:

$$g^{\mu\nu} = \begin{pmatrix} e^{-2\xi} & 0 & 0 & 0 \\ 0 & e^{-2\xi} \cosh^2 \beta & 0 & 0 \\ 0 & 0 & e^{-2\xi} \cosh^2 \beta & e^{-2\xi} \sinh \beta \cosh \beta \\ 0 & 0 & e^{-2\xi} \sinh \beta \cosh \beta & e^{-2\xi} \cosh^2 \beta \end{pmatrix}. \quad (14.243)$$

We now calculate the transformed actions (14.201) and (14.202). The relevant quantities which could contain time slicing corrections are $D_\mu A^\mu$ and $\Gamma_\mu{}^{\mu\nu}$. The former quantity, being equal to

$\partial_i A_i$, vanishes in the transverse gauge under consideration. The calculation of $\Gamma_{\mu}^{\mu\nu}$ is somewhat tedious (see Appendix 14B) but yields a surprisingly simple result:

$$\Gamma_{\mu}^{\mu\nu} = (-1, 0, 0, 0). \quad (14.244)$$

Because of this simplicity, the transformed sliced action is easily written down. It is split into two parts,

$$\mathcal{A}_{\text{tot}}^\epsilon = \mathcal{A}_{\varphi\beta}^\epsilon + \mathcal{A}_{\varphi\gamma}^\epsilon, \quad (14.245)$$

one containing only the coordinates ξ, β ,

$$\begin{aligned} \mathcal{A}_{\xi\beta}^\epsilon = & \frac{M}{2\epsilon_s} [(\Delta\xi)_n^2 \cosh^2 \beta_n + (\Delta\beta_n)^2] + \frac{i\hbar}{2} \Delta\xi_n \\ & - \epsilon_s \left[-\frac{e^2 e^{\xi_n}}{\cosh^2 \beta_n} + \frac{\hbar^2 (l_{\text{extra}}^2 + 1/4)}{2M \cosh^2 \beta_n} - \frac{E e^{2\xi_n}}{\cosh^2 \beta_n} \right], \end{aligned} \quad (14.246)$$

the other dealing predominantly with φ, γ ,

$$\begin{aligned} \mathcal{A}_{\varphi\gamma}^\epsilon = & \frac{M \cosh^2 \beta_n}{2\epsilon_s} [(\Delta\varphi_n)^2 + (\Delta\gamma_n)^2 - 2\Delta\gamma_n \Delta\varphi_n \tanh \beta_n] \\ & + \hbar q \tanh \beta_n \Delta\varphi_n - \epsilon_s \frac{\hbar^2 q^2}{2M \cosh^2 \beta_n}. \end{aligned} \quad (14.247)$$

Hence the fixed-energy amplitude becomes

$$\begin{aligned} (\mathbf{x}_b | \mathbf{x}_a)_E \approx & \int_0^\infty dS \int_0^{4\pi} d\gamma_a \frac{1}{2\pi i \hbar \epsilon_s r_a^2 / M \cosh \beta_a} \prod_{n=1}^N \left[\int \frac{dr_n d\beta_n}{2\pi i \hbar \epsilon_s / M \cosh^2 \beta_{n+1}} \right] \\ & \times \exp \left(\frac{i}{\hbar} \sum_{n=1}^{N+1} \mathcal{A}_{\xi\beta}^\epsilon \right) (\varphi_b \gamma_b S | \varphi_a \gamma_a 0)_{[\beta]}. \end{aligned} \quad (14.248)$$

The last factor is a pseudotime evolution amplitude in the angles φ, γ which is still a functional of $\beta(t)$, as indicated by the subscript $[\beta]$,

$$\begin{aligned} (\varphi_b \gamma_b S | \varphi_a \gamma_a 0)_{[\beta]} \approx & \sum_{\varphi_{N+1} = \varphi_b + 2\pi l_b^\varphi} \sum_{\gamma_{N+1} = \gamma_b + 4\pi l_b^\gamma} \\ & \times \frac{1}{2\pi i \hbar \epsilon_s / M \cosh \beta_b} \prod_{n=1}^N \left[\int \frac{d\varphi_n d\gamma_n}{2\pi i \hbar \epsilon_s / M \cosh \beta_n} \right] \exp \left(\frac{i}{\hbar} \sum_{n=1}^{N+1} \mathcal{A}_{\varphi\gamma}^\epsilon \right). \end{aligned} \quad (14.249)$$

The sums over l_b^φ, l_b^γ account for the cyclic properties of the angles φ and γ with the periods 2π and 4π , respectively, at a fixed coordinate \mathbf{x}_b (as in the examples in Section 6.1).

We now introduce auxiliary momentum variables p_n^φ, p_n^γ and go over to the canonical form of the amplitude (14.249):

$$\begin{aligned} (\varphi_b \gamma_b S | \varphi_a \gamma_a 0)_{[\beta]} \approx & \prod_{n=1}^N \left[\int d\varphi_n \right] \prod_{n=1}^{N+1} \left[\int \frac{dp_n^\varphi}{2\pi\hbar} \right] \prod_{n=1}^N \left[\int d\gamma_n \right] \prod_{n=1}^{N+1} \left[\int \frac{dp_n^\gamma}{2\pi\hbar} \right] \\ & \times \exp \left[\frac{i}{\hbar} \sum_{n=1}^{N+1} \left(p_n^\varphi \Delta\varphi_n + p_n^\gamma \Delta\gamma_n \right. \right. \\ & \left. \left. - \frac{\epsilon_s}{2M} [(p_n^\varphi)^2 + (p_n^\gamma + \hbar q)^2 + 2p_n^\varphi (p_n^\gamma + \hbar q) \tanh \beta_n] + \epsilon_s \frac{p_n^\gamma \hbar q}{M \cosh^2 \beta_n} \right) \right]. \end{aligned} \quad (14.250)$$

The momenta p_n^γ are dummy integration variables and can be replaced by $p_n^\gamma - \hbar q$. The $d\varphi_n, d\gamma_n$ -integrals run over the full extended zone schemes $\varphi_n, \gamma_n \in (-\infty, \infty)$ and enforce the equality of all p_n^γ . At the end, only the integrals over a common single momentum p^φ, p^γ remain and we arrive at

$$\begin{aligned} & (\varphi_b \gamma_b S | \varphi_a \gamma_a 0)_{[\beta]} \tag{14.251} \\ & \approx e^{-iq(\gamma_b - \gamma_a)} \sum_{l_b^\varphi = -\infty}^{\infty} \sum_{l_b^\gamma = -\infty}^{\infty} \int \frac{dp_\varphi}{2\pi\hbar} \int \frac{dp_\gamma}{2\pi\hbar} e^{ip_\varphi(\varphi_b + 2\pi l_b^\varphi - \varphi_a)/\hbar} e^{ip_\gamma(\gamma_b + 4\pi l_b^\gamma - \gamma_a)/\hbar} \\ & \times \exp \left\{ -\frac{i}{\hbar} \sum_{n=1}^{N+1} \left[\frac{1}{2M\epsilon_s} (p_\varphi^2 + p_\gamma^2 + 2p_\varphi p_\gamma \tanh \beta_n) - \epsilon_s \frac{(p_\gamma - \hbar q)\hbar q}{M \cosh^2 \beta_n} \right] \right\}. \end{aligned}$$

We can now do the sums over l_b^φ, l_b^γ which force the momenta p_φ to integer values and p_γ to half-integer values by Poisson's formula, so that

$$\begin{aligned} & (\varphi_b \gamma_b S | \varphi_a \gamma_a 0)_{[\beta]} = e^{-iq(\gamma_b - \gamma_a)} \sum_{m_1, m_2} \frac{1}{2\pi} e^{im_1(\varphi_b - \varphi_a)} \frac{1}{4\pi} e^{im_2(\gamma_b - \gamma_a)} \tag{14.252} \\ & \times \exp \left\{ -\frac{i}{\hbar} \sum_{n=1}^{N+1} \left[\frac{\hbar^2}{2M\epsilon_s} (m_1^2 + m_2^2 + 2m_1 m_2 \tanh \beta_n) - \frac{\epsilon_s \hbar^2 (m_2 - q)q}{M \cosh^2 \beta_n} \right] \right\}. \end{aligned}$$

With this, the expression for the fixed-energy amplitude (14.248) of the dionium atom contains the magnetic charge only at three places: the extra centrifugal barrier in $\mathcal{A}_{\xi\beta}^\epsilon$, the phase factor of the remaining integral over γ_a , and the last term in (14.252). This last term, however, can be dropped since the integral over γ_a forces the half-integer number m_2 to become equal to $\hbar q$. The γ_b -integral over the remaining functional of $\beta(t)$ gives, incidentally,

$$\begin{aligned} & \int_0^{4\pi} d\gamma_a (\varphi_b \gamma_b S | \varphi_a \gamma_a 0)_{[\beta]} = \sum_{m_1} \frac{1}{2\pi} e^{im_1(\varphi_b - \varphi_a)} \\ & \times \exp \left\{ -\frac{i}{\hbar} \sum_{n=1}^{N+1} \left[\frac{\hbar^2}{2M\epsilon_s} [m_1^2 + q^2 + 2m_1 q \tanh \beta_n] \right] \right\}. \tag{14.253} \end{aligned}$$

The time-sliced expression has the parameter q at precisely the same places as the previous formal one. This proves that formula (14.220) with (14.221) is unchanged by time slicing corrections, thus completing the solution of the path integral of the dionium atom.

Note that after inserting (14.253), the time-sliced path integral (14.248) is a combination of a general Rosen-Morse system in β and a Morse system in ξ .

Let us end this discussion by the remark that like the Coulomb system, the dionium atom can be treated in a purely group-theoretic way, using only operations within the dynamical group $O(4,2)$. This is explained in Appendix 14C.

14.7 Time-Dependent Duru-Kleinert Transformation

By generalizing the above transformation method to time-dependent regulating functions, we can derive further relations between amplitudes of different physical systems. In the path-dependent time transformation $dt = ds f_l(\mathbf{x}) f_r(\mathbf{x})$ regularizing the path integrals, we may allow for functions $f_l(\mathbf{p}, \mathbf{x}, t)$ and $f_r(\mathbf{p}, \mathbf{x}, t)$ depending on positions, momenta, and time. Such functions complicate the subsequent transformation to new coordinates \mathbf{q} , in which the kinetic term of the amplitude (12.47) with respect to the pseudotime s has the standard form $(M/2)\mathbf{q}'^2(s)$. In particular,

a momentum dependence of f_l and f_r leads to involved formulas, which is the reason why this case has not yet been investigated (just like the even more general case where the right-hand side of the transformation $dt = ds f$ contains terms proportional to $d\mathbf{x}$). If one restricts the transformation to depend only on time and uses the special splitting with the regulating functions $f_l = f$ and $f_r = 1$, or $f_l = 1$ and $f_r = f$, the result in one spatial dimension is relatively simple. On the basis of Section 12.3, the following relation is found [instead of (14.26)] between the time evolution amplitude of an initial system and a fixed-energy amplitude of the transformed systems at $\mathcal{E} = 0$:

$$(x_b t_b | x_a t_a) = g(q_b, t_b) g(q_a, t_a) \{q_b t_b | q_a t_a\}_{\mathcal{E}=0}, \quad (14.254)$$

where $\{q_b t_b | q_a t_a\}_{\mathcal{E}=0}$ denotes the spacetime extension of the fixed-pseudoenergy amplitude. It is calculated by time-slicing the expression

$$\int_0^\infty dS \{x_b t_b | \hat{\mathcal{U}}_E(S) | x_a t_a\} \quad (14.255)$$

on the right-hand side of (12.55), transforming the coordinates x to q , and adapting the normalization to the completeness relation of the states

$$\int dx \int dt |q t\rangle \langle q t| = 1. \quad (14.256)$$

This leads to the path integral representation

$$\{q_b t_b | q_a t_a\}_{\mathcal{E}} = \int_0^\infty dS \int dE e^{-iE(t_b - t_a)/\hbar} \int \mathcal{D}q(s) e^{i\mathcal{A}_{E,\mathcal{E}}^{\text{DK}}/\hbar}, \quad (14.257)$$

with the DK-transformed action

$$\begin{aligned} \mathcal{A}_{E,\mathcal{E}}^{\text{DK}} = \int_0^S ds \left\{ \frac{M}{2} \dot{q}^2(s) - f(q(s), t(s)) [V(q(s), t) - E] + \mathcal{E} \right. \\ \left. - V_{\text{eff}}(q(s), t(s)) - \Delta V_{\text{eff}}(q(s), t(s)) \right\}. \end{aligned} \quad (14.258)$$

Note that the initial potential may depend explicitly on time. The function $t(s)$ is now given by the time-dependent differential equation

$$\frac{dt}{ds} = f(x, t). \quad (14.259)$$

The coordinate transformation also depends on time,

$$x = h(q, t), \quad (14.260)$$

and satisfies the equation

$$h'^2(q, t) = f(h(q, t), t), \quad (14.261)$$

where $h'(q, t) \equiv \partial_q h(q, t)$ [compare (14.15)]. The function $f(q(s), t(s))$ used in (14.258) is an abbreviation for $f(h(q, t), t)$ evaluated at the time $t = t(s)$.

In addition to the effective potential V_{eff} determined by Eq. (14.18), there is now a further contribution which is due to the time dependence of $h(q, t)$ [17]:

$$\Delta V_{\text{eff}} = Mh'^2 \int dq h' \ddot{h} \mp i\hbar \dot{h}' h'. \quad (14.262)$$

The upper sign must be used if the relation between t and s is calculated from the time-sliced postpoint recursion relation

$$t_{n+1} - t_n = \epsilon_s f(q_{n+1}, t_{n+1}). \quad (14.263)$$

The lower sign holds when solving the prepoint relation

$$t_{n+1} - t_n = \epsilon_s f(q_n, t_n). \quad (14.264)$$

Note that the first term of ΔV_{eff} contributes even at the classical level. If a function $h(q, t)$ is found satisfying Newton's equation of motion

$$M\ddot{h} = -\frac{\partial V(h, t)}{\partial h}, \quad (14.265)$$

with $V(h) \equiv V(x)|_{x=h}$, then the first term eliminates the potential in the action (14.258), and the transformed system is classically free. This happens if the new coordinate $q(t)$ associated with x, t is identified with the initial value, at some time t_0 , of the classical orbit running through x, t . These are trivially time-independent and therefore behave like the coordinates of a free particle (see the subsequent example).

The normalization factor $g(q, t)$ is determined by the differential equation

$$\frac{g'}{g} = \frac{1}{2} \frac{h''}{h'} + i \frac{M}{\hbar} h' \dot{h}. \quad (14.266)$$

The solution reads

$$g(q, t) = e^{i\Lambda(q, t)} \sqrt{h'(q, t)}, \quad (14.267)$$

with

$$\Lambda(q, t) = \pm \frac{M}{\hbar} \int^q dq h' \dot{h}. \quad (14.268)$$

Thus, in addition to the normalization factor in (14.26), the time-dependent DK relation (14.254) also contains a phase factor.

As an example [18], we transform the amplitude of a harmonic oscillator to that of a free particle. The classical orbits are given by $x(t) = x_0 \cos \omega t$, so that the transformation $x(t) = h(q, t) = q \cos \omega t$ leads to a coordinate $q(t)$ which moves without acceleration. For brevity, we write $\cos \omega t$ as $c(t)$. Obviously, $f(q, t) = c^2(t)$ is a pure function of the time [19], and the differential relation between the time t and the pseudotime s is integrated to

$$S = \frac{1}{\omega} \frac{\sin \omega(t_b - t_a)}{c(t_b)c(t_a)}. \quad (14.269)$$

This equation can be solved for $t_a(S)$ at fixed t_b , or for $t_b(S)$ at fixed t_a . The solution $t_a(S)$ is obtained from the time-sliced postpoint recursion relation (14.263), while $t_b(S)$ arises from the prepoint recursion (14.264). The DK action (14.258) is simplified in these two cases to

$$\mathcal{A}_{E,\mathcal{E}}^{\text{DK}} = \frac{M}{2} \frac{(q_b - q_a)^2}{S} \pm i\hbar \log \frac{c(t_b)}{c(t_a)} + E \left\{ \begin{array}{l} [t_b - t_a(S)] \\ [t_b(S) - t_a] \end{array} \right\} + \mathcal{E}S. \quad (14.270)$$

The E -integration in (14.257) yields in the first case

$$\{q_b t_b | q_a t_a\}_{\mathcal{E}} = \int_0^\infty dS \delta(t_b - t_a(S)) \frac{c(t_a)}{c(t_b)} \frac{e^{(i/\hbar)M(q_b - q_a)^2/2S}}{\sqrt{2\pi\hbar i S/M}}, \quad (14.271)$$

and the integration over S using $-dt_a(S)/dS = c^2(t_a)$ results in

$$\{q_b t_b | q_a t_a\}_{\mathcal{E}} = \frac{1}{c(t_b)c(t_a)} \frac{e^{(i/\hbar)M(q_b - q_a)^2/2S}}{\sqrt{2\pi\hbar i S/M}}. \quad (14.272)$$

The same amplitude is obtained for the lower sign in (14.270) with $dt_b(S)/dS = c^2(t_b)$. After inserting this together with (18.671) and (14.268) into (14.254) [the integration there gives $\Lambda(q, t) = (M/\hbar)q^2 c(t)\dot{c}(t)/2$], we obtain

$$(x_b t_b | x_a t_a) = e^{(i/\hbar)M[q_b^2 c(t_b)\dot{c}(t_b) - q_a^2 c(t_a)\dot{c}(t_a)]/2} \frac{1}{\sqrt{c(t_b)c(t_a)}} \frac{e^{(i/\hbar)M(q_b - q_a)^2/2S}}{\sqrt{2\pi\hbar i S/M}}. \quad (14.273)$$

Since q_b and q_a are equal to $x_b/c(t_b)$ and $x_a/c(t_a)$, respectively, a few trigonometric identities lead to the well-known expression (2.175) for the amplitude of the harmonic oscillator.

It is obvious that a combination of this transformation with a time-independent Duru-Kleinert transformation makes it possible to reduce also the path integral of the Coulomb system to that of a free particle.

It will be interesting to find out which hitherto unsolved path integrals can be integrated by means of such generalized DK transformations. Applications to statistical problems have been given in Ref. [21].

Appendix 14A Remarks on the DK Transformation of Time-Sliced Radial Coulomb Problem

Here we show that due to the catastrophic centrifugal barriers in the multiple integrals of a time-sliced formulation, the DK relation has to be used twice to transform the radial amplitude of the Coulomb problem to the radial harmonic oscillator. An intermediate Morse potential is needed to have no divergent integrals. The use of the DK transformation with the regulating function $f(r) = r$ and a pseudotime s satisfying $dt = dsr(s)$ (which were successful in two and three dimensions), removes the Coulomb singularity, but it weakens the centrifugal barrier insufficiently to a still catastrophic $1/r$ -singularity.

Let us exhibit the failure of this direct transformation. The starting point is the pseudotime-sliced amplitude (13.8),

$$\langle \mathbf{x}_b | \hat{\mathcal{U}}_E(s) | \mathbf{x}_a \rangle \approx \frac{r_b^\lambda r_a^{1-\lambda}}{\sqrt{2\pi\epsilon_s \hbar r^{1-\lambda} r^\lambda / M}^{D_C/2}} \prod_{n=1}^N \left[\int \frac{d^{D_C} \Delta x_n}{\sqrt{2\pi\epsilon_s \hbar r_n / M}^{D_C}} \right] e^{-\mathcal{A}_E^N / \hbar}, \quad (14A.1)$$

with the action

$$\mathcal{A}_E^N = -(N+1)\epsilon_s e^2 + \sum_{n=1}^{N+1} \left[\frac{M}{2\epsilon_s} \frac{(x_n - x_{n-1})^2}{r_n^{1-\lambda} r_{n-1}^\lambda} + \epsilon_s E r_n^{1-\lambda} r_{n-1}^\lambda \right]. \quad (14A.2)$$

In contrast to Chapter 13, we work here conveniently with an imaginary-time. In any dimension D_C , the amplitude has the angular decomposition

$$\langle \mathbf{x}_b | \hat{\mathcal{U}}_E(s) | \mathbf{x}_a \rangle = \frac{1}{(r_b r_a)^{D_C-1/2}} \sum \langle r_b | \hat{\mathcal{U}}_E(s) | r_a \rangle_l Y_{lm}(\hat{\mathbf{x}}_b) Y_{lm}^*(\hat{\mathbf{x}}_a). \quad (14A.3)$$

The action for the radial amplitude is obtained by decomposing

$$\mathcal{A}_E^N = -(N+1)\epsilon_s e^2 + \sum_{n=1}^{N+1} \left[\frac{M}{2\epsilon_s r_n^{1-\lambda} r_{n-1}^\lambda} (r_n^2 + r_{n-1}^2 - 2r_n r_{n-1} \cos \vartheta_n) + \epsilon_s E r_n \right], \quad (14A.4)$$

where ϑ_n is the angle between \mathbf{x}_n and \mathbf{x}_{n-1} . We have replaced $E r_n^{1-\lambda} r_{n-1}^\lambda$ by $E r_n$ since the difference is of order ϵ_s^2 and thus negligible.

We now go through the same steps as in Section 8.5. For an individual time slice, the ϑ_n -part of the exponential is expanded as

$$\exp\left(\frac{M}{\epsilon_s} r_n^\lambda r_{n-1}^{1-\lambda} \cos \vartheta_n\right) = e^h \sum_{l_c=0}^{\infty} \tilde{a}_{l_c}(h) \sum_{\mathbf{r}} Y_{l_c \mathbf{r}}(\hat{\mathbf{x}}_b) Y_{l_c \mathbf{r}}^*(\hat{\mathbf{x}}_a), \quad (14A.5)$$

with

$$a_{l_c}(h) = \left(\frac{2\pi}{h}\right)^{(D_C-1)/2} \tilde{I}_{D_C/2-1+l_c}(h), \quad h = \frac{M}{\hbar\epsilon_s} r_n^\lambda r_{n-1}^{1-\lambda} \quad (14A.6)$$

[recall (8.130) and (8.101)]: The radial part of the propagator is then

$$\langle r_b | \hat{\mathcal{U}}_E(s) | r_a \rangle_{l_c} \approx \frac{r_b^\lambda r_a^{1-\lambda}}{\sqrt{2\pi\hbar\epsilon_s r_b^{1-\lambda} r_a^\lambda / M}^{D_C/2}} \prod_{n=2}^{N+1} \left[\int \frac{d\Delta r_n r_{n-1}^{-1/2}}{\sqrt{2\pi\hbar\epsilon_s / M}} \right] e^{-\mathcal{A}_E^N / \hbar}, \quad (14A.7)$$

with the radial action

$$\mathcal{A}_E^N = -(N+1)\epsilon_s e^2 + \sum_{n=1}^{N+1} \left[\frac{M}{2\epsilon_s} \frac{(r_n - r_{n-1})^2}{r_n^{1-\lambda} r_{n-1}^\lambda} - \hbar \log \tilde{I}_{D_C/2-1+l_c} \left(\frac{M}{\hbar\epsilon_s} r_n^\lambda r_{n-1}^{1-\lambda} \right) - \epsilon_s E r_n \right]. \quad (14A.8)$$

At this place we simplify the calculation by choosing the symmetric splitting parameter $\lambda = 1/2$. Going over to square root coordinates

$$u_n = \sqrt{r_n}, \quad (14A.9)$$

we calculate

$$\begin{aligned} \Delta r_n &= (u_n + u_{n-1}) \Delta u_n, \\ &= 2u_n (1 - \Delta u_n / 2u_n) \Delta u_n, \\ \frac{\partial \Delta r_n}{\partial \Delta u_n} &= 2u_n (1 - \Delta u_n / u_n), \\ r_{n-1}^{-1/2} &= u_n^{-1} (1 - \Delta u_n / u_n)^{-1}, \end{aligned} \quad (14A.10)$$

transforming the measure of integration into

$$\frac{\sqrt{u_b u_a}}{\sqrt{2\pi\hbar\epsilon_s/M}} \prod_{n=1}^N \int \frac{d\Delta u_n}{\sqrt{2\pi\hbar\epsilon_s/M}}. \quad (14A.11)$$

Note that there are no higher Δu_n correction terms. The kinetic energy is

$$\frac{4\bar{u}_n^2(\Delta u_n)^2}{2\epsilon_s u_n u_{n-1}} = \frac{4}{2\epsilon_s} \left[(\Delta u_n)^2 + \frac{1}{4} \frac{(\Delta u_n)^4}{u_n^2} + \dots \right]. \quad (14A.12)$$

The $(\Delta u_n)^4$ -term can be replaced right away by its expectation value and renders an effective potential

$$V_{\text{eff}}(u_n^2) = \epsilon_s \hbar^2 \frac{1}{2 \cdot 4M} \frac{3}{4u_n^2}. \quad (14A.13)$$

The radial amplitude becomes simply

$$\langle r_b | \hat{\mathcal{U}}_E(s) | r_a \rangle_{l_C} \approx \frac{\sqrt{u_b u_a}}{\sqrt{2\pi\hbar\epsilon_s/M}} \prod_{n=2}^{N+1} \left[\int_0^\infty \frac{2du_n}{\sqrt{2\pi\hbar\epsilon_s/M}} \right] e^{-\mathcal{A}_E^N/\hbar}, \quad (14A.14)$$

with

$$\mathcal{A}_E^N = -(N+1)\epsilon_s + \sum_{n=1}^{N+1} \left[\frac{4M}{2} \frac{(\Delta u_n)^2}{2\epsilon_s} + V_{\text{eff}}(u_n^2) - \hbar \log \tilde{I}_{D_C/2-1+l_C} \left(\frac{M}{\hbar\epsilon_s} u_n u_{n-1} \right) \right]. \quad (14A.15)$$

Due to the $1/u_n^2$ -singularity in $V_{\text{eff}}(u_n^2)$, the time-sliced path integral does not exist. Apart from the ϵ_s/u_n^2 -term, there should be infinitely many terms of increasing order of the type $(\epsilon_s/u_n^2)^2, \dots$, whose resummation is needed to obtain the correct threshold small- u_n behavior of the amplitude as discussed in Section 8.2. To have the usual kinetic term of the harmonic oscillator $M_{\mathcal{O}}(\Delta u_n)^2/2\epsilon_s$, we must identify $4M$ with the oscillator mass $M_{\mathcal{O}}$ [called μ in (13.27); see also (14.99) with $M_{\mathcal{C}} \equiv M$],

$$M_{\mathcal{O}} = 4M. \quad (14A.16)$$

The centrifugal barrier in (14A.15) resides in

$$-\hbar \log \tilde{I}_{D_C/2-1+l_C} \left(\frac{M_{\mathcal{O}}/4}{\hbar\epsilon_s} u_n u_{n-1} \right) + \epsilon_s \hbar^2 \frac{3}{8M_{\mathcal{O}}u_n^2} + \dots, \quad (14A.17)$$

and is given by

$$\epsilon_s \frac{\hbar^2}{2M_{\mathcal{O}}} \frac{4}{u_n u_{n-1}} \left[\left(\frac{D_C}{2} - 1 + l_C \right)^2 - \frac{1}{4} \right] + \epsilon_s \hbar^2 \frac{3}{8M_{\mathcal{O}}u_n^2} + \dots. \quad (14A.18)$$

This can be rewritten more explicitly as

$$\epsilon_s \frac{\hbar}{2M_{\mathcal{O}}} \frac{1}{u_n u_{n-1}} \left[(D_C - 2 + 2l_C)^2 - \frac{1}{4} \right]. \quad (14A.19)$$

The expression in parentheses is identified with the parameter $\mu_{\mathcal{O}}$ of the harmonic oscillator, which appears in the subscript of the Bessel function in (8.140). This implies

$$\mu_{\mathcal{O}} = 2\mu_{\mathcal{C}}, \quad (14A.20)$$

in agreement with the relation (14.100). Indeed, the higher terms in the expansion (14A.18) must all conspire to sum up to the Bessel-regulated centrifugal barrier in the time-sliced radial amplitude of the harmonic oscillator

$$-\hbar \log \tilde{I}_{D_C-2+2l_C} \left(\frac{M_C}{\hbar \epsilon_s} u_n u_{n-1} \right). \quad (14A.21)$$

This is quite hard to verify term by term, although it must happen.

These difficulties are avoided by using the stronger regulating function $f = r^2$, which transform the radial Coulomb problem to the Morse problem. Instead of the pseudotime evolution amplitude (14A.1), we have

$$\langle \mathbf{x}_E | \hat{U}_e(s) | \mathbf{x}_a \rangle \approx \frac{r_b^2 r_a^{2-2\lambda}}{\sqrt{2\pi \epsilon_s \hbar r_b^{2-2\lambda} r_a^{2\lambda} / M}}^{D_C/2} \prod_{n=1}^N \left[\int \frac{d^{D_C} \Delta x_n}{\sqrt{2\pi \epsilon_s \hbar r_n^2 / M}^{D_C}} \right] e^{-\mathcal{A}_E^{fN} / \hbar}, \quad (14A.22)$$

with the time-sliced transformed action

$$\mathcal{A}_E^{fN} = -(N+1)\epsilon_s e^2 + \sum_{n=1}^{N+1} \left[\frac{M}{2\epsilon_s r_n^{2-2\lambda} r_{n-1}^{2\lambda}} (r_n^2 + r_{n-1}^2 - 2r_n r_{n-1} \cos \vartheta_n) - \epsilon_s E r_n^2 \right]. \quad (14A.23)$$

For $\lambda = 1/2$, the $\cos \Delta \vartheta_n$ -term is now free of the radial variables $r_n, r_{n-1}, r_n, r_{n-1}$, and the angular decomposition of the amplitude as in (14A.3)–(14A.8) gives the radial amplitude with a time-sliced action

$$\mathcal{A}_E^{fN} = -(N+1)\epsilon_s e^2 + \sum_{n=1}^{N+1} \left[\frac{M}{2\epsilon_s} \frac{(r_n - r_{n-1})^2}{r_n r_{n-1}} - \hbar \log \tilde{I}_{D_C/2-1+l_C} \left(\frac{M}{\hbar \epsilon_s} \right) - \epsilon_s E r_n^2 \right]. \quad (14A.24)$$

Since r_n, r_{n-1} are absent in the Bessel function, the limit of small ϵ_s is now uniform in the integration variables r_n and the logarithmic term in the energy can directly be replaced by

$$\epsilon_s \frac{\hbar}{2M_C} \left[(D_C/2 - 1 + l_C)^2 - 1/4 \right], \quad (14A.25)$$

where we have added the subscripts \mathcal{C} , for clarity. To perform the integration over the r_n variables, one goes over to new coordinates x with

$$r = h(x) = e^x. \quad (14A.26)$$

The measure of integration is

$$\frac{\sqrt{r_b r_a}}{\sqrt{2\pi \hbar \epsilon_s / M}^{N+1}} \prod_{n=2}^{N+1} \int \frac{d\Delta r_n}{r_{n-1}}. \quad (14A.27)$$

Expanding $1/r_{n-1}$ around the postpoint r_n gives

$$\frac{1}{r_{n-1}} = \frac{1}{r_n} \left(\frac{r_n}{r_{n-1}} \right) = \frac{e^{\Delta x_n}}{e^{x_n}}. \quad (14A.28)$$

We now write (dropping subscripts n)

$$\Delta r = e^x - e^{x-\Delta x} = e^x (1 - e^{-\Delta x}), \quad (14A.29)$$

and find the Jacobian

$$\frac{\partial \Delta r}{\partial \Delta x} = e^x e^{-\Delta x}. \quad (14A.30)$$

In the x -coordinates, the measure becomes simply

$$\frac{e^{(x_b+x_a)/2}}{\sqrt{2\pi\hbar\epsilon_s/M}^{N+1}} \prod_{n=2}^{N+1} \int d\Delta x_n. \quad (14A.31)$$

The kinetic term in the action turns into

$$\mathcal{A}_E^N = \sum_{n=1}^{N+1} \frac{M}{\epsilon_s} (1 - \cos \Delta x_n), \quad (14A.32)$$

and has the expansions

$$\mathcal{A}_E^N = \sum_{n=1}^{N+1} \frac{M}{2\epsilon_s} \left[(\Delta x)^2 - \frac{1}{12} (\Delta x_n)^4 + \dots \right]. \quad (14A.33)$$

The higher-order terms contribute with higher powers of ϵ_s *uniformly* in x . They can be treated as usual. This is why the path-dependent time transformation of the radial Coulomb system to a radial oscillator with the regulating function $f = r^2$ is free of problems.

Appendix 14B Affine Connection of Dionium Atom

From the transformation matrices (14.240), we calculate the derivatives [setting $q^\mu = (\xi, \beta, \varphi, \gamma)$ and using the abbreviation $f_{,\xi} \equiv \partial_\xi f$]

$$e^i_{\mu,\xi} = e^i_{\mu}, \quad (14B.1)$$

$$e^i_{\mu,\beta} = \begin{pmatrix} -e^\xi \frac{\sinh \beta}{\cosh^2 \beta} \cos \phi & -e^\xi \frac{1 - \sinh^2 \beta}{\cosh^3 \beta} \cos \phi & e^\xi \frac{\sinh \beta}{\cosh^2 \beta} \sin \phi & 0 \\ -e^\xi \frac{\sinh \beta}{\cosh^2 \beta} \sin \phi & -e^\xi \frac{1 - \sinh^2 \beta}{\cosh^3 \beta} \sin \phi & -e^\xi \frac{\sinh \beta}{\cosh^2 \beta} \cos \phi & 0 \\ -e^\xi \cosh^{-2} \beta & 2e^\xi \frac{\sinh \beta}{\cosh^3 \beta} & 0 & 0 \\ 0 & 0 & -e^\xi \cosh^{-2} \beta & 0 \end{pmatrix}, \quad (14B.2)$$

$$e^i_{\mu,\phi} = \begin{pmatrix} -e^\xi \cosh^{-1} \beta \sin \phi & e^\xi \frac{\sinh \beta}{\cosh^2 \beta} \sin \phi & -e^\xi \cosh^{-1} \beta \cos \phi & 0 \\ e^\xi \cosh^{-1} \beta \cos \phi & -e^\xi \frac{\sinh \beta}{\cosh^2 \beta} \cos \phi & -e^\xi \cosh^{-1} \beta \sin \phi & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{pmatrix}, \quad (14B.3)$$

$$e^i_{\mu,\alpha} = 0. \quad (14B.4)$$

From these we find $\Gamma_{\mu\nu\lambda} = e^i_\lambda e^i_{\nu,\mu}$ by contraction with e^i_λ :

$$\Gamma_{\xi\mu\nu} = g_{\mu\nu}, \quad (14B.5)$$

$$\Gamma_{\beta\mu\nu} = \begin{pmatrix} 0 & e^{2\xi} \cosh^{-2} \beta & 0 & 0 \\ -e^{2\xi} \cosh^{-2} & -e^{2\xi} \frac{\sinh \beta}{\cosh^3 \beta} & 0 & 0 \\ 0 & 0 & 0 & -e^{2\xi} \cosh^{-2} \beta \\ 0 & 0 & 0 & 0 \end{pmatrix}, \quad (14B.6)$$

$$\Gamma_{\phi\mu\nu} = \begin{pmatrix} 0 & 0 & e^{2\xi} \cosh^{-2} \beta & 0 \\ 0 & 0 & -e^{2\xi} \frac{\sinh \beta}{\cosh^3 \beta} & 0 \\ -e^{2\xi} \cosh^{-2} & e^{2\xi} \frac{\sinh \beta}{\cosh^3 \beta} & 0 & 0 \\ 0 & 0 & 0 & 0 \end{pmatrix}, \quad (14B.7)$$

$$\Gamma_{\alpha\mu\nu} = 0. \quad (14B.8)$$

A contraction with the inverse metric $g^{\mu\nu}$ yields $\Gamma_{\mu}{}^\mu{}_\nu = (-1, 0, 0, 0)$, as stated in Eq. (14.244).

Appendix 14C Algebraic Aspects of Dionium States

In Appendix 13A we have shown that certain combinations of x^μ and ∂_μ operators satisfy the commutation rules of the Lie algebra of the group $O(4,2)$ [see Eqs. (13A.11)]. This permits solving all dynamical problems via group operations. In the case $l_0 = q$ (i.e., $l_{\text{extra}} = 0$), the group-theoretic approach can be extended to include the dionium atom. In fact, it is easy to see [20] that the Lie algebra of $O(4,2)$ remains the same if the generators L_{AB} ($A, B = 1, \dots, 6$) of Eq. (13A.11) are extended to ($x^i \equiv x_i$)

$$\begin{aligned}
 \hat{L}_{ij} &= -\frac{i}{2}(x_i \partial_{x_j} - x_j \partial_{x_i}) + q \frac{r}{\mathbf{x}_\perp^2} x_\perp^k, \\
 \hat{L}_{i4} &= \frac{1}{2} \left[-x^i \partial_{\mathbf{x}}^2 - x^i + 2\partial_{x^i} \mathbf{x} \partial_{\mathbf{x}} + 2iq \frac{r}{\mathbf{x}_\perp^2} (\mathbf{x}_\perp \times \nabla)_i - (-)^{\delta_{i3}} q^2 \frac{x_i}{\mathbf{x}_\perp^2} \right], \\
 \hat{L}_{i5} &= \frac{1}{2} \left[-x^i \partial_{\mathbf{x}}^2 + x^i + 2\partial_{x^i} \mathbf{x} \partial_{\mathbf{x}} + 2iq \frac{r}{\mathbf{x}_\perp^2} (\mathbf{x}_\perp \times \nabla)_i - (-)^{\delta_{i3}} q^2 \frac{x_i}{\mathbf{x}_\perp^2} \right], \\
 \hat{L}_{i6} &= -ir \partial_{x^i} - \frac{q}{\mathbf{x}_\perp^2} (\mathbf{x} \times \mathbf{x}_\perp)_i, \\
 \hat{L}_{45} &= -i(\mathbf{x} \partial_{\mathbf{x}} + 1), \\
 \hat{L}_{46} &= \frac{1}{2} \left[-r \partial_{\mathbf{x}}^2 - r + 2iq \frac{z}{\mathbf{x}_\perp^2} (\mathbf{x} \times \nabla)_3 + q^2 \frac{r}{\mathbf{x}_\perp^2} \right], \\
 \hat{L}_{56} &= \frac{1}{2} \left[-r \partial_{\mathbf{x}}^2 + r + 2iq \frac{z}{\mathbf{x}_\perp^2} (\mathbf{x} \times \nabla)_3 + q^2 \frac{r}{\mathbf{x}_\perp^2} \right]. \tag{14C.1}
 \end{aligned}$$

The representation space is now characterized by the eigenvalue of the operator $\hat{L}_{05} = -ir \partial_{x^4} = -i \partial_\gamma = -\frac{1}{2}(\hat{a}^\dagger \hat{a} - \hat{b}^\dagger \hat{b})$ being equal to q . The wave functions are generalizations of the $q = 0$ -wave functions of the Coulomb system.

Path Integrals in Polymer Physics

The use of path integrals is not confined to the quantum-mechanical description point particles in spacetime. An important field of applications lies in polymer physics where they are an ideal tool for studying the statistical fluctuations of line-like physical objects.

15.1 Polymers and Ideal Random Chains

A polymer is a long chain of many identical molecules connected with each other at joints which allow for spatial rotations. A large class of polymers behaves approximately like an idealized *random chain*. This is defined as a chain of N links of a fixed length a , whose rotational angles occur all with equal probability (see Fig. 15.1). The probability distribution of the end-to-end distance vector $\mathbf{x}_b - \mathbf{x}_a$ of such an object is given by

$$P_N(\mathbf{x}_b - \mathbf{x}_a) = \prod_{n=1}^N \left[\int d^3\Delta\mathbf{x}_n \frac{1}{4\pi a^2} \delta(|\Delta\mathbf{x}_n| - a) \right] \delta^{(3)}(\mathbf{x}_b - \mathbf{x}_a - \sum_{n=1}^N \Delta\mathbf{x}_n). \quad (15.1)$$

The last δ -function makes sure that the vectors $\Delta\mathbf{x}_n$ of the chain elements add up correctly to the distance vector $\mathbf{x}_b - \mathbf{x}_a$. The δ -functions under the product enforce the fixed length of the chain elements. The length a is also called the *bond length* of the random chain.

The angular probabilities of the links are spherically symmetric. The factors $1/4\pi a^2$ ensure the proper normalization of the individual one-link probabilities

$$P_1(\Delta\mathbf{x}) = \frac{1}{4\pi a^2} \delta(|\Delta\mathbf{x}| - a) \quad (15.2)$$

in the integral

$$\int d^3x_b P_1(\mathbf{x}_b - \mathbf{x}_a) = 1. \quad (15.3)$$

The same normalization holds for each N :

$$\int d^3x_b P_N(\mathbf{x}_b - \mathbf{x}_a) = 1. \quad (15.4)$$

Figure 15.1 Random chain consisting of N links $\Delta \mathbf{x}_n$ of length a connecting $\mathbf{x}_a = \mathbf{x}_0$ and $\mathbf{x}_b = \mathbf{x}_N$.

If the second δ -function in (15.1) is Fourier-decomposed as

$$\delta^{(3)}\left(\mathbf{x}_b - \mathbf{x}_a - \sum_{n=1}^N \Delta \mathbf{x}_n\right) = \int \frac{d^3 k}{(2\pi)^3} e^{i\mathbf{k}(\mathbf{x}_b - \mathbf{x}_a) - i\mathbf{k} \sum_{n=1}^N \Delta \mathbf{x}_n}, \quad (15.5)$$

we see that $P_N(\mathbf{x}_b - \mathbf{x}_a)$ has the Fourier representation

$$P_N(\mathbf{x}_b - \mathbf{x}_a) = \int \frac{d^3 k}{(2\pi)^3} e^{i\mathbf{k}(\mathbf{x}_b - \mathbf{x}_a)} \tilde{P}_N(\mathbf{k}), \quad (15.6)$$

with

$$\tilde{P}_N(\mathbf{k}) = \prod_{n=1}^N \left[\int d^3 \Delta x_n \frac{1}{4\pi a^2} \delta(|\Delta \mathbf{x}_n| - a) e^{-i\mathbf{k} \Delta \mathbf{x}_n} \right]. \quad (15.7)$$

Thus, the Fourier transform $\tilde{P}_N(\mathbf{k})$ factorizes into a product of N Fourier-transformed one-link probabilities:

$$\tilde{P}_N(\mathbf{k}) = [\tilde{P}_1(\mathbf{k})]^N. \quad (15.8)$$

These are easily calculated:

$$\tilde{P}_1(\mathbf{k}) = \int d^3 \Delta \mathbf{x} \frac{1}{4\pi a^2} \delta(|\Delta \mathbf{x}| - a) e^{-i\mathbf{k} \Delta \mathbf{x}} = \frac{\sin ka}{ka}. \quad (15.9)$$

The desired end-to-end probability distribution is then given by the integral

$$\begin{aligned} P_N(\mathbf{R}) &= \int \frac{d^3 k}{(2\pi)^3} [\tilde{P}_1(\mathbf{k})]^N e^{i\mathbf{k} \mathbf{R}} \\ &= \frac{1}{2\pi^2 R} \int_0^\infty dk k \sin kR \left[\frac{\sin ka}{ka} \right]^N, \end{aligned} \quad (15.10)$$

where we have introduced the end-to-end distance vector

$$\mathbf{R} \equiv \mathbf{x}_b - \mathbf{x}_a. \quad (15.11)$$

The generalization of the one-link distribution to D dimensions is

$$P_1(\Delta\mathbf{x}) = \frac{1}{S_D a^{D-1}} \delta(|\Delta\mathbf{x}| - a), \quad (15.12)$$

with S_D being the surface of a unit sphere in D dimensions [see Eq. (1.558)].

To calculate

$$\tilde{P}_1(\mathbf{k}) = \int d^D \Delta\mathbf{x} \frac{1}{S_D a^{D-1}} \delta(|\Delta\mathbf{x}| - a) e^{-i\mathbf{k}\Delta\mathbf{x}}, \quad (15.13)$$

we insert for $e^{-i\mathbf{k}\Delta\mathbf{x}} = e^{-ik|\Delta\mathbf{x}|\cos\Delta\vartheta}$ the expansion (8.130) with (8.101), and use $Y_{0,0}(\hat{\mathbf{x}}) = 1/\sqrt{S_D}$ to perform the integral as in (8.250). Using the relation between modified and ordinary Bessel functions $J_\nu(z)$ ¹

$$I_\nu(e^{-i\pi/2}z) = e^{-i\pi/2} J_\nu(z), \quad (15.14)$$

this gives

$$\tilde{P}_1(\mathbf{k}) = \frac{\Gamma(D/2)}{(ka/2)^{D/2-1}} J_{D/2-1}(ka), \quad (15.15)$$

where $J_\mu(z)$ is the Bessel function.

15.2 Moments of End-to-End Distribution

The end-to-end distribution of a random chain is, of course, invariant under rotations so that the Fourier-transformed probability can only have even Taylor expansion coefficients:

$$\tilde{P}_N(\mathbf{k}) = [\tilde{P}_1(\mathbf{k})]^N = \sum_{l=0}^{\infty} P_{N,2l} \frac{(ka)^{2l}}{(2l)!}. \quad (15.16)$$

The expansion coefficients provide us with a direct measure for the even moments of the end-to-end distribution. These are defined by

$$\langle R^{2l} \rangle \equiv \int d^D R R^{2l} P_N(\mathbf{R}). \quad (15.17)$$

The relation between $\langle R^{2l} \rangle$ and $P_{N,2l}$ is found by expanding the exponential under the inverse of the Fourier integral (15.6):

$$\tilde{P}_N(\mathbf{k}) = \int d^D R e^{-i\mathbf{k}\mathbf{R}} P_N(\mathbf{R}) = \sum_{n=0}^{\infty} \int d^D R \frac{(-i\mathbf{k}\mathbf{R})^n}{n!} P_N(\mathbf{R}), \quad (15.18)$$

¹I.S. Gradshteyn and I.M. Ryzhik, *op. cit.*, Formula 8.406.1.

and observing that the angular average of $(\mathbf{kR})^n$ is related to the average of R^n in D dimensions by

$$\langle (\mathbf{kR})^n \rangle = k^n \langle R^n \rangle \begin{cases} 0, & n = \text{odd}, \\ \frac{(n-1)!!(D-2)!!}{(D+n-2)!!}, & n = \text{even}. \end{cases} \quad (15.19)$$

The three-dimensional result $1/(n+1)$ follows immediately from the angular average $(1/2) \int_{-1}^1 d\cos\theta \cos^n\theta$ being $1/(n+1)$ for even n . In D dimensions, it is most easily derived by assuming, for a moment, that the vectors \mathbf{R} have a Gaussian distribution $P_N^{(0)}(\mathbf{R}) = (D/2\pi Na^2)^{3/2} e^{-\mathbf{R}^2 D/2Na^2}$. Then the expectation values of all products of R_i can be expressed in terms of the pair expectation value

$$\langle R_i R_j \rangle^{(0)} = \frac{1}{D} \delta_{ij} a^2 N \quad (15.20)$$

via Wick's rule (3.305). The result is

$$\langle R_{i_1} R_{i_2} \cdots R_{i_n} \rangle^{(0)} = \frac{1}{D^{n/2}} \delta_{i_1 i_2 i_3 \dots i_n} a^n N^{n/2}, \quad (15.21)$$

with the contraction tensor $\delta_{i_1 i_2 i_3 \dots i_n}$ of Eqs. (8.64) and (13.89), which has the recursive definition

$$\delta_{i_1 i_2 i_3 \dots i_n} = \delta_{i_1 i_2} \delta_{i_3 i_4 \dots i_n} + \delta_{i_1 i_3} \delta_{i_2 i_4 \dots i_n} + \dots + \delta_{i_1 i_n} \delta_{i_2 i_3 \dots i_{n-1}}. \quad (15.22)$$

A full contraction of the indices gives, for even n , the Gaussian expectation values:

$$\langle R^n \rangle^{(0)} = \frac{(D+n-2)!!}{(D-2)!! D^{n/2}} a^n N^{n/2} = \frac{\Gamma(D/2 + n/2)}{\Gamma(D/2)} \frac{2^{n/2}}{D^{n/2}} a^n N^{n/2}, \quad (15.23)$$

for instance

$$\langle R^4 \rangle^{(0)} = \frac{(D+2)}{D} a^4 N^2, \quad \langle R^6 \rangle^{(0)} = \frac{(D+2)(D+4)}{D^2} a^6 N^3. \quad (15.24)$$

By contracting (15.21) with $k_{i_1} k_{i_2} \cdots k_{i_n}$ we find

$$\langle (\mathbf{kR})^n \rangle^{(0)} = (n-1)!! \frac{1}{D^{n/2}} (ka)^n N^{n/2} = k^n \langle (R)^n \rangle^{(0)} d_n, \quad (15.25)$$

with

$$d_n = \frac{(n-1)!!(D-2)!!}{(D+n-2)!!}. \quad (15.26)$$

Relation (15.25) holds for *any* rotation-invariant size distribution of \mathbf{R} , in particular for $P_N(\mathbf{R})$, thus proving Eq. (15.17) for random chains. Hence, the expansion coefficients $P_{N,2l}$ are related to the moments $\langle R^{2l} \rangle_N$ by

$$P_{N,2l} = (-1)^l d_{2l} \langle R^{2l} \rangle, \quad (15.27)$$

and the moment expansion (15.16) becomes

$$\tilde{P}_N(\mathbf{k}) = \sum_{l=0}^{\infty} \frac{(-1)^l (ka)^{2l}}{(2l)!} d_{2l} \langle R^{2l} \rangle. \quad (15.28)$$

Let us calculate the even moments $\langle R^{2l} \rangle$ of the polymer distribution $P_N(\mathbf{R})$ explicitly for $D = 3$. We expand the logarithm of the Fourier transform $\tilde{P}_N(\mathbf{k})$ as follows:

$$\log \tilde{P}_N(\mathbf{k}) = N \log \tilde{P}_1(\mathbf{k}) = N \log \left(\frac{\sin ka}{ka} \right) = N \sum_{l=1}^{\infty} \frac{2^{2l} (-1)^l B_{2l}}{(2l)! 2l} (ka)^{2l}, \quad (15.29)$$

where B_l are the Bernoulli numbers $B_2 = 1/6, B_4 = -1/30, \dots$. Then we note that for a Taylor series of an arbitrary function $y(x)$

$$y(x) = \sum_{n=1}^{\infty} \frac{a_n}{n!} x^n, \quad (15.30)$$

the exponential function $e^{y(x)}$ has the expansion

$$e^{y(x)} = \sum_{n=1}^{\infty} \frac{b_n}{n!} x^n, \quad (15.31)$$

with the coefficients

$$\frac{b_n}{n!} = \sum_{\{m_i\}} \prod_{i=0}^n \frac{1}{m_i!} \left(\frac{a_i}{i!} \right)^{m_i}. \quad (15.32)$$

The sum over the powers $m_i = 0, 1, 2, \dots$ obeys the constraint

$$n = \sum_{i=1}^n i \cdot m_i. \quad (15.33)$$

Note that the expansion coefficients a_n of $y(x)$ are the cumulants of the expansion coefficients b_n of $e^{y(x)}$ as defined in Section 3.17. For the coefficients a_n of the expansion (15.29),

$$a_n = \begin{cases} -N 2^{2l} (-1)^l B_{2l} / 2l & \text{for } n = 2l, \\ 0 & \text{for } n = 2l + 1, \end{cases} \quad (15.34)$$

we find, via the relation (15.27), the moments

$$\langle R^{2l} \rangle = a^{2l} (-1)^l (2l + 1)! \sum_{\{m_i\}} \prod_{i=1}^l \frac{1}{m_i!} \left[\frac{N 2^{2i} (-1)^i B_{2i}}{(2i)! 2i} \right]^{m_i}, \quad (15.35)$$

with the sum over $m_i = 0, 1, 2, \dots$ constrained by

$$l = \sum_{i=1}^l i \cdot m_i. \quad (15.36)$$

For $l = 1$ and 2 we obtain the moments

$$\langle R^2 \rangle = a^2 N, \quad \langle R^4 \rangle = \frac{5}{3} a^4 N^2 \left(1 - \frac{2}{5N} \right). \quad (15.37)$$

In the limit of large N , the leading behavior of the moments is the same as in (15.20) and (15.24). The linear growth of $\langle R^2 \rangle$ with the number of links N is characteristic for a random chain. In the presence of interactions, there will be a different power behavior expressed as a so-called *scaling law*

$$\langle R^2 \rangle \propto a^2 N^{2\nu}. \quad (15.38)$$

The number ν is called the *critical exponent* of this scaling law. It is intuitively obvious that ν must be a number between $\nu = 1/2$ for a random chain as in (15.37), and $\nu = 1$ for a completely stiff chain.

Note that the knowledge of all moments of the end-to-end distribution determines completely the shape of the distribution by an expansion

$$P_L(\mathbf{R}) = \frac{1}{S_D R^{D-1}} \sum_{n=0}^{\infty} \langle R^n \rangle \frac{(-1)^n}{n!} \partial_R^n \delta(R). \quad (15.39)$$

This can easily be verified by calculating the integrals (15.17) using the integrals formula

$$\int dz z^n \partial_z^n \delta(z) = (-1)^n n!. \quad (15.40)$$

15.3 Exact End-to-End Distribution in Three Dimensions

Consider the Fourier representation (15.10), rewritten as

$$P_N(\mathbf{R}) = \frac{i}{4\pi^2 a^2 R} \int_{-\infty}^{\infty} d\eta \eta e^{-i\eta R/a} \left(\frac{\sin \eta}{\eta} \right)^N, \quad (15.41)$$

with the dimensionless integration variable $\eta \equiv ka$. By expanding

$$\sin^N \eta = \frac{1}{(2i)^N} \sum_{n=0}^N (-1)^n \binom{N}{n} \exp[i(N-2n)\eta], \quad (15.42)$$

we find the finite series

$$P_N(\mathbf{R}) = \frac{1}{2^{N+2} i^{N-1} \pi^2 a^2 R} \sum_{n=0}^N (-1)^n \binom{N}{n} I_N(N-2n-R/a), \quad (15.43)$$

where $I_N(x)$ are the integrals

$$I_N(x) \equiv \int_{-\infty}^{\infty} d\eta \frac{e^{i\eta x}}{\eta^{N-1}}. \quad (15.44)$$

For $N \geq 2$, these integrals are all singular. The singularity can be avoided by noting that the initial integral (15.41) is perfectly regular at $\eta = 0$. We therefore replace the expression $(\sin \eta/\eta)^N$ in the integrand by $[\sin(\eta - i\epsilon)/(\eta - i\epsilon)]^N$. This regularizes each term in the expansion (15.43) and leads to well-defined integrals:

$$I_N(x) = \int_{-\infty}^{\infty} d\eta \frac{e^{ix(\eta - i\epsilon)}}{(\eta - i\epsilon)^{N-1}}. \quad (15.45)$$

For $x < 0$, the contour of integration can be closed by a large semicircle in the lower half-plane. Since the lower half-plane contains no singularity, the residue theorem shows that

$$I_N(x) = 0, \quad x < 0. \quad (15.46)$$

For $x > 0$, on the other hand, an expansion of the exponential function in powers of $\eta^{-i\epsilon}$ produces a pole, and the residue theorem yields

$$I_N(x) = \frac{2\pi i^{N-1}}{(N-2)!} x^{N-2}, \quad x > 0. \quad (15.47)$$

Hence we arrive at the finite series

$$P_N(\mathbf{R}) = \frac{1}{2^{N+1}(N-2)!\pi a^2 R} \sum_{0 \leq n \leq (N-R/a)/2} (-1)^n \binom{N}{n} (N-2n-R/a)^{N-2}. \quad (15.48)$$

The distribution is displayed for various values of N in Fig. 15.2, where we have plotted $2\pi R^2 \sqrt{N} P_N(\mathbf{R})$ against the rescaled distance variable $\rho = R/\sqrt{N}a$. With this N -dependent rescaling all curves have the same unit area. Note that they converge rapidly towards a universal zero-order distribution

$$P_N^{(0)}(\mathbf{R}) = \sqrt{\frac{3}{2\pi N a^2}} \exp\left\{-\frac{3R^2}{2N a^2}\right\} \rightarrow P_L^{(0)}(\mathbf{R}) = \sqrt{\frac{D}{2\pi a L}} e^{-DR^2/2aL}. \quad (15.49)$$

In the limit of large N , the length L will be used as a subscript rather than the diverging N . The proof of the limit is most easily given in Fourier space. For large N at finite $k^2 a^2 N$, the N th power of the quantity $\tilde{P}_1(\mathbf{k})$ in Eq. (15.15) can be approximated by

$$[\tilde{P}_1(\mathbf{k})]^N \sim e^{-Nk^2 a^2/2D}. \quad (15.50)$$

Then the Fourier transform (15.10) is performed with the zero-order result (15.49). In Fig. 15.2 we see that this large- N limit is approached uniformly in $\rho = R/\sqrt{N}a$. The approach to this limit is studied analytically in the following two sections.

Figure 15.2 End-to-end distribution $P_N(\mathbf{R})$ of random chain with N links. The functions $2\pi R^2\sqrt{N}P_N(\mathbf{R})$ are plotted against $R/\sqrt{N}a$ which gives all curves the same unit area. Note the fast convergence for growing N . The dashed curve is the continuum distribution $P_L^{(0)}(\mathbf{R})$ of Eq. (15.49). The circles on the abscissa mark the maximal end-to-end distance.

15.4 Short-Distance Expansion for Long Polymer

At finite N , we expect corrections which are expandable in the form

$$P_N(\mathbf{R}) = P_N^{(0)}(\mathbf{k}) \left[1 + \sum_{n=1}^{\infty} \frac{1}{N^n} C_n(R^2/Na^2) \right], \tag{15.51}$$

where the functions $C_n(x)$ are power series in x starting with x^0 .

Let us derive this expansion. In three dimensions, we start from (15.29) and separate the right-hand side into the leading k^2 -term and a remainder

$$\tilde{C}(\mathbf{k}) \equiv \exp \left[N \sum_{l=2}^{\infty} \frac{2^{2l}(-1)^l B_{2l}}{(2l)!2l} (k^2 a^2)^l \right]. \tag{15.52}$$

Exponentiating both sides of (15.29), the end-to-end probability factorizes as

$$\tilde{P}_N(\mathbf{k}) = e^{-Na^2k^2/6} \tilde{C}(\mathbf{k}). \tag{15.53}$$

The function $\tilde{C}(\mathbf{k})$ is now expanded in a power series

$$\tilde{C}(\mathbf{k}) = 1 + \sum_{\substack{n=1,2,\dots \\ l=2n,2n+1,\dots}} \tilde{C}_{n,l} N^n (a^2 k^2)^l, \tag{15.54}$$

with the lowest coefficients

$$\begin{aligned}\tilde{C}_{1,2} &= -\frac{1}{180}, & \tilde{C}_{1,3} &= -\frac{1}{2835}, \\ \tilde{C}_{1,4} &= -\frac{1}{37800}, & \tilde{C}_{2,4} &= \frac{1}{64800}, \quad \dots\end{aligned}\quad (15.55)$$

For any dimension D , we factorize

$$\tilde{P}_N(\mathbf{k}) = e^{-Na^2k^2/2D}\tilde{C}(\mathbf{k}) \quad (15.56)$$

and find $\tilde{C}(\mathbf{k})$ by expanding (15.15) in powers of k and proceeding as before. This gives the coefficients

$$\begin{aligned}\tilde{C}_{1,2} &= -1/4D^2(D+2), \\ \tilde{C}_{1,3} &= -1/3D^3(D+2)(D+4), \\ \tilde{C}_{1,4} &= -(5D+12)/8D^4(D+2)^2(D+4)(D+6), \\ \tilde{C}_{2,4} &= 1/32D^4(D+2)^2.\end{aligned}\quad (15.57)$$

We now Fourier-transform (15.56). The leading term in $\tilde{C}(\mathbf{k})$ yields the zero-order distribution (15.49) in D dimensions,

$$P_N^{(0)}(\mathbf{R}) = \sqrt{\frac{D}{2\pi Na^2}}^D e^{-DR^2/2Na^2}, \quad (15.58)$$

or, written in terms of the reduced distance variable $\rho = R/Na$,

$$P_N^{(0)}(\mathbf{R}) = \sqrt{\frac{D}{2\pi Na^2}}^D e^{-DN\rho^2/2}. \quad (15.59)$$

To account for the corrections in $\tilde{C}(\mathbf{k})$ we take the expansion (15.54), emphasize the dependence on k^2a^2 by writing

$$\tilde{C}(\mathbf{k}) = \bar{C}(k^2a^2),$$

and observe that in the Fourier transform

$$P_N(\mathbf{R}) = \int \frac{d^3k}{(2\pi)^3} e^{i\mathbf{k}\mathbf{R}} P_N(\mathbf{k}) = \int \frac{d^3k}{(2\pi)^3} e^{i\mathbf{k}\mathbf{R}} e^{-Nk^2a^2/2D} \bar{C}(k^2a^2), \quad (15.60)$$

the series can be pulled out of the integral by replacing each power $(k^2a^2)^p$ by $(-2D\partial_N)^p$. The result has the form

$$P_N(\mathbf{R}) = \bar{C}(-2D\partial_N) \int \frac{d^3k}{(2\pi)^3} e^{i\mathbf{k}\mathbf{R}} e^{-Nk^2a^2/2D} = \bar{C}(-2D\partial_N) P_N^{(0)}(\mathbf{R}). \quad (15.61)$$

Going back to coordinate space, we obtain an expansion

$$P_N(\mathbf{R}) = \left(\frac{D}{2\pi Na^2}\right)^{D/2} e^{-DN\rho^2/2} C(R). \quad (15.62)$$

For $D = 3$, the function $C(R)$ is given by the series

$$C(R) = 1 + \sum_{\substack{n=1 \\ l=0, \dots, 2n}}^{\infty} C_{n,l} N^{-n} (N\rho^2)^l, \quad (15.63)$$

with the coefficients

$$C_{1,l} = \left(-\frac{3}{4}, \frac{3}{2}, -\frac{9}{20} \right), \quad C_{2,l} = \left(\frac{29}{160}, -\frac{69}{40}, \frac{981}{400}, -\frac{1341}{1400}, \frac{81}{800} \right). \quad (15.64)$$

For any D , we find the coefficients

$$\begin{aligned} C_{1,l} &= \left(-\frac{D}{4}, \frac{D}{2}, -\frac{D^2}{4(D+2)} \right), \\ C_{2,l} &= \left(\frac{(3D^2 - 2D + 8)D}{96(D+2)}, -\frac{(D^2 + 2D + 8)D}{8(D+2)}, \frac{(3D^2 + 14D + 40)D^2}{16(D+2)^2}, \right. \\ &\quad \left. -\frac{(3D^2 + 22D + 56)D^3}{24(D+2)^2(D+4)}, \frac{D^4}{32(D+2)^2} \right). \end{aligned} \quad (15.65)$$

15.5 Saddle Point Approximation to Three-Dimensional End-to-End Distribution

Another study of the approach to the limiting distribution (15.49) proceeds via the saddle point approximation. For this, the integral in (15.41) is rewritten as

$$\int_{-\infty}^{\infty} d\eta \eta e^{-Nf(\eta)}, \quad (15.66)$$

with

$$f(\eta) = i\frac{R}{Na}\eta - \log\left(\frac{\sin \eta}{\eta}\right). \quad (15.67)$$

The extremum of f lies at $\eta = \bar{\eta}$, where $\bar{\eta}$ solves the equation

$$\coth(i\bar{\eta}) - \frac{1}{i\bar{\eta}} = \frac{R}{Na}. \quad (15.68)$$

The function on the left-hand side is known as the *Langevin function*:

$$L(x) \equiv \coth x - \frac{1}{x}. \quad (15.69)$$

The extremum lies at the imaginary position $\bar{\eta} \equiv -i\bar{x}$ with \bar{x} being determined by the equation

$$L(\bar{x}) = \frac{R}{Na}. \quad (15.70)$$

The extremum is a minimum of $f(\eta)$ since

$$f''(\bar{\eta}) = L'(\bar{x}) = -\frac{1}{\sinh^2 \bar{x}} + \frac{1}{\bar{x}^2} > 0. \quad (15.71)$$

By shifting the integration contour vertically into the complex η plane to make it run through the minimum at $-i\bar{x}$, we obtain

$$\begin{aligned} P_N(\mathbf{R}) &\approx -\frac{1}{4i\pi^2 a^2 R} e^{-Nf(\bar{\eta})} \int_{-\infty}^{\infty} d\eta (-i\bar{x} + \eta) \exp\left\{-\frac{N}{2} f''(\bar{\eta}) \eta^2\right\} \\ &= \frac{\bar{\eta}}{4\pi^2 a^2 R} \sqrt{\frac{2\pi}{N f''(\bar{x})}} e^{-Nf(\bar{\eta})}. \end{aligned} \quad (15.72)$$

When expressed in terms of the reduced distance $\rho \equiv R/Na \in [0, 1]$, this reads

$$P_N(\mathbf{R}) \approx \frac{1}{(2\pi Na^2)^{3/2}} \frac{L^i(\rho)^2}{\rho \{1 - [L^i(\rho)/\sinh L^i(\rho)]^2\}^{1/2}} \left\{ \frac{\sinh L^i(\rho)}{L^i(\rho) \exp[\rho L^i(\rho)]} \right\}^N. \quad (15.73)$$

Here we have introduced the inverse Langevin function $L^i(\rho)$ since it allows us to express \bar{x} as

$$\bar{x} = L^i(\rho) \quad (15.74)$$

[inverting Eq. (15.70)]. The result (15.73) is valid in the entire interval $\rho \in [0, 1]$ corresponding to $R \in [0, Na]$; it ignores corrections of the order $1/N$. By expanding the right-hand side in a power series in ρ , we find

$$P_N(\mathbf{R}) = \mathcal{N} \left(\frac{3}{2\pi Na^2} \right)^{3/2} \exp\left(-\frac{3R^2}{2Na^2}\right) \left(1 + \frac{3R^2}{2N^2 a^2} - \frac{9R^4}{20N^3 a^4} + \dots \right), \quad (15.75)$$

with some normalization constant \mathcal{N} . At each order of truncation, \mathcal{N} is determined in such a way that $\int d^3 R P_N(\mathbf{R}) = 1$. As a check we take the limit $\rho^2 \ll 1/N$ and find powers in ρ which agree with those in (15.62), for $D = 3$, with the expansion (15.63) of the correction factor.

15.6 Path Integral for Continuous Gaussian Distribution

The limiting end-to-end distribution (15.49) is equal to the imaginary-time amplitude of a free particle in natural units with $\hbar = 1$:

$$(\mathbf{x}_b \tau_b | \mathbf{x}_a \tau_a) = \frac{1}{\sqrt{2\pi(\tau_b - \tau_a)/M}^D} \exp\left[-\frac{M}{2} \frac{(\mathbf{x}_b - \mathbf{x}_a)^2}{\tau_b - \tau_a}\right]. \quad (15.76)$$

We merely have to identify

$$\mathbf{x}_b - \mathbf{x}_a \equiv \mathbf{R}, \quad (15.77)$$

and replace

$$\tau_b - \tau_a \rightarrow Na, \quad (15.78)$$

$$M \rightarrow D/a. \quad (15.79)$$

Thus we can describe a polymer with $R^2 \ll Na^2$ by the path integral

$$P_L(\mathbf{R}) = \int \mathcal{D}^D x \exp \left\{ -\frac{D}{2a} \int_0^L ds [\mathbf{x}'(s)]^2 \right\} = \sqrt{\frac{D}{2\pi a}} e^{-DR^2/2La}. \quad (15.80)$$

The number of time slices is here N [in contrast to (2.66) where it was $N+1$], and the total length of the polymer is $L = Na$.

Let us calculate the Fourier transformation of the distribution (15.80):

$$\tilde{P}_L(\mathbf{q}) = \int d^D R e^{-i\mathbf{q}\cdot\mathbf{R}} P_L(\mathbf{R}). \quad (15.81)$$

After a quadratic completion the integral yields

$$\tilde{P}_L(\mathbf{q}) = e^{-Laq^2/2D}, \quad (15.82)$$

with the power series expansion

$$\tilde{P}_L(\mathbf{q}) = \sum_{l=0}^{\infty} (-1)^l \frac{q^{2l}}{l!} \left(\frac{La}{2D} \right)^l. \quad (15.83)$$

Comparison with the moments (15.23) shows that we can rewrite this as

$$\tilde{P}_L(\mathbf{q}) = \sum_{l=0}^{\infty} (-1)^l \frac{q^{2l}}{l!} \frac{\Gamma(D/2)}{2^{2l}\Gamma(D/2+l)} \langle R^{2l} \rangle. \quad (15.84)$$

This is a completely general relation: the expansion coefficients of the Fourier transform yield directly the moments of a function, up to trivial numerical factors specified by (15.84).

The end-to-end distribution determines rather directly the structure factor of a dilute solution of polymers which is observable in static neutron and light scattering experiments:

$$S(\mathbf{q}) = \frac{1}{L^2} \int_0^L ds \int_0^L ds' \langle e^{i\mathbf{q}\cdot[\mathbf{x}(s)-\mathbf{x}(s')]} \rangle. \quad (15.85)$$

The average over all polymers running from $\mathbf{x}(0)$ to $\mathbf{x}(L)$ can be written, more explicitly, as

$$\begin{aligned} \langle e^{i\mathbf{q}\cdot[\mathbf{x}(s)-\mathbf{x}(s')]} \rangle &= \int d^D x(L) \int d^D (x(s')-x(s)) \int d^D x(0) \\ &\times P_{L-s'}(\mathbf{x}(L)-\mathbf{x}(s')) e^{-i\mathbf{q}\cdot\mathbf{x}(s')} P_{s'-s}(\mathbf{x}(s')-\mathbf{x}(s)) e^{i\mathbf{q}\cdot\mathbf{x}(s)} P_{s-0}(\mathbf{x}(s)-\mathbf{x}(0)). \end{aligned} \quad (15.86)$$

The integrals over initial and final positions give unity due to the normalization (15.4), so that we remain with

$$\langle e^{i\mathbf{q}\cdot[\mathbf{x}(s)-\mathbf{x}(s')]} \rangle = \int d^D R e^{-i\mathbf{q}\cdot\mathbf{R}} P_{s'-s}(\mathbf{R}). \quad (15.87)$$

Since this depends only on $L' \equiv |s' - s|$ and not on $s + s'$, we decompose the double integral in over s and s' in (15.85) into $2 \int_0^L dL'(L - L')$ and obtain

$$S(\mathbf{q}) = \frac{2}{L^2} \int_0^L dL'(L - L') \int d^D R e^{i\mathbf{q}\cdot\mathbf{R}(L')} P_{L'}(\mathbf{R}), \quad (15.88)$$

or, recalling (15.81),

$$S(\mathbf{q}) = \frac{2}{L^2} \int_0^L dL'(L - L') \tilde{P}_{L'}(\mathbf{q}). \quad (15.89)$$

Inserting (15.82) we obtain the *Debye structure factor* of Gaussian random paths:

$$S^{\text{Gauss}}(\mathbf{q}) = \frac{2}{x^2} (x - 1 + e^{-x}), \quad x \equiv \frac{q^2 a L}{2D}. \quad (15.90)$$

This function starts out like $1 - x/3 + x^2/12 + \dots$ for small q and falls off like q^{-2} for $q^2 \gg 2D/aL$. The Taylor coefficients are determined by the moments of the end-to-end distribution. By inserting (15.84) into (15.89) we obtain:

$$S(\mathbf{q}) = \sum_{l=0}^{\infty} (-1)^l q^{2l} \frac{\Gamma(D/2)}{2^{2l} l! \Gamma(l + D/2)} \frac{2}{L^2} \int_0^L dL'(L - L') \langle R^{2l} \rangle. \quad (15.91)$$

Although the end-to-end distribution (15.80) agrees with the true polymer distribution (15.1) for $R \ll \sqrt{N}a$, it is important to realize that the nature of the fluctuations in the two expressions is quite different. In the polymer expression, the length of each link $\Delta\mathbf{x}_n$ is fixed. In the sliced action of the path integral Eq. (15.80),

$$\mathcal{A}^N = a \sum_{n=1}^N \frac{M}{2} \frac{(\Delta\mathbf{x}_n)^2}{a^2}, \quad (15.92)$$

on the other hand, each small section fluctuates around zero with a mean square

$$\langle (\Delta\mathbf{x}_n)^2 \rangle_0 = \frac{a}{M} = \frac{a^2}{D}. \quad (15.93)$$

Yet, if the end-to-end distance of the polymer is small compared to the completely stretched configuration, the distributions are practically the same. There exists a qualitative difference only if the polymer is almost completely stretched. While the polymer distribution vanishes for $R > Na$, the path integral (15.80) gives a nonzero value for arbitrarily large R . Quantitatively, however, the difference is insignificant since it is exponentially small (see Fig. 15.2).

15.7 Stiff Polymers

The end-to-end distribution of real polymers found in nature is never the same as that of a random chain. Usually, the joints do not allow for an equal probability of all spherical angles. The forward angles are often preferred and the polymer is *stiff* at shorter distances. Fortunately, if averaged over many links, the effects of the stiffness becomes less and less relevant. For a very long random chain with a finite stiffness one finds the same linear dependence of the square end-to-end distance on the length $L = Na$ as for ideal random chains which has, according to Eq. (15.23), the Gaussian expectations:

$$\langle R^2 \rangle = aL, \quad \langle R^{2l} \rangle = \frac{(D + 2l - 2)!!}{(D - 2)!! D^l} (aL)^l. \quad (15.94)$$

For a stiff chain, the expectation value $\langle R^2 \rangle$ will increase aL to $a_{\text{eff}}L$, where a_{eff} is the *effective bond length*. In the limit of a very large stiffness, called the *rod limit*, the law (15.94) turns into

$$\langle R^2 \rangle \equiv L^2, \quad \langle R^{2l} \rangle \equiv L^{2l}, \quad (15.95)$$

i.e., the effective bond length a_{eff} increases to L . This intuitively obvious statement can easily be found from the normalized end-to-end distribution, which coincides in the rod limit with the one-link expression (15.12):

$$P_L^{\text{rod}}(\mathbf{R}) = \frac{1}{S_D R^{D-1}} \delta(R - L), \quad (15.96)$$

and yields [recall (15.17)]

$$\langle R^n \rangle = \int d^D R R^n P_L^{\text{rod}}(\mathbf{R}) = \int_0^\infty dR R^n \delta(R - L) = L^n. \quad (15.97)$$

By expanding $P_L^{\text{rod}}(\mathbf{R})$ in powers of L , we obtain the series

$$P_L^{\text{rod}}(\mathbf{R}) = \frac{1}{S_D R^{D-1}} \sum_{n=0}^{\infty} L^n \langle R^n \rangle \frac{(-1)^n}{n!} \partial_R^n \delta(R). \quad (15.98)$$

An expansion of this form holds for any stiffness: the moments of the distribution are the Taylor coefficients of the expansion of $P_L(\mathbf{R})$ into a series of derivatives of $\delta(R)$ -functions.

Let us also calculate the Fourier transformation (15.81) of this distribution. Recalling (15.15), we find

$$\tilde{P}_L^{\text{rod}}(\mathbf{q}) = \tilde{P}^{\text{rod}}(qL) \equiv \frac{\Gamma(D/2)}{(qL/2)^{D/2-1}} J_{D/2-1}(qL). \quad (15.99)$$

For an arbitrary rotationally symmetric $P_L(\mathbf{R}) = P_L(R)$, we simply have to superimpose these distributions for all R :

$$\tilde{P}_L(\mathbf{q}) = S_D \int_0^\infty dR R^{D-1} \tilde{P}^{\text{rod}}(qL) P_L(R). \quad (15.100)$$

This is simply proved by decomposing and performing the Fourier transformation (15.81) on $P_L(R) = \int_0^\infty dR' \delta(R - R') P_{R'}^{\text{rod}}(\mathbf{R}) = S_D \int_0^\infty dR' R'^{D-1} P_{R'}^{\text{rod}}(\mathbf{R}) P_L(R')$, and performing the Fourier transformation (15.81) on $P_{R'}^{\text{rod}}(\mathbf{R})$. In $D = 3$ dimensions, (15.100) takes the simple form:

$$\tilde{P}_L(\mathbf{q}) = 4\pi \int_0^\infty dR R^2 \frac{\sin qR}{qR} P_L(R). \quad (15.101)$$

Inserting the power series expansion for the Bessel function²

$$J_\nu(z) = \left(\frac{z}{2}\right)^\nu \sum_{l=0}^{\infty} \frac{(-1)^l (z/2)^{2l}}{l! \Gamma(\nu + l + 1)} \quad (15.102)$$

into (15.99), and this into (15.100), we obtain

$$\tilde{P}_L(\mathbf{q}) = \sum_{l=0}^{\infty} (-1)^l \left(\frac{q}{2}\right)^{2l} \frac{\Gamma(D/2)}{l! \Gamma(D/2 + l)} S_D \int_0^\infty dR R^{D-1} R^{2l} P_L(R), \quad (15.103)$$

in agreement with the general expansion (15.84). The same result is obtained by inserting into (15.103) the expansion (15.98) and using the integrals $\int_0^\infty dR R^m \partial_R^n \delta(R) = \delta_{mn} (-1)^n n!$, which are proved by n partial integrations.

The structure factor of a completely stiff polymer (rod limit) is obtained by inserting (15.99) into (15.89). The resulting $S^{\text{rod}}(\mathbf{q})$ depends only on qL :

$$S^{\text{rod}}(qL) = \frac{4-2D}{q^2 L^2} + \left(\frac{2}{qL}\right)^{D/2} \Gamma(D/2) J_{D/2-2}(qL) + 2F(1/2; 3/2, D/2; -q^2 L^2/4), \quad (15.104)$$

where $F(a; b, c; z)$ is the hypergeometric function (1.453). For $D = 3$, the integral (15.89) reduces to $(2/L^2) \int_0^L dL' (L - L') (\sin qL') / qL'$, as in the similar equation (15.9), and the result is simply

$$S^{\text{rod}}(z) = \frac{2}{z^2} [\cos z - 1 + z \text{Si}(z)], \quad \text{Si}(z) \equiv \int_0^z \frac{dt}{t} \sin t. \quad (15.105)$$

This starts out like $1 - z^2/36 + z^4/1800 + \dots$. For large z we use the limit of the sine integral³ $\text{Si}(z) \rightarrow \pi/2$ to find $S^{\text{rod}}(\mathbf{q}) \rightarrow \pi/qL$.

For of an arbitrary rotationally symmetric end-to-end distribution $P_L(R)$, the structure factor can be expressed, by analogy with (15.100), as a superposition of rod limits:

$$S_L(\mathbf{q}) = S_D \int_0^\infty dR R^{D-1} S^{\text{rod}}(\mathbf{q}R) P_L(R). \quad (15.106)$$

When passing from long to short polymers at a given stiffness, there is a crossover between the moments (15.94) and (15.95) and the behaviors of the structure function. Let us study this in detail.

15.7.1 Sliced Path Integral

The stiffness of a polymer pictured in Fig. 15.1 may be parameterized by the bending energy

$$E_{\text{bend}}^N = \frac{\kappa}{2a} \sum_{n=1}^N (\mathbf{u}_n - \mathbf{u}_{n-1})^2, \quad (15.107)$$

where \mathbf{u}_n are the unit vectors specifying the directions of the links. The initial and final link directions of the polymer have a distribution

$$(\mathbf{u}_b L | \mathbf{u}_a 0) = \frac{1}{A} \prod_{n=1}^{N-1} \left[\int \frac{d\mathbf{u}_n}{A} \right] \exp \left[-\frac{\kappa}{2ak_B T} \sum_{n=1}^N (\mathbf{u}_n - \mathbf{u}_{n-1})^2 \right], \quad (15.108)$$

where A is some normalization constant, which we shall choose such that the measure of integration coincides with that of a time-sliced path integral *near* a unit sphere in Eq. (8.151). Comparison of the bending energy (15.107) with the Euclidean action (8.152) we identify

$$\frac{Mr^2}{\hbar\epsilon} = \frac{\kappa}{ak_B T}, \quad (15.109)$$

and see that we must replace $N \rightarrow N - 1$ and set

$$A = \sqrt{2\pi ak_B T / \kappa}^{D-1}. \quad (15.110)$$

The result of the integrations in (15.108) is then known from Eq. (8.156):

$$(\mathbf{u}_b L | \mathbf{u}_a 0) = \sum_{l=0}^{\infty} \left[\tilde{I}_{l+D/2-1}(h) \right]^N \sum_{\mathbf{m}} Y_{l\mathbf{m}}(\mathbf{u}_b) Y_{l\mathbf{m}}^*(\mathbf{u}_a), \quad h \equiv \frac{\kappa}{ak_B T}, \quad (15.111)$$

with the modified Bessel function $\tilde{I}_{l+D/2-1}(z)$ of Eq. (8.11).

The partition function of the polymer is obtained by integrating over all final and averaging over all initial link directions [1]:

$$\begin{aligned} Z_N &= \int \frac{d\mathbf{u}_a}{S_D} \prod_{n=1}^N \left[\int \frac{d\mathbf{u}_n}{A} \right] \exp \left[-\frac{\kappa}{2ak_B T} \sum_{n=1}^N (\mathbf{u}_n - \mathbf{u}_{n-1})^2 \right] \\ &= \int d\mathbf{u}_b \int \frac{d\mathbf{u}_a}{S_D} (\mathbf{u}_b L | \mathbf{u}_a 0). \end{aligned} \quad (15.112)$$

Inserting here the spectral representation (15.111) we find

$$Z_N = \left[\tilde{I}_{D/2-1} \left(\frac{\kappa}{ak_B T} \right) \right]^N = \left[\sqrt{\frac{2\pi\kappa}{ak_B T}} e^{-\kappa/ak_B T} I_{D/2-1} \left(\frac{\kappa}{ak_B T} \right) \right]^N. \quad (15.113)$$

Knowing this we may define the normalized distribution function

$$P_N(\mathbf{u}_b, \mathbf{u}_a) = \frac{1}{Z_N} (\mathbf{u}_b L | \mathbf{u}_a 0), \quad (15.114)$$

whose integral over \mathbf{u}_a as well as over \mathbf{u}_b is unity:

$$\int d\mathbf{u}_b P_N(\mathbf{u}_b, \mathbf{u}_a) = \int d\mathbf{u}_a P_N(\mathbf{u}_b, \mathbf{u}_a) = 1. \quad (15.115)$$

15.7.2 Relation to Classical Heisenberg Model

The above partition function is closely related to the partition function of the one-dimensional classical Heisenberg model of ferromagnetism which is defined by

$$Z_N^{\text{Heis}} \equiv \int \frac{d\mathbf{u}_a}{S_D} \prod_{n=1}^N \left[\int d\mathbf{u}_n \right] \exp \left[\frac{J}{k_B T} \sum_{n=1}^N \mathbf{u}_n \cdot \mathbf{u}_{n-1} \right], \quad (15.116)$$

where J are interaction energies due to exchange integrals of electrons in a ferromagnet. This differs from (15.112) by a trivial normalization factor, being equal to

$$Z_N^{\text{Heis}} = \left[\sqrt{\frac{2\pi J}{k_B T}}^{2-D} I_{D/2-1} \left(\frac{J}{k_B T} \right) \right]^N. \quad (15.117)$$

Identifying $J \equiv \kappa/a$ we may use the Heisenberg partition functions for all calculations of stiff polymers. As an example take the correlation function between neighboring tangent vectors $\langle \mathbf{u}_n \cdot \mathbf{u}_{n-1} \rangle$. In order to calculate this we observe that the partition function (15.116) can just as well be calculated exactly with a slight modification that the interaction strength J of the Heisenberg model depends on the link n . The result is the corresponding generalization of (15.117):

$$Z_N^{\text{Heis}}(J_1, \dots, J_N) = \prod_{n=1}^N \left[\sqrt{\frac{2\pi J_n}{k_B T}}^{2-D} I_{D/2-1} \left(\frac{J_n}{k_B T} \right) \right]. \quad (15.118)$$

This expression may be used as a generating function for expectation values $\langle \mathbf{u}_n \cdot \mathbf{u}_{n-1} \rangle$ which measure the degree of alignment of neighboring spin directions. Indeed, we find directly

$$\langle \mathbf{u}_n \cdot \mathbf{u}_{n-1} \rangle = (k_B T) \frac{dZ_N^{\text{Heis}}(J_1, \dots, J_N)}{dJ_n} \Big|_{J_n=J} = \frac{I_{D/2}(J/k_B T)}{I_{D/2-1}(J/k_B T)}. \quad (15.119)$$

This expectation value measures directly the internal energy per link of the chain. Indeed, since the free energy is $F_N = -k_B T \log Z_N^{\text{Heis}}$, we obtain [recall (1.548)]

$$E_N = N \langle \mathbf{u}_n \cdot \mathbf{u}_{n-1} \rangle = N \frac{I_{D/2}(J/k_B T)}{I_{D/2-1}(J/k_B T)}. \quad (15.120)$$

Let us also calculate the expectation value of the angle between next-to-nearest neighbors $\langle \mathbf{u}_{n+1} \cdot \mathbf{u}_{n-1} \rangle$. We do this by considering the expectation value

$$\langle (\mathbf{u}_{n+1} \cdot \mathbf{u}_n)(\mathbf{u}_n \cdot \mathbf{u}_{n-1}) \rangle = (k_B T)^2 \frac{d^2 Z_N^{\text{Heis}}(J_1, \dots, J_N)}{dJ_{n+1} dJ_n} \Big|_{J_n=J} = \left[\frac{I_{D/2}(J/k_B T)}{I_{D/2-1}(J/k_B T)} \right]^2. \quad (15.121)$$

Then we prove that the left-hand side is in fact equal to the desired expectation value $\langle \mathbf{u}_{n+1} \cdot \mathbf{u}_{n-1} \rangle$. For this we decompose the last vector \mathbf{u}_{n+1} into a component

Figure 15.3 Neighboring links for the calculation of expectation values.

parallel to \mathbf{u}_n and a component perpendicular to it: $\mathbf{u}_{n+1} = (\mathbf{u}_{n+1} \cdot \mathbf{u}_n) \mathbf{u}_n + \mathbf{u}_{n+1}^\perp$. The corresponding decomposition of the expectation value $\langle \mathbf{u}_{n+1} \cdot \mathbf{u}_{n-1} \rangle$ is $\langle \mathbf{u}_{n+1} \cdot \mathbf{u}_{n-1} \rangle = \langle (\mathbf{u}_{n+1} \cdot \mathbf{u}_n)(\mathbf{u}_n \cdot \mathbf{u}_{n-1}) \rangle + \langle \mathbf{u}_{n+1}^\perp \cdot \mathbf{u}_{n-1} \rangle$. Now, the energy in the Boltzmann factor depends only on $(\mathbf{u}_{n+1} \cdot \mathbf{u}_n) + (\mathbf{u}_n \cdot \mathbf{u}_{n-1}) = \cos \theta_{n+1,n} + \cos \theta_{n,n-1}$, so that the integral over \mathbf{u}_{n+1}^\perp runs over a surface of a sphere of radius $\sin \theta_{n+1,n}$ in $D - 1$ dimensions [recall (8.117)] and the Boltzmann factor does not depend on the angles. The integral receives therefore equal contributions from \mathbf{u}_{n+1}^\perp and $-\mathbf{u}_{n+1}^\perp$, and vanishes. This proves that

$$\langle \mathbf{u}_{n+1} \cdot \mathbf{u}_{n-1} \rangle = \langle \mathbf{u}_{n+1} \cdot \mathbf{u}_n \rangle \langle \mathbf{u}_n \cdot \mathbf{u}_{n-1} \rangle = \left[\frac{I_{D/2}(J/k_B T)}{I_{D/2-1}(J/k_B T)} \right]^2, \quad (15.122)$$

and further, by induction, that

$$\langle \mathbf{u}_l \cdot \mathbf{u}_k \rangle = \left[\frac{I_{D/2}(J/k_B T)}{I_{D/2-1}(J/k_B T)} \right]^{|l-k|}. \quad (15.123)$$

For the polymer, this implies an exponential falloff

$$\langle \mathbf{u}_l \cdot \mathbf{u}_k \rangle = e^{-|l-k|a/\xi}, \quad (15.124)$$

where ξ is the *persistence length*

$$\xi = -a / \log \left[\frac{I_{D/2}(\kappa/ak_B T)}{I_{D/2-1}(\kappa/ak_B T)} \right]. \quad (15.125)$$

For $D = 3$, this is equal to

$$\xi = -\frac{a}{\log [\coth(\kappa/ak_B T) - ak_B T/\kappa]}. \quad (15.126)$$

Knowing the correlation functions it is easy to calculate the magnetic susceptibility. The total magnetic moment is

$$\mathbf{M} = a \sum_{n=0}^N \mathbf{u}_n, \quad (15.127)$$

so that we find the total expectation value

$$\langle \mathbf{M}^2 \rangle = a^2(N+1) \frac{1 + e^{-a/\xi}}{1 - e^{-a/\xi}} - 2a^2 e^{-a/\xi} \frac{1 - e^{-(N+1)a/\xi}}{(1 - e^{-a/\xi})^2}. \quad (15.128)$$

The susceptibility is directly proportional to this. For more details see [2].

15.7.3 End-to-End Distribution

A modification of the path integral (15.108) yields the distribution of the end-to-end distance at given initial and final directions of the polymer links:

$$\mathbf{R} = \mathbf{x}_b - \mathbf{x}_a = a \sum_{n=1}^N \mathbf{u}_n \quad (15.129)$$

of the stiff polymer:

$$\begin{aligned} P_N(\mathbf{u}_b, \mathbf{u}_a; \mathbf{R}) &= \frac{1}{Z_N} \frac{1}{A} \prod_{n=2}^{N-1} \left[\int \frac{d\mathbf{u}_n}{A} \right] \delta^{(D)}(\mathbf{R} - a \sum_{n=1}^N \mathbf{u}_n) \\ &\times \exp \left[-\frac{\kappa}{2ak_B T} \sum_{n=1}^{N-1} (\mathbf{u}_{n+1} - \mathbf{u}_n)^2 \right], \end{aligned} \quad (15.130)$$

whose integral over \mathbf{R} leads back to the distribution $P_N(\mathbf{u}_b, \mathbf{u}_a)$:

$$\int d^D R P_N(\mathbf{u}_b, \mathbf{u}_a; \mathbf{R}) = P_N(\mathbf{u}_b, \mathbf{u}_a). \quad (15.131)$$

If we integrate in (15.130) over all final directions and average over the initial ones, we obtain the physically more accessible end-to-end distribution

$$P_N(\mathbf{R}) = \int d\mathbf{u}_b \int \frac{d\mathbf{u}_a}{S_D} P_N(\mathbf{u}_b, \mathbf{u}_a; \mathbf{R}). \quad (15.132)$$

The sliced path integral, as it stands, does not yet give quite the desired probability. Two small corrections are necessary, the same that brought the integral *near* the surface of a sphere to the path integral *on* the sphere in Section 8.9. After including these, we obtain a proper overall normalization of $P_N(\mathbf{u}_b, \mathbf{u}_a; \mathbf{R})$.

15.7.4 Moments of End-to-End Distribution

Since the $\delta^{(D)}$ -function in (15.130) contains vectors \mathbf{u}_n of unit length, the calculation of the complete distribution is not straightforward. Moments of the distribution, however, which are defined by the integrals

$$\langle R^{2l} \rangle = \int d^D R R^{2l} P_N(\mathbf{R}), \quad (15.133)$$

are relatively easy to find from the multiple integrals

$$\begin{aligned} \langle R^{2l} \rangle &= \frac{1}{Z_N} \int d^D R \frac{1}{A} \int d\mathbf{u}_b \prod_{n=2}^{N-1} \left[\int \frac{d\mathbf{u}_n}{A} \right] \left[\int \frac{d\mathbf{u}_a}{S_D} \right] \delta^{(D)}(\mathbf{R} - \sum_{n=1}^N a\mathbf{u}_n) \\ &\times R^{2l} \exp \left[-\frac{\kappa}{2ak_B T} \sum_{n=1}^{N-1} (\mathbf{u}_{n+1} - \mathbf{u}_n)^2 \right]. \end{aligned} \quad (15.134)$$

Performing the integral over \mathbf{R} gives

$$\begin{aligned} \langle R^{2l} \rangle = & \frac{1}{Z_N} \frac{1}{A} \int d\mathbf{u}_b \prod_{n=2}^{N-1} \left[\int \frac{d\mathbf{u}_n}{A} \right] \left[\int \frac{d\mathbf{u}_a}{S_D} \right] \left(a \sum_{n=1}^N \mathbf{u}_n \right)^{2l} \\ & \times \exp \left[-\frac{\kappa}{2ak_B T} \sum_{n=1}^{N-1} (\mathbf{u}_{n+1} - \mathbf{u}_n)^2 \right]. \end{aligned} \quad (15.135)$$

Due to the normalization property (15.115), the trivial moment is equal to unity:

$$\langle 1 \rangle = \int d^D R P_N(\mathbf{R}) = \int d\mathbf{u}_b \int \frac{d\mathbf{u}_a}{S_D} P_N(\mathbf{u}_b, \mathbf{u}_a | L) = 1. \quad (15.136)$$

15.8 Continuum Formulation

Some properties of stiff polymers are conveniently studied in the continuum limit of the sliced path integral (15.108), in which the bond length a goes to zero and the link number to infinity so that $L = Na$ stays constant. In this limit, the bending energy (15.107) becomes

$$E_{\text{bend}} = \frac{\kappa}{2} \int_0^L ds (\partial_s \mathbf{u})^2, \quad (15.137)$$

where

$$\mathbf{u}(s) = \frac{d}{ds} \mathbf{x}(s), \quad (15.138)$$

is the unit tangent vector of the space curve along which the polymer runs. The parameter s is the arc length of the line elements, i.e., $ds = \sqrt{d\mathbf{x}^2}$.

15.8.1 Path Integral

If the continuum limit is taken purely formally on the product of integrals (15.108), we obtain a path integral

$$(\mathbf{u}_b L | \mathbf{u}_a 0) = \int \mathcal{D}\mathbf{u} e^{-(\kappa/2k_B T) \int_0^L ds [\mathbf{u}'(s)]^2}, \quad (15.139)$$

This coincides with the Euclidean version of a path integral for a particle on the surface of a sphere. It is a nonlinear σ -model (recall p. 637).

The result of the integration has been given in Section 8.9 where we found that it does not quite agree with what we would obtain from the continuum limit of the discrete solution (15.111) using the limiting formula (8.157), which is

$$P(\mathbf{u}_b, \mathbf{u}_a | L) = \sum_{l=0}^{\infty} \exp \left(-L \frac{k_B T}{2\kappa} L_2 \right) \sum_{\mathbf{m}} Y_{l\mathbf{m}}(\mathbf{u}_b) Y_{l\mathbf{m}}^*(\mathbf{u}_a), \quad (15.140)$$

with

$$L_2 = (D/2 - 1 + l)^2 - 1/4. \quad (15.141)$$

For a particle on a sphere, the discrete expression (15.130) requires a correction since it does not contain the proper time-sliced action and measure. According to Section 8.9 the correction replaces L_2 by the eigenvalues of the square angular momentum operator in D dimensions, \hat{L}^2 ,

$$L_2 \rightarrow \hat{L}^2 = l(l + D - 2). \quad (15.142)$$

After this replacement the expectation of the trivial moment $\langle 1 \rangle$ in (15.136) is equal to unity since it gives the distribution (15.140) the proper normalization:

$$\int d\mathbf{u}_b P(\mathbf{u}_b, \mathbf{u}_a | L) = 1. \quad (15.143)$$

This follows from the integral

$$\int d\mathbf{u}_b \sum_{\mathbf{m}} Y_{l\mathbf{m}}^*(\mathbf{u}_b) Y_{l\mathbf{m}}(\mathbf{u}_a) = \delta_{l0}, \quad (15.144)$$

which was derived in (8.250). Thus, with \hat{L}^2 in (15.140) instead of L_2 , no extra normalization factor is required. The sum over $Y_{l\mathbf{m}}(\mathbf{u}_2) Y_{l\mathbf{m}}^*(\mathbf{u}_1)$ may furthermore be rewritten in terms of Gegenbauer polynomials using the addition theorem (8.126), so that we obtain

$$P(\mathbf{u}_b, \mathbf{u}_a | L) = \sum_{l=0}^{\infty} \exp\left(-L \frac{k_B T}{2\kappa} \hat{L}^2\right) \frac{1}{S_D} \frac{2l + D - 2}{D - 2} C_l^{(D/2-1)}(\mathbf{u}_2 \mathbf{u}_1). \quad (15.145)$$

15.8.2 Correlation Functions and Moments

We are now ready to evaluate the expectation values of R^{2l} . In the continuum approximation we write

$$R^{2l} = \left[\int_0^L ds \mathbf{u}(s) \right]^{2l}. \quad (15.146)$$

The expectation value of the lowest moment $\langle R^2 \rangle$ is given by the double-integral over the correlation function $\langle \mathbf{u}(s_2) \mathbf{u}(s_1) \rangle$:

$$\langle R^2 \rangle = \int_0^L ds_2 \int_0^L ds_1 \langle \mathbf{u}(s_2) \mathbf{u}(s_1) \rangle = 2 \int_0^L ds_2 \int_0^{s_2} ds_1 \langle \mathbf{u}(s_2) \mathbf{u}(s_1) \rangle. \quad (15.147)$$

The correlation function is calculated from the path integral via the composition law as in Eq. (3.301), which yields here

$$\begin{aligned} \langle \mathbf{u}(s_2) \mathbf{u}(s_1) \rangle &= \int d\mathbf{u}_b \int \frac{d\mathbf{u}_a}{S_D} \int d\mathbf{u}_2 \int d\mathbf{u}_1 \\ &\times P(\mathbf{u}_b, \mathbf{u}_2 | L - s_2) \mathbf{u}_2 P(\mathbf{u}_2, \mathbf{u}_1 | s_2 - s_1) \mathbf{u}_1 P(\mathbf{u}_1, \mathbf{u}_a | s_1). \end{aligned} \quad (15.148)$$

The integrals over \mathbf{u}_a and \mathbf{u}_b remove the initial and final distributions via the normalization integral (15.143), leaving

$$\langle \mathbf{u}(s_2)\mathbf{u}(s_1) \rangle = \int d\mathbf{u}_2 \int \frac{d\mathbf{u}_1}{S_D} \mathbf{u}_2 \mathbf{u}_1 P(\mathbf{u}_2, \mathbf{u}_1 | s_2 - s_1). \quad (15.149)$$

Due to the manifest rotational invariance, the normalized integral over \mathbf{u}_1 can be omitted. By inserting the spectral representation (15.145) with the eigenvalues (15.142) we obtain

$$\begin{aligned} \langle \mathbf{u}(s_2)\mathbf{u}(s_1) \rangle &= \int d\mathbf{u}_2 \mathbf{u}_2 \mathbf{u}_1 P(\mathbf{u}_2, \mathbf{u}_1 | s_2 - s_1) \\ &= \sum_l e^{-(s_2-s_1)k_B T \hat{L}^2 / 2\kappa} \left[\int d\mathbf{u}_2 \mathbf{u}_2 \mathbf{u}_1 \frac{1}{S_D} \frac{2l + D - 2}{D - 2} C_l^{(D/2-1)}(\mathbf{u}_2 \mathbf{u}_1) \right]. \end{aligned} \quad (15.150)$$

We now calculate the integral in the brackets with the help of the recursion relation (15.152) for the Gegenbauer functions⁴

$$z C_l^{(\nu)}(z) = \frac{1}{2(\nu + l)} \left[(2\nu + l - 1) C_{l-1}^{(\nu)}(z) + (l + 1) C_{l+1}^{(\nu)}(z) \right]. \quad (15.151)$$

Obviously, the integral over \mathbf{u}_2 lets only the term $l = 1$ survive. This, in turn, involves the integral

$$\int d\mathbf{u}_2 C_0^{(D/2-1)}(\cos \theta) = S_D. \quad (15.152)$$

The $l = 1$ -factor $D/(D - 2)$ in (15.150) is canceled by the first $l = 1$ -factor in the recursion (15.151) and we obtain the correlation function

$$\langle \mathbf{u}(s_2)\mathbf{u}(s_1) \rangle = \exp \left[-(s_2 - s_1) \frac{k_B T}{2\kappa} (D - 1) \right], \quad (15.153)$$

where $D - 1$ in the exponent is the eigenvalue of $\hat{L}^2 = l(l + D - 2)$ at $l = 1$. The correlation function (15.153) agrees with the sliced result (15.124) if we identify the continuous version of the persistence length (15.126) with

$$\xi \equiv 2\kappa/k_B T (D - 1). \quad (15.154)$$

Indeed, taking the limit $a \rightarrow 0$ in (15.125), we find with the help of the asymptotic behavior (8.12) precisely the relation (15.154).

After performing the double-integral in (15.147) we arrive at the desired result for the first moment:

$$\langle R^2 \rangle = 2 \left\{ \xi L - \xi^2 \left[1 - e^{-L/\xi} \right] \right\}. \quad (15.155)$$

⁴I.S. Gradshteyn and I.M. Ryzhik, *op. cit.*, Formula 8.933.1.

This is valid for *all* D . The result may be compared with the expectation value of the squared magnetic moment of the Heisenberg chain in Eq. (15.128), which reduces to this in the limit $a \rightarrow 0$ at fixed $L = (N + 1)a$.

For small L/ξ , the second moment (15.155) has the large-stiffness expansion

$$\langle R^2 \rangle = L^2 \left[1 - \frac{1}{3} \frac{L}{\xi} + \frac{1}{12} \left(\frac{L}{\xi} \right)^2 - \frac{1}{60} \left(\frac{L}{\xi} \right)^3 + \dots \right], \quad (15.156)$$

the first term being characteristic for a completely stiff chain [see Eq. (15.95)]. For large L/ξ , on the other hand, we find the small-stiffness expansion

$$\langle R^2 \rangle \approx 2\xi L \left(1 - \frac{\xi}{L} \right) + \dots, \quad (15.157)$$

where the dots denote exponentially small terms. The first term agrees with relation (15.94) for a random chain with an effective bond length

$$a_{\text{eff}} = 2\xi = \frac{4}{D-1} \frac{\kappa}{k_B T}. \quad (15.158)$$

The calculation of higher expectations $\langle R^{2l} \rangle$ becomes rapidly complicated. Take, for instance, the moment $\langle R^4 \rangle$, which is given by the quadruple integral over the four-point correlation function

$$\langle R^4 \rangle = 8 \int_0^L ds_4 \int_0^{s_4} ds_3 \int_0^{s_3} ds_2 \int_0^{s_2} ds_1 \delta_{i_4 i_3 i_2 i_1} \langle u_{i_4}(s_4) u_{i_3}(s_3) u_{i_2}(s_2) u_{i_1}(s_1) \rangle, \quad (15.159)$$

with the symmetric pair contraction tensor of Eq. (15.22):

$$\delta_{i_4 i_3 i_2 i_1} \equiv (\delta_{i_4 i_3} \delta_{i_2 i_1} + \delta_{i_4 i_2} \delta_{i_3 i_1} + \delta_{i_4 i_1} \delta_{i_3 i_2}). \quad (15.160)$$

The factor 8 and the symmetrization of the indices arise when bringing the integral

$$R^4 = \int_0^L ds_4 \int_0^L ds_3 \int_0^L ds_2 \int_0^L ds_1 (\mathbf{u}(s_4) \mathbf{u}(s_3)) (\mathbf{u}(s_2) \mathbf{u}(s_1)) \quad (15.161)$$

to the s -ordered form in (15.159). This form is needed for the s -ordered evaluation of the \mathbf{u} -integrals which proceeds by a direct extension of the previous procedure for $\langle R^2 \rangle$. We write down the extension of expression (15.148) and perform the integrals over \mathbf{u}_a and \mathbf{u}_b which remove the initial and final distributions via the normalization integral (15.143), leaving $\delta_{i_4 i_3 i_2 i_1}$ times an integral [the extension of (15.149)]:

$$\begin{aligned} \langle \mathbf{u}_{i_4}(s_4) \mathbf{u}_{i_3}(s_3) \mathbf{u}_{i_2}(s_2) \mathbf{u}_{i_1}(s_1) \rangle &= \int d\mathbf{u}_4 \int d\mathbf{u}_3 \int d\mathbf{u}_2 \int \frac{d\mathbf{u}_1}{S_D} \\ &\times u_{i_4} u_{i_3} u_{i_2} u_{i_1} P(\mathbf{u}_4, \mathbf{u}_3 | s_4 - s_3) P(\mathbf{u}_3, \mathbf{u}_2 | s_3 - s_2) P(\mathbf{u}_2, \mathbf{u}_1 | s_2 - s_1). \end{aligned} \quad (15.162)$$

The normalized integral over \mathbf{u}_1 can again be omitted. Still, the expression is complicated. A somewhat tedious calculation yields

$$\begin{aligned} \langle R^4 \rangle = & \frac{4(D+2)}{D} L^2 \xi^2 - 8L\xi^3 \left(\frac{D^2 + 6D - 1}{D^2} - \frac{D-7}{D+1} e^{-L/\xi} \right) \\ & + 4\xi^4 \left[\frac{D^3 + 23D^2 - 7D + 1}{D^3} - 2 \frac{(D+5)^2}{(D+1)^2} e^{-L/\xi} + \frac{(D-1)^5}{D^3(D+1)^2} e^{-2DL/(D-1)\xi} \right]. \end{aligned} \quad (15.163)$$

For small values of L/ξ , we find the large-stiffness expansion

$$\langle R^4 \rangle = L^4 \left[1 - \frac{2L}{3\xi} + \frac{25D-17}{90(D-1)} \left(\frac{L}{\xi} \right)^2 - 4 \frac{7D^2-8D+3}{315(D-1)^2} \left(\frac{L}{\xi} \right)^3 + \dots \right], \quad (15.164)$$

the leading term being equal to (15.95) for a completely stiff chain.

In the opposite limit of large L/ξ , the small-stiffness expansion is

$$\langle R^4 \rangle = 4 \frac{D+2}{D} L^2 \xi^2 \left[1 - 2 \frac{D^2 + 6D - 1}{D(D+2)} \frac{\xi}{L} + \frac{D^3 + 23D^2 - 7D + 1}{D^2(D+2)} \left(\frac{\xi}{L} \right)^2 \right] + \dots, \quad (15.165)$$

where the dots denote exponentially small terms. The leading term agrees again with the expectation $\langle R^4 \rangle$ of Eq. (15.94) for a random chain whose distribution is (15.49) with an effective link length $a_{\text{eff}} = 2\xi$ of Eq. (15.158). The remaining terms are corrections caused by the stiffness of the chain.

It is possible to find a correction factor to the Gaussian distribution which maintains the unit normalization and ensures that the moment $\langle R^2 \rangle$ has the small- ξ exact expansion (15.157) whereas $\langle R^2 \rangle$ is equal to (15.165) up to the first correction term in ξ/L . This has the form

$$P_L(\mathbf{R}) = \sqrt{\frac{D}{4\pi L\xi}} e^{-DR^2/4L\xi} \left\{ 1 - \frac{2D-1}{4} \frac{\xi}{L} + \frac{3D-1}{4} \frac{R^2}{L^2} - \frac{D(4D-1)}{16(D+2)} \frac{R^4}{\xi L^3} \right\}. \quad (15.166)$$

In three dimensions, this was first written down by Daniels [3]. It is easy to match also the moment $\langle R^4 \rangle$ by adding in the curly brackets the following terms

$$\frac{1-7D+23D^2+D^3}{D+1} \left[\frac{D+2}{8D} \frac{\xi^2}{L^2} \left(1 + \frac{R^2}{\xi L} \right) + \frac{1}{32} \frac{R^4}{L^4} \right]. \quad (15.167)$$

These terms do not, however, improve the fits to Monte Carlo data for $\xi > 1/10L$, since the expansion is strongly divergent.

From the approximation (15.166) with the additional term (15.167) we calculate the small-stiffness expansion of all *even and odd* moments as follows:

$$\langle R^n \rangle = \frac{2^n \Gamma(D/2 + n/2)}{D^{n/2} \Gamma(D/2)} L^n \xi^n \left[1 + A_1 \frac{\xi}{L} + A_2 \left(\frac{\xi}{L} \right)^2 + \dots \right], \quad (15.168)$$

where

$$A_1 = n \frac{n-2-2d^2-4d(n-1)}{4d(2+d)}, \quad A_2 = n(n-2) \frac{1-7d+23d^2+d^3}{8d^2(1+d)}. \quad (15.169)$$

15.9 Schrödinger Equation and Recursive Solution for End-to-End Distribution Moments

The most efficient way of calculating the moments of the end-to-end distribution proceeds by setting up a Schrödinger equation satisfied by (15.112) and solving it recursively with similar methods as developed in 3.19 and Appendix 3C.

15.9.1 Setting up the Schrödinger Equation

In the continuum limit, we write (15.112) as a path integral [compare (15.139)]

$$P_L(\mathbf{R}) \propto \int d\mathbf{u}_b \int d\mathbf{u}_a \int \mathcal{D}^{D-1}\mathbf{u} \delta^{(D)}\left(\mathbf{R} - \int_0^L ds \mathbf{u}(s)\right) e^{-(\bar{\kappa}/2) \int_0^L ds [\mathbf{u}'(s)]^2}, \quad (15.170)$$

where we have introduced the reduced stiffness

$$\bar{\kappa} = \frac{\kappa}{k_B T} = (D-1) \frac{\xi}{2}, \quad (15.171)$$

for brevity. After a Fourier representation of the δ -function, this becomes

$$P_L(\mathbf{R}) \propto \int_{-i\infty}^{i\infty} \frac{d^D \lambda}{2\pi i} e^{\bar{\kappa} \boldsymbol{\lambda} \cdot \mathbf{R}/2} \int d\mathbf{u}_b \int d\mathbf{u}_a (\mathbf{u}_b L | \mathbf{u}_a 0)^\lambda, \quad (15.172)$$

where

$$(\mathbf{u}_b L | \mathbf{u}_a 0)^\lambda \equiv \int_{\mathbf{u}(0)=\mathbf{u}_a}^{\mathbf{u}(L)=\mathbf{u}_b} \mathcal{D}^{D-1}\mathbf{u} e^{-(\bar{\kappa}/2) \int_0^L ds \{[\mathbf{u}'(s)]^2 + \boldsymbol{\lambda} \cdot \mathbf{u}(s)\}} \quad (15.173)$$

describes a point particle of mass $M = \bar{\kappa}$ moving on a unit sphere. In contrast to the discussion in Section 8.7 there is now an additional external field $\boldsymbol{\lambda}$ which prevents us from finding an exact solution. However, all even moments $\langle R_{i_1} R_{i_2} \cdots R_{i_{2l}} \rangle$ of the end-to-end distribution (15.172) can be extracted from the expansion coefficients in powers of λ_i of the integral $\int d\mathbf{u}_b \int d\mathbf{u}_a$ over (15.173). The presence of these directional integrals permits us to assume the external electric field $\boldsymbol{\lambda}$ to point in the z -direction, or the D th direction in D -dimensions. Then $\boldsymbol{\lambda} = \lambda \hat{z}$, and the moments $\langle R^{2l} \rangle$ are proportional to the derivatives $(2/\bar{\kappa})^{2l} \partial_\lambda^{2l} \int d\mathbf{u}_b \int d\mathbf{u}_a (\mathbf{u}_b L | \mathbf{u}_a 0)^\lambda$. The proportionality factors have been calculated in Eq. (15.84). It is unnecessary to know these since we can always use the rod limit (15.95) to normalize the moments.

To find these derivatives, we perform a perturbation expansion of the path integral (15.173) around the solvable case $\lambda = 0$.

In natural units with $\bar{\kappa} = 1$, the path integral (15.173) solves obviously the imaginary-time Schrödinger equation

$$\left(-\frac{1}{2} \Delta_{\mathbf{u}} + \frac{1}{2} \boldsymbol{\lambda} \cdot \mathbf{u} + \frac{d}{d\tau} \right) (\mathbf{u} \tau | \mathbf{u}_a 0)^\lambda = 0, \quad (15.174)$$

where $\Delta_{\mathbf{u}}$ is the Laplacian on a unit sphere. In the probability distribution (15.211), only the integrated expression

$$\psi(z, \tau; \lambda) \equiv \int d\mathbf{u}_a (\mathbf{u} \tau | \mathbf{u}_a 0)^\lambda \quad (15.175)$$

appears, which is a function of $z = \cos \theta$ only, where θ is the angle between \mathbf{u} and the electric field $\boldsymbol{\lambda}$. For $\psi(z, \tau; \lambda)$, the Schrödinger equation reads

$$\hat{H} \psi(z, \tau; \lambda) = -\frac{d}{d\tau} \psi(z, \tau; \lambda), \quad (15.176)$$

with the simpler Hamiltonian operator

$$\begin{aligned} \hat{H} &\equiv \hat{H}_0 + \lambda \hat{H}_I = -\frac{1}{2} \Delta + \lambda z \\ &= -\frac{1}{2} \left[(1 - z^2) \frac{d^2}{dz^2} - (D - 1) z \frac{d}{dz} \right] + \frac{1}{2} \lambda z. \end{aligned} \quad (15.177)$$

Now the desired moments (15.135) can be obtained from the coefficient of $\lambda^{2l}/(2l)!$ of the power series expansion of the z -integral over (15.175) at imaginary time $\tau = L$:

$$f(L; \lambda) \equiv \int_{-1}^1 dz \psi(z, L; \lambda). \quad (15.178)$$

15.9.2 Recursive Solution of Schrödinger Equation.

The function $f(L; \lambda)$ has a spectral representation

$$f(L; \lambda) = \sum_{l=0}^{\infty} \frac{\int_{-1}^1 dz \varphi^{(l)\dagger}(z) \exp(-E^{(l)}L) \int_{-1}^1 dz_a \varphi^{(l)}(z_a)}{\int_{-1}^1 dz \varphi^{(l)\dagger}(z) \varphi^{(l)}(z)}, \quad (15.179)$$

where $\varphi^{(l)}(z)$ are the solutions of the time-independent Schrödinger equation $\hat{H}\varphi^{(l)}(z) = E^{(l)}\varphi^{(l)}(z)$. Applying perturbation theory to this problem, we start from the eigenstates of the unperturbed Hamiltonian $\hat{H}_0 = -\Delta/2$, which are given by the Gegenbauer polynomials $C_l^{D/2-1}(z)$ with the eigenvalues $E_0^{(l)} = l(l+D-2)/2$. Following the methods explained in 3.19 and Appendix 3C we now set up a recursion scheme for the perturbation expansion of the eigenvalues and eigenfunctions [4]. Starting point is the expansion of energy eigenvalues and wave-functions in powers of the coupling constant λ :

$$E^{(l)} = \sum_{j=0}^{\infty} \epsilon_j^{(l)} \lambda^j, \quad |\varphi^{(l)}\rangle = \sum_{l', i=0}^{\infty} \gamma_{l', i}^{(l)} \lambda^i \alpha_{l'} |l'\rangle. \quad (15.180)$$

The wave functions $\varphi^{(l)}(z)$ are the scalar products $\langle z | \varphi^{(l)}(\lambda) \rangle$. We have inserted extra normalization constants $\alpha_{l'}$ for convenience which will be fixed soon. The unperturbed state vectors $|l\rangle$ are normalized to unity, but the state vectors $|\varphi^{(l)}\rangle$ of

the interacting system will be normalized in such a way, that $\langle \varphi^{(l)} | l \rangle = 1$ holds to all orders, implying that

$$\gamma_{l,i}^{(l)} = \delta_{i,0} \quad \gamma_{k,0}^{(l)} = \delta_{l,k}. \quad (15.181)$$

Inserting the above expansions into the Schrödinger equation, projecting the result onto the base vector $\langle k | \alpha_k$, and extracting the coefficient of λ^j , we obtain the equation

$$\gamma_{k,i}^{(l)} \epsilon_0^{(k)} + \sum_{j=0}^{\infty} \frac{\alpha_j}{\alpha_k} V_{k,j} \gamma_{j,i-1}^{(l)} = \sum_{j=0}^i \epsilon_j^{(l)} \gamma_{k,i-j}^{(l)}, \quad (15.182)$$

where $V_{k,j} = \lambda \langle k | z | j \rangle$ are the matrix elements of the interaction between unperturbed states. For $i = 0$, Eq. (15.182) is satisfied identically. For $i > 0$, it leads to the following two recursion relations, one for $k = l$:

$$\epsilon_i^{(l)} = \sum_{n=\pm 1} \gamma_{l+n,i-1}^{(l)} W_n^{(l)}, \quad (15.183)$$

the other one for $k \neq l$:

$$\gamma_{k,i}^{(l)} = \frac{\sum_{j=1}^{i-1} \epsilon_j^{(l)} \gamma_{k,i-j}^{(l)} - \sum_{n=\pm 1} \gamma_{k+n,i-1}^{(l)} W_n^{(l)}}{\epsilon_0^{(k)} - \epsilon_0^{(l)}}, \quad (15.184)$$

where only $n = -1$ and $n = 1$ contribute to the sums over n since

$$W_n^{(l)} \equiv \frac{\alpha_{l+n}}{\alpha_l} \langle l | z | l+n \rangle = 0, \quad \text{for } n \neq \pm 1. \quad (15.185)$$

The vanishing of $W_n^{(l)}$ for $n \neq \pm 1$ is due to the band-diagonal form of the matrix of the interaction z in the unperturbed basis $|n\rangle$. It is this property which makes the sums in (15.183) and (15.184) finite and leads to recursion relations with a finite number of terms for all $\epsilon_i^{(l)}$ and $\gamma_{k,i}^{(l)}$. To calculate $W_n^{(l)}$, it is convenient to express $\langle l | z | l+n \rangle$ as matrix elements between unnormalized noninteracting states $|n\rangle$ as

$$\langle l | z | l+n \rangle = \frac{\{l | z | l+n\}}{\sqrt{\{l | l\} \{l+n | l+n\}}}, \quad (15.186)$$

where expectation values are defined by the integrals

$$\{k | F(z) | l\} \equiv \int_{-1}^1 C_k^{D/2-1}(z) F(z) C_l^{D/2-1}(z) (1-z^2)^{(D-3)/2} dz, \quad (15.187)$$

from which we find⁵

$$\{l | l\} = \frac{2^{4-D} \Gamma(l+D-2) \pi}{l! (2l+D-2) \Gamma(D/2-1)^2}. \quad (15.188)$$

⁵I.S. Gradshteyn and I.M. Ryzhik, *op. cit.*, Formulas 7.313.1 and 7.313.2.

Expanding the numerator of (15.186) with the help of the recursion relation (15.151) for the Gegenbauer polynomials written now in the form

$$(l+1)|l+1\rangle = (2l+D-2)z|l\rangle - (l+D-3)|l-1\rangle, \quad (15.189)$$

we find the only non-vanishing matrix elements to be

$$\langle l+1|z|l\rangle = \frac{l+1}{2l+D-2}\langle l+1|l+1\rangle, \quad (15.190)$$

$$\langle l-1|z|l\rangle = \frac{l+D-3}{2l+D-2}\langle l-1|l-1\rangle. \quad (15.191)$$

Inserting these together with (15.188) into (15.186) gives

$$\langle l|z|l-1\rangle = \sqrt{\frac{l(l+D-3)}{(2l+D-2)(2l+D-4)}}, \quad (15.192)$$

and a corresponding result for $\langle l|z|l+1\rangle$. We now fix the normalization constants α_l by setting

$$W_1^{(l)} = \frac{\alpha_{l+1}}{\alpha_l} \langle l|z|l+1\rangle = 1 \quad (15.193)$$

for all l , which determines the ratios

$$\frac{\alpha_l}{\alpha_{l+1}} = \langle l|z|l+1\rangle = \sqrt{\frac{(l+1)(l+D-2)}{(2l+D)(2l+D-2)}}. \quad (15.194)$$

Setting further $\alpha_1 = 1$, we obtain

$$\alpha_l = \left[\prod_{j=1}^l \frac{(2l+D-2)(2l+D-4)}{l(l+D-3)} \right]^{1/2}. \quad (15.195)$$

Using this we find from (15.185) the remaining nonzero $W_n^{(l)}$ for $n = -1$:

$$W_{-1}^{(l)} = \frac{l(l+D-3)}{(2l+D-2)(2l+D-4)}. \quad (15.196)$$

We are now ready to solve the recursion relations of (15.183) and (15.184) $\gamma_{k,i}^{(l)}$ and $\epsilon_i^{(l)}$ order by order in i . For the initial order $i = 0$, the values of the $\gamma_{k,i}^{(l)}$ are given by Eq. (15.181). The coefficients $\epsilon_i^{(l)}$ are equal to the unperturbed energies $\epsilon_0^{(l)} = E_0^{(l)} = l(l+D-2)/2$. For each $i = 1, 2, 3, \dots$, there is only a finite number of non-vanishing $\gamma_{k,j}^{(l)}$ and $\epsilon_j^{(l)}$ with $j < i$ on the right-hand sides of (15.183) and (15.184) which allows us to calculate $\gamma_{k,i}^{(l)}$ and $\epsilon_i^{(l)}$ on the left-hand sides. In this way it is easy to find the perturbation expansions for the energy and the wave functions to high orders.

Inserting the resulting expansions (15.180) into Eq. (15.179), only the totally symmetric parts in $\varphi^{(l)}(z)$ will survive the integration in the numerators, i.e., we may insert only

$$\varphi_{\text{symm}}^{(l)}(z) = \langle z | \varphi_{\text{symm}}^{(l)} \rangle = \sum_{i=0}^{\infty} \gamma_{0,i}^{(l)} \lambda^i \langle z | 0 \rangle. \quad (15.197)$$

The denominators of (15.179) become explicitly $\sum_{l',i} |\gamma_{l',i}^{(l)} \alpha_{l'}|^2 \lambda^{2i}$, where the sum over i is limited by power of λ^2 up to which we want to carry the perturbation series; also l' is restricted to a finite number of terms only, because of the band-diagonal structure of the $\gamma_{l',i}^{(l)}$.

Extracting the coefficients of the power expansion in λ from (15.179) we obtain all desired moments of the end-to-end distribution, in particular the second and fourth moments (15.155) and (15.164). Higher even moments are easily found with the help of a **Mathematica** program, which is available for download in notebook form [5]. The expressions are too lengthy to be written down here. We may, however, expand the even moments $\langle R^n \rangle$ in powers of L/ξ to find a general large-stiffness expansion valid for all even *and odd* n :

$$\frac{\langle R^n \rangle}{L^n} = 1 - \frac{nL}{6\xi} + \frac{n(-13-n+5D(1+n))L^2}{360(D-1)\xi^2} - a_3 \frac{L^3}{\xi^3} + a_4 \frac{L^4}{\xi^4} + \dots, \quad (15.198)$$

where

$$a_3 = n \frac{444 - 63n + 15n^2 + 7D^2(4 + 15n + 5n^2) + 2D(-124 - 141n + 7n^2)}{45360(D-1)^2},$$

$$a_4 = \frac{n}{5443200(d-1)^3} (D_0 + D_1 d + D_2 d^2 + D_3 d^3), \quad (15.199)$$

with

$$D_0 = 3(-5610 + 2921n - 822n^2 + 67n^3), \quad D_1 = 8490 + 12103n - 3426n^2 + 461n^3,$$

$$D_2 = 45(-2 - 187n - 46n^2 + 7n^3), \quad D_4 = 35(-6 + 31n + 30n^2 + 5n^3). \quad (15.200)$$

The lowest odd moments are, up to order l^4 ,

$$\frac{\langle R \rangle}{L} = 1 - \frac{l}{6} + \frac{5D-7}{180(D-1)} l^2 - \frac{33-43D+14D^2}{3780(D-1)^2} l^3 - \frac{861-1469D+855D^2-175D^3}{453600(D-1)^3} l^4 \dots,$$

$$\frac{\langle R^3 \rangle}{L^3} = 1 - \frac{l}{2} + \frac{5D-4}{30(D-1)} l^2 - \frac{195-484D+329D^2}{7560(-1+d)^2} l^3 - \frac{609-2201D+2955D^2-1435D^3}{151200(D-1)^3} l^4 \dots$$

15.9.3 From Moments to End-to-End Distribution for $L=3$

We now use the recursively calculated moments to calculate the end-to-end distribution itself. It can be parameterized by an analytic function of $r = R/L$ [4]:

$$P_L(\mathbf{R}) \propto r^k (1 - r^\beta)^m, \quad (15.201)$$

whose moments are exactly calculable:

$$\langle r^{2l} \rangle = \frac{\Gamma\left(\frac{3+k+2l}{\beta}\right) \Gamma\left(\frac{3+k}{\beta} + m + 1\right)}{\Gamma\left(\frac{3+k}{\beta}\right) \Gamma\left(\frac{3+k+2l}{\beta} + m + 1\right)}. \tag{15.202}$$

We now adjust the three parameters k , β , and m to fit the three most important moments of this distribution to the exact values, ignoring all others. If the distances were distributed uniformly over the interval $r \in [0, 1]$, the moments would be $\langle r^{2l} \rangle^{\text{unif}} = 1/(2l + 2)$. Comparing our exact moments $\langle r^{2l} \rangle(\xi)$ with those of the uniform distribution we find that $\langle r^{2l} \rangle(\xi)/\langle r^{2l} \rangle^{\text{unif}}$ has a maximum for n close to $n_{\text{max}}(\xi) \equiv 4\xi/L$. We identify the most important moments as those with $n = n_{\text{max}}(\xi)$ and $n = n_{\text{max}}(\xi) \pm 1$. If $n_{\text{max}}(\xi) \leq 1$, we choose the lowest even moments $\langle r^2 \rangle$, $\langle r^4 \rangle$, and $\langle r^6 \rangle$. In particular, we have fitted $\langle r^2 \rangle$, $\langle r^4 \rangle$ and $\langle r^6 \rangle$ for small persistence length $\xi < L/2$. For $\xi = L/2$, we have started with $\langle r^4 \rangle$, for $\xi = L$ with $\langle r^8 \rangle$ and for $\xi = 2L$ with $\langle r^{16} \rangle$, including always the following two higher even moments. After these adjustments, whose results are shown in Fig. 15.4, we obtain the distributions shown in Fig.15.6 for various persistence lengths ξ . They are in excellent agreement with the Monte Carlo data (symbols) and better than the one-loop perturbative results (thin curves) of Ref. [6], which are good only for very stiff polymers. The **Mathematica** program to do these fits are available from the internet address given in Footnote 5.

Figure 15.4 Paramters k , β , and m for a best fit of end-to-end distribution (15.201).

For small persistence lengths $\xi/L = 1/400, 1/100, 1/30$, the curves are well approximated by Gaussian random chain distributions on a lattice with lattice constant $a_{\text{eff}} = 2\xi$, i.e., $P_L(\mathbf{R}) \rightarrow e^{-3R^2/4L\xi}$ [recall (15.75)]. This ensures that the lowest moment $\langle R^2 \rangle = a_{\text{eff}}L$ is properly fitted. In fact, we can easily check that our fitting program yields for the parameters k, β, m in the end-to-end distribution (15.201) the $\xi \rightarrow 0$ behavior: $k \rightarrow -\xi$, $\beta \rightarrow 2 + 2\xi$, $m \rightarrow 3/4\xi$, so that (15.201) tends to the correct Gaussian behavior.

In the opposite limit of large ξ , we find that $k \rightarrow 10\xi - 7/2$, $\beta \rightarrow 40\xi + 5$, $m \rightarrow 10$, which has no obvious analytic approach to the exact limiting behavior $P_L(\mathbf{R}) \rightarrow (1 - r)^{-5/2} e^{-1/4\xi(1-r)}$, although the distribution at $\xi = 2$ is fitted numerically extremely well.

The distribution functions can be inserted into Eq. (15.89) to calculate the structure factors shown in Fig. 15.5. They interpolate smoothly between the Debye limit (15.90) and the stiff limit (15.105).

Figure 15.5 Structure functions for different persistence lengths $\xi/L = 1/400, 1/100, 1/30, 1/10, 1/5, 1/2, 1, 2$, (from bottom to top) following from the end-to-end distributions in Fig. 15.6. The curves with low ξ almost coincide in this plot over the ξ -dependent abscissa. The very stiff curves fall off like $1/q$, the soft ones like $1/q^2$ [see Eqs. (15.105) and (15.90)].

15.9.4 Large-Stiffness Approximation to End-to-End Distribution

The full end-to-end distribution (15.132) cannot be calculated exactly. It is, however, quite easy to find a satisfactory approximation for large stiffness [6].

We start with the expression (15.170) for the end-to-end distribution $P_L(\mathbf{R})$. In Eq. (3.233) we have shown that a harmonic path integral including the integrals over the end points can be found, up to a trivial factor, by summing over all paths with Neumann boundary conditions. These are satisfied if we expand the fields $\mathbf{u}(s)$ into a Fourier series of the form (2.452):

$$\mathbf{u}(s) = \mathbf{u}_0 + \boldsymbol{\eta}(s) = \mathbf{u}_0 + \sum_{n=1}^{\infty} \mathbf{u}_n \cos \nu_n s, \quad \nu_n = n\pi/L. \quad (15.203)$$

Let us parametrize the unit vectors \mathbf{u} in D dimensions in terms of the first $D - 1$ -dimensional coordinates $u^\mu \equiv q^\mu$ with $\mu = 1, \dots, D - 1$. The D th component is then given by a power series

$$\sigma \equiv \sqrt{1 - q^2} \approx 1 - q^2/2 - (q^2)^2/8 + \dots \quad (15.204)$$

The we approximate the action harmonically as follows:

$$\begin{aligned} \mathcal{A} &= \mathcal{A}^{(0)} + \mathcal{A}^{\text{int}} = \frac{\bar{\kappa}}{2} \int_0^L ds [\mathbf{u}'(s)]^2 + \frac{1}{2} \delta(0) \log(1 - q^2) \\ &\approx \frac{\bar{\kappa}}{2} \int_0^L ds [q'(s)]^2 - \frac{1}{2} \delta(0) \int_0^L ds q^2. \end{aligned} \quad (15.205)$$

The last term comes from the invariant measure of integration $d^{D-1}q/\sqrt{1-q^2}$ [recall (10.636) and (10.641)].

Assuming, as before, that \mathbf{R} points into the z , or D th, direction we factorize

$$\begin{aligned} \delta^{(D)}\left(\mathbf{R}-\int_0^L ds \mathbf{u}(s)\right) &= \delta\left(R-L+\int_0^L ds \left\{\frac{1}{2}q^2(s)+\frac{1}{8}[q^2(s)]^2+\dots\right\}\right) \\ &\times \delta^{(D-1)}\left(\int_0^L ds q(s)\right), \end{aligned} \quad (15.206)$$

where $R \equiv |\mathbf{R}|$. The second δ -function on the right-hand side enforces

$$\bar{q} = L^{-1} \int_0^L ds q^\mu(s) = 0, \quad \mu = 1, \dots, d-1, \quad (15.207)$$

and thus the vanishing of the zero-frequency parts q_0^μ in the first $D-1$ components of the Fourier decomposition (15.203).

It was shown in Eqs. (10.632) and (10.642) that the last δ -function has a distorting effect upon the measure of path integration which must be compensated by a Faddeev-Popov action

$$\mathcal{A}_e^{\text{FP}} = \frac{D-1}{2L} \int_0^L ds q^2, \quad (15.208)$$

where the number D of dimensions of q^μ -space (10.642) has been replaced by the present number $D-1$.

In the large-stiffness limit we have to take only the first harmonic term in the action (15.205) into account, so that the path integral (15.170) becomes simply

$$P_L(\mathbf{R}) \propto \int_{\text{NBC}} \mathcal{D}'^{D-1} q \delta\left(R-L+\int_0^L ds \frac{1}{2}q^2(s)\right) e^{-(\bar{\kappa}/2) \int_0^L ds [q'(s)]^2}. \quad (15.209)$$

The subscript of the integral emphasizes the Neumann boundary conditions. The prime on the measure of the path integral indicates the absence of the zero-frequency component of $q^\mu(s)$ in the Fourier decomposition due to (15.207). Representing the remaining δ -function in (15.209) by a Fourier integral, we obtain

$$P_L(\mathbf{R}) \propto \bar{\kappa} \int_{-i\infty}^{i\infty} \frac{d\omega^2}{2\pi i} e^{\bar{\kappa}\omega^2(L-R)} \int_{\text{NBC}} \mathcal{D}'^{D-1} q \exp\left[-\frac{\bar{\kappa}}{2} \int_0^L ds (q'^2 + \omega^2 q^2)\right]. \quad (15.210)$$

The integral over all paths with Neumann boundary conditions is known from Eq. (2.456). At zero average path, the result is

$$\int_{\text{NBC}} \mathcal{D}'^{D-1} q \exp\left[-\frac{\bar{\kappa}}{2} \int_0^L ds (q'^2 + \omega^2 q^2)\right] \propto \left(\frac{\omega L}{\sinh \omega L}\right)^{(D-1)/2}, \quad (15.211)$$

so that

$$P_L(\mathbf{R}) \propto \bar{\kappa} \int_{-i\infty}^{i\infty} \frac{d\omega^2}{2\pi i} e^{\bar{\kappa}\omega^2(L-R)} \left(\frac{\omega L}{\sinh \omega L}\right)^{(D-1)/2}. \quad (15.212)$$

The integral can easily be done in $D = 3$ dimensions using the original product representation (2.455) of $\omega L / \sinh \omega L$, where

$$P_L(\mathbf{R}) \propto \bar{\kappa} \int_{-i\infty}^{i\infty} \frac{d\omega^2}{2\pi i} e^{\bar{\kappa}\omega^2(L-R)} \prod_{n=1}^{\infty} \left(1 + \frac{\omega^2}{\nu_n^2}\right)^{-1}. \quad (15.213)$$

If we shift the contour of integration to the left we run through poles at $\omega^2 = -\nu_k^2$ with residues

$$\sum_{k=1}^{\infty} \nu_k^2 \prod_{n(\neq k)=1}^{\infty} \left(1 - \frac{k^2}{n^2}\right)^{-1}. \quad (15.214)$$

The product is evaluated by the limit procedure for small ϵ :

$$\begin{aligned} \left\{ \prod_{n=1}^{\infty} \left[1 - \frac{(k+\epsilon)^2}{n^2}\right]^{-1} \right\} \left[1 - \frac{(k+\epsilon)^2}{k^2}\right] &\rightarrow \frac{(k+\epsilon)\pi}{\sin(k+\epsilon)\pi} \frac{-2\epsilon}{k} \rightarrow \frac{-2\epsilon\pi}{\sin(k+\epsilon)\pi} \\ &\rightarrow -\frac{2\epsilon\pi}{\cos k\pi \sin \epsilon\pi} \rightarrow 2(-1)^{k+1}. \end{aligned} \quad (15.215)$$

Hence we obtain [6]

$$P_L(\mathbf{R}) \propto \sum_{k=1}^{\infty} 2(-1)^{k+1} \bar{\kappa} \nu_k^2 e^{-\bar{\kappa}\nu_k^2(L-R)}. \quad (15.216)$$

It is now convenient to introduce the reduced end-to-end distance $r \equiv R/L$ and the *flexibility* of the polymer $l \equiv L/\xi$, and replace $\bar{\kappa} \nu_k^2 (L-R) \rightarrow k^2 \pi^2 (1-r)/l$ so that (15.216) becomes

$$P_L(\mathbf{R}) = \mathcal{N} L(\mathbf{R}) = \mathcal{N} \sum_{k=1}^{\infty} (-1)^{k+1} k^2 \pi^2 e^{-k^2 \pi^2 (1-r)/l}, \quad (15.217)$$

where \mathcal{N} is a normalization factor determined to satisfy

$$\int d^3 R P_L(\mathbf{R}) = 4\pi L^3 \int_0^{\infty} dr r^2 P_L(\mathbf{R}) = 1. \quad (15.218)$$

The sum must be evaluated numerically, and leads to the distributions shown in Fig. 15.6.

The above method is inconvenient if $D \neq 3$, since the simple pole structure of (15.213) is no longer there. For general D , we expand

$$\left(\frac{\omega L}{\sinh \omega L}\right)^{(D-1)/2} = (\omega L)^{(D-1)/2} \sum_{k=0}^{\infty} (-1)^k \binom{-(D-1)/2}{k} e^{-(2k+(D-1)/2)\omega L}, \quad (15.219)$$

and obtain from (15.212):

$$P_L(\mathbf{R}) \propto \sum_{k=0}^{\infty} (-1)^k \binom{-(D-1)/2}{k} I_k(R/L), \quad (15.220)$$

Figure 15.6 Normalized end-to-end distribution of stiff polymer according to our analytic formula (15.201) plotted for persistence lengths $\xi/L = 1/400, 1/100, 1/30, 1/10, 1/5, 1/2, 1, 2$ (fat curves). They are compared with the Monte Carlo calculations (symbols) and with the large-stiffness approximation (15.217) (thin curves) of Ref. [6] which fits well for $\xi/L = 2$ and 1 but becomes bad small $\xi/L < 1$. For very small values such as $\xi/L = 1/400, 1/100, 1/30$, our theoretical curves are well approximated by Gaussian random chain distributions on a lattice with lattice constant $a_{\text{eff}} = 2\xi$ of Eq. (15.158) which ensures that the lowest moments $\langle R^2 \rangle = a_{\text{eff}}L$ are properly fitted. The Daniels approximation (15.166) fits our theoretical curves well up to larger $\xi/L \approx 1/10$.

with the integrals

$$I_k(r) \equiv \int_{-i\infty}^{i\infty} \frac{d\bar{\omega}}{2\pi i} \bar{\omega}^{(D+1)/2} e^{-[2k+(D-1)/2]\bar{\omega}+(D-1)\bar{\omega}^2(1-r)/2l}, \tag{15.221}$$

where $\bar{\omega}$ is the dimensionless variable ωL . The integrals are evaluated with the help of the formula⁶

$$\int_{-i\infty}^{i\infty} \frac{dx}{2\pi i} x^\nu e^{\beta x^2/2 - qx} = \frac{1}{\sqrt{2\pi}\beta^{(\nu+1)/2}} e^{-q^2/4\beta} D_\nu\left(q/\sqrt{\beta}\right), \tag{15.222}$$

where $D_\nu(z)$ is the parabolic cylinder functions which for integer ν are proportional to Hermite polynomials:⁷

$$D_n(z) = \frac{1}{\sqrt{2}^n} e^{-z^2/4} H_n(z/\sqrt{2}). \tag{15.223}$$

Thus we find

⁶I.S. Gradshteyn and I.M. Ryzhik, *op. cit.*, Formulas 3.462.3 and 3.462.4.

⁷*ibid.*, Formula 9.253.

$$I_k(r) = \frac{1}{\sqrt{2\pi}} \left[\frac{l}{(D-1)(1-r)} \right]^{(D+3)/4} e^{-\frac{[2k+(D-1)/2]^2}{4(D-1)(1-r)/l}} D_{(D+1)/2} \left(\frac{2k+(D-1)/2}{\sqrt{(D-1)(1-r)/l}} \right), \tag{15.224}$$

which becomes for $D = 3$

$$I_k(r) = \frac{1}{2\sqrt{2\pi}} \frac{1}{\sqrt{2(1-r)/l}} e^{-\frac{(2k+1)^2}{4(1-r)/l}} H_2 \left(\frac{2k+1}{2\sqrt{(1-r)/l}} \right). \tag{15.225}$$

If the sum (15.220) is performed numerically for $D = 3$, and the integral over $P_L(\mathbf{R})$ is normalized to satisfy (15.218), the resulting curves fall on top of those in Fig. 15.6 which were calculated from (15.217). In contrast to (15.217), which converges rapidly for small r , the sum (15.220) convergent rapidly for r close to unity.

Let us compare the low moments of the above distribution with the exact moments in Eqs. (15.156) and (15.164). in the large-stiffness expansion. We set $\bar{\omega} \equiv \omega L$ and expand

$$f(\bar{\omega}^2) \equiv \sqrt{\frac{\bar{\omega}^{D-1}}{\sinh \bar{\omega}}} \tag{15.226}$$

in a power series

$$f(\bar{\omega}^2) = 1 - \frac{D-1}{2^2 \cdot 3} \bar{\omega}^2 + \frac{(D-1)(5D-1)}{2^5 \cdot 3^2 \cdot 5} \bar{\omega}^4 - \frac{(D-1)(15+14D+35D^2)}{2^7 \cdot 3^4 \cdot 5 \cdot 7} \bar{\omega}^6 + \dots \tag{15.227}$$

Under the integral (15.212), each power of $\bar{\omega}^2$ may be replaced by a differential operator

$$\bar{\omega}^2 \rightarrow \hat{\omega}^2 \equiv -\frac{L}{\bar{\kappa}} \frac{d}{dr} = -\frac{2l}{D-1} \frac{d}{dr}. \tag{15.228}$$

The expansion $f(\hat{\omega}^2)$ can then be pulled out of the integral, which by itself yields a δ -function, so that we obtain $P_L(\mathbf{R})$ in the form $f(\hat{\omega}^2) \delta(r-1)$, which is a series of derivatives of δ -functions of $r-1$ starting with

$$P_L(\mathbf{R}) \propto \left[1 + \frac{l}{6} \frac{d}{dr} + \frac{(-1+5D)l^2}{360(D-1)} \frac{d^2}{dr^2} + \frac{(15+14D+35D^2)l^3}{45360(D-1)^2} \frac{d^3}{dr^3} + \dots \right] \delta(r-1). \tag{15.229}$$

From this we find easily the moments

$$\langle R^m \rangle = \int d^D R R^m P_L(\mathbf{R}) \propto \int_0^\infty dr r^{D-1} r^m P_L(\mathbf{R}). \tag{15.230}$$

Let us introduce auxiliary expectation values with respect to the simple integrals $\langle f(r) \rangle_1 \propto \int dr f(r) P_L$, rather than to D -dimensional volume integrals. The unnormalized moments $\langle r^m \rangle$ are then given by $\langle r^{D-1+m} \rangle_1$. Within these one-dimensional expectations, the moments of $z = r - 1$ are

$$\langle (r-1)^n \rangle_1 \propto \int_0^\infty dr (r-1)^n P_L(\mathbf{R}). \tag{15.231}$$

The moments $\langle r^m \rangle \langle [1+(r-1)]^m \rangle = \langle [1+(r-1)]^{D-1+m} \rangle_1$ are obtained by expanding the binomial in powers of $r-1$ and using the integrals $\int dz z^m \delta^{(n)}(z) = (-1)^m m! \delta_{mn}$ to find, up to the third power in $L/\xi = l$,

$$\begin{aligned} \langle R^0 \rangle &= \mathcal{N} \left[1 - \frac{D-1}{6}l + \frac{(5D-1)(D-2)}{360}l^2 - \frac{(35D^3+14D+15)(D-2)(D-3)}{45360(D-1)}l^3 \right], \\ \langle R^2 \rangle &= \mathcal{N}L^2 \left[1 - \frac{D+1}{6}l + \frac{(5D-1)D(D+1)}{360(D-1)}l^2 - \frac{(35D^2+14D+15)D(D+1)}{45360(D-1)}l^3 \right], \\ \langle R^4 \rangle &= \mathcal{N}L^4 \left[1 - \frac{D+3}{6}l + \frac{(5D-1)(D+2)(D+3)}{360(D-1)}l^2 \right. \\ &\quad \left. - \frac{(35D^2+14D+15)(D+1)(D+2)(D+3)}{45360(D-1)^2}l^3 \right]. \end{aligned}$$

The zeroth moment determines the normalization factor \mathcal{N} to ensure that $\langle R^0 \rangle = 1$. Dividing this out of the other moments yields

$$\langle R^2 \rangle = L^2 \left[1 - \frac{1}{3}l + \frac{13D-9}{180(D-1)}l^2 - \frac{8}{945}l^3 + \dots \right], \tag{15.232}$$

$$\langle R^4 \rangle = L^4 \left[1 - \frac{2}{3}l + \frac{23D-11}{90(D-1)}l^2 - \frac{123D^2-98D+39}{1890(D-1)^2}l^3 + \dots \right]. \tag{15.233}$$

These agree up to the l -terms with the exact expansions (15.156) and (15.164) [or with the general formula (15.198)]. For $D = 3$, these expansions become

$$\langle R^2 \rangle = L^2 \left[1 - \frac{1}{3}l + \frac{1}{12}l^2 - \frac{8}{945}l^3 + \dots \right], \tag{15.234}$$

$$\langle R^4 \rangle = L^4 \left[1 - \frac{2}{3}l + \frac{29}{90}l^2 - \frac{71}{630}l^3 + \dots \right]. \tag{15.235}$$

Remarkably, these happen to agree in one more term with the exact expansions (15.156) and (15.164) than expected, as will be understood after Eq. (15.295).

15.9.5 Higher Loop Corrections

Let us calculate perturbative corrections to the large-stiffness limit. For this we replace the harmonic path integral (15.210) by the full expression

$$P(r; L) = S_D^{-1} \int_{\text{NBC}} \mathcal{D}'^{D-1} q(s) \delta \left(r - L^{-1} \int_0^L ds \sqrt{1 - q^2(s)} \right) e^{-\mathcal{A}^{\text{tot}}[q] - \mathcal{A}^{\text{cor}}[q_b, q_a]}, \tag{15.236}$$

where

$$\mathcal{A}_{\text{tot}}[q] = \frac{1}{2\varepsilon} \int_0^L ds [g_{\mu\nu}(q) \dot{q}^\mu(s) \dot{q}^\nu(s) - \varepsilon \delta(s, s) \log g(q(s))] + \mathcal{A}^{\text{FP}} - \varepsilon L \frac{R}{8}. \tag{15.237}$$

For convenience, we have introduced here the parameter $\varepsilon = k_B T / \kappa = 1/\bar{\kappa}$, the reduced *inverse stiffness*, related to the flexibility $l \equiv L/\xi$ by $l = \varepsilon L(d-1)/2$. We also have added the correction term $\varepsilon L R/8$ to have a unit normalization of the partition function

$$Z = S_D \int_0^\infty dr r^{D-1} P(r; L) = 1. \tag{15.238}$$

The Faddeev-Popov action, whose harmonic approximation was used in (15.208), is now

$$\mathcal{A}^{\text{FP}}[q] = -(D-1) \log \left(L^{-1} \int_0^L ds \sqrt{1-q^2(s)} \right), \quad (15.239)$$

To perform higher-order calculations we have added an extra action which corrects for the omission of fluctuations of the velocities at the endpoints when restricting the paths to Neumann boundary conditions with zero end-point velocities. The extra action contains, of course, only at the endpoints and reads [7]

$$\mathcal{A}^{\text{cor}}[q_b, q_a] = -\log J[q_b, q_a] = -[q^2(0) + q^2(L)]/4. \quad (15.240)$$

Thus we represent the partition function (15.238) by the path integral with Neumann boundary conditions

$$Z = \int_{\text{NBC}} \mathcal{D}'^{D-1} q(s) \exp \{ -\mathcal{A}_{\text{tot}}[q] - \mathcal{A}^{\text{cor}}[q_b, q_a] - \mathcal{A}^{\text{FP}}[q] \}. \quad (15.241)$$

A similar path integral can be set up for the moments of the distribution. We express the square distance \mathbf{R}^2 in coordinates (15.207) as

$$\mathbf{R}^2 = \int_0^L ds \int_0^L ds' \mathbf{u}(s) \cdot \mathbf{u}(s') = \left(\int_0^L ds \sqrt{1-q^2(s)} \right)^2 = R^2, \quad (15.242)$$

we find immediately the following representation for all, even and odd, moments [compare (15.147)]

$$\langle (\mathbf{R}^2)^n \rangle = \left\langle \left[\int_0^L \int_0^L ds ds' \mathbf{u}(s) \cdot \mathbf{u}(s') \right]^n \right\rangle \quad (15.243)$$

in the form

$$\langle R^n \rangle = \int_{\text{NBC}} \mathcal{D}'^{D-1} q(s) \exp \{ -\mathcal{A}_{\text{tot}}[q] - \mathcal{A}_{\text{cor}}[q_b, q_a] - \mathcal{A}_n^{\text{FP}}[q] \}. \quad (15.244)$$

This differs from Eq. (15.241) only by in the Faddeev-Popov action for these moments, which is

$$\mathcal{A}_n^{\text{FP}}[q] = -(n+D-1) \log \left(L^{-1} \int_0^L ds \sqrt{1-q^2(s)} \right), \quad (15.245)$$

rather than (15.239).

There is no need to divide the path integral (15.244) by Z since this has unit normalization, as will be verified order by order in the perturbation expansion. The Green function of the operator d^2/ds^2 with these boundary conditions has the form

$$\Delta'_N(s, s') = \frac{L}{3} - \frac{|s-s'|}{2} - \frac{(s+s')}{2} + \frac{(s^2+s'^2)}{2L}. \quad (15.246)$$

The zero temporal average (15.207) manifests itself in the property

$$\int_0^L ds \Delta'_N(s, s') = 0. \quad (15.247)$$

In the following we shall simply write $\Delta(s, s')$ for $\Delta'_N(s, s')$, for brevity.

Partition Function and Moments Up to Four Loops

We are now prepared to perform the explicit perturbative calculation of the partition function and all even moments in powers of the inverse stiffness ε up to order $\varepsilon^2 \propto l^2$. This requires evaluating Feynman diagrams up to four loops. The associated integrals will contain products of distributions, which will be calculated unambiguously with the help of our simple formulas in Chapter 10.

For a systematic treatment of the expansion parameter ε , we rescale the coordinates $q^\mu \rightarrow \varepsilon q^\mu$, and rewrite the path integral (15.244) as

$$\langle R^n \rangle = \int_{\text{NBC}} \mathcal{D}'^{D-1} q(s) \exp \{ -\mathcal{A}_{\text{tot},n}[q; \varepsilon] \}, \quad (15.248)$$

with the total action

$$\begin{aligned} \mathcal{A}_{\text{tot},n}[q; \varepsilon] &= \int_0^L ds \left[\frac{1}{2} \left(\dot{q}^2 + \varepsilon \frac{(q\dot{q})^2}{1 - \varepsilon q^2} \right) + \frac{1}{2} \delta(0) \log(1 - \varepsilon q^2) \right] \\ &- \sigma_n \log \left[\frac{1}{L} \int_0^L ds \sqrt{1 - \varepsilon q^2} \right] - \frac{\varepsilon}{4} [q^2(0) + q^2(L)] - \varepsilon L \frac{R}{8}. \end{aligned} \quad (15.249)$$

The constant σ_n is an abbreviation for

$$\sigma_n \equiv n + (d - 1). \quad (15.250)$$

For $n = 0$, the path integral (15.248) must yield the normalized partition function $Z = 1$.

For the perturbation expansion we separate

$$\mathcal{A}_{\text{tot},n}[q; \varepsilon] = \mathcal{A}^{(0)}[q] + \mathcal{A}_n^{\text{int}}[q; \varepsilon], \quad (15.251)$$

with a free action

$$\mathcal{A}^{(0)}[q] = \frac{1}{2} \int_0^L ds \dot{q}^2(s), \quad (15.252)$$

and a large-stiffness expansion of the interaction

$$\mathcal{A}_n^{\text{int}}[q; \varepsilon] = \varepsilon \mathcal{A}_n^{\text{int}1}[q] + \varepsilon^2 \mathcal{A}_n^{\text{int}2}[q] + \dots \quad (15.253)$$

The free part of the path integral (15.248) is normalized to unity:

$$Z^{(0)} \equiv \int_{\text{NBC}} \mathcal{D}'^{D-1} q(s) e^{-\mathcal{A}^{(0)}[q]} = \int_{\text{NBC}} \mathcal{D}'^{D-1} q(s) e^{-(1/2) \int_0^L ds \dot{q}^2(s)} = 1. \quad (15.254)$$

The first expansion term of the interaction (15.253) is

$$\mathcal{A}_n^{\text{int}1}[q] = \frac{1}{2} \int_0^L ds \{ [q(s)\dot{q}(s)]^2 - \rho_n(s) q^2(s) \} - L \frac{R}{8}, \quad (15.255)$$

where

$$\rho_n(s) \equiv \delta_n + [\delta(s) + \delta(s - L)]/2, \quad \delta_n \equiv \delta(0) - \sigma_n/L. \quad (15.256)$$

The second term in $\rho_n(s)$ represents the end point terms in the action (15.249) and is important for canceling singularities in the expansion.

The next expansion term in (15.253) reads

$$\begin{aligned} \mathcal{A}_n^{\text{int}2}[q] &= \frac{1}{2} \int_0^L ds \left\{ [q(s)\dot{q}(s)]^2 - \frac{1}{2} \left[\delta(0) - \frac{\sigma_n}{2L} \right] q^2(s) \right\} q^2(s) \\ &+ \frac{\sigma_n}{8L^2} \int_0^L ds \int_0^L ds' q^2(s) q^2(s'). \end{aligned} \quad (15.257)$$

The perturbation expansion of the partition function in powers of ε consists of expectation values of the interaction and its powers to be calculated with the free partition function (15.254). For an arbitrary functional of $q(s)$, these expectation values will be denoted by

$$\langle F[q] \rangle_0 \equiv \int_{\text{NBC}} \mathcal{D}'^{D-1} q(s) F[q] e^{-(1/2) \int_0^L ds \dot{q}^2(s)}. \quad (15.258)$$

With this notation, the perturbative expansion of the path integral (15.248) reads

$$\begin{aligned} \langle R^n \rangle / L^n &= 1 - \langle \mathcal{A}_n^{\text{int}}[q; \varepsilon] \rangle_0 + \frac{1}{2} \langle \mathcal{A}_n^{\text{int}}[q; \varepsilon]^2 \rangle_0 - \dots \\ &= 1 - \varepsilon \langle \mathcal{A}_n^{\text{int}1}[q] \rangle_0 + \varepsilon^2 \left(-\langle \mathcal{A}_n^{\text{int}2}[q] \rangle_0 + \frac{1}{2} \langle \mathcal{A}_n^{\text{int}1}[q]^2 \rangle_0 \right) - \dots \end{aligned} \quad (15.259)$$

For the evaluation of the expectation values we must perform all possible Wick contractions with the basic propagator

$$\langle q^\mu(s) q^\nu(s') \rangle_0 = \delta^{\mu\nu} \Delta(s, s'), \quad (15.260)$$

where $\Delta(s, s')$ is the Green function (15.246) of the unperturbed action (15.252). The relevant loop integrals I_i and H_i are calculated using the dimensional regularization rules of Chapter 10. They are listed in Appendix 15A and Appendix 15B.

We now state the results for various terms in the expansion (15.259):

$$\begin{aligned} \langle \mathcal{A}_n^{\text{int}1}[q] \rangle_0 &= \frac{(D-1)}{2} \left[\frac{\sigma_n}{L} I_1 + D I_2 - \frac{1}{2} \Delta(0, 0) - \frac{1}{2} \Delta(L, L) \right] - L \frac{R}{8} = L \frac{(D-1)n}{12}, \\ \langle \mathcal{A}_n^{\text{int}2}[q] \rangle_0 &= \frac{(D^2-1)}{4} \left[\left(\delta(0) + \frac{\sigma_n}{2L} \right) I_3 + 2(D+2) I_4 \right] + \frac{(D-1)\sigma_n}{8L^2} [(D-1) I_1^2 + 2I_5] \\ &= L^3 \frac{(D^2-1)}{120} \delta(0) + L^2 \frac{(D-1)}{1440} [(25D^2 + 36D + 23) + n(11D + 5)], \\ \frac{1}{2} \langle \mathcal{A}_n^{\text{int}1}[q]^2 \rangle_0 &= \frac{L^2}{2} \left\{ \frac{(D-1)L}{12} \left[\left(\delta(0) + \frac{D}{2L} \right) - \left(\delta_n + \frac{2}{L} \right) \right] - \frac{R}{8} \right\}^2 \\ &+ \frac{(D-1)}{4} [H_1^n - 2(H_2^n + H_3^n - H_5) + H_6 - 4D(H_4^n - H_7 - H_{10}) \\ &+ H_{11} + 2D^2(H_8 + H_9)] + \frac{(D-1)}{4} [DH_{12} + 2(D+2)H_{13} + DH_{14}] \\ &= \frac{L^2}{2} \left[\frac{(D-1)n}{12} \right]^2 + L^3 \frac{(D-1)}{120} \delta(0) \\ &+ L^2 \frac{(D-1)}{1440} [(25D^2 - 22D + 25) + 4(n + 4D - 2)] \\ &+ L^3 \frac{(D-1)D}{120} \delta(0) + L^2 \frac{(D-1)}{720} (29D - 1). \end{aligned} \quad (15.261)$$

Inserting these results into Eq. (15.259), we find all *even and odd moments* up to order $\varepsilon^2 \propto l^2$

$$\begin{aligned} \langle R^n \rangle / L^n &= 1 - \varepsilon L \frac{(D-1)n}{12} + \varepsilon^2 L^2 \left[\frac{(D-1)^2 n^2}{288} + \frac{(D-1)(4n + 5D - 13)n}{1440} \right] - \mathcal{O}(\varepsilon^3) \\ &= 1 - \frac{n}{6} l + \left[\frac{n^2}{72} + \frac{(4n + 5D - 13)n}{360(D-1)} \right] l^2 - \mathcal{O}(l^3). \end{aligned} \quad (15.262)$$

For $n = 0$ this gives the properly normalized partition function $Z = 1$. For all n it reproduces the large-stiffness expansion (15.198) up to order l^4 .

Correlation Function Up to Four Loops

As an important test of the correctness of our perturbation theory we calculating the correlation function up to four loops and verify that it yields the simple expression (15.153), which reads in the present units

$$G(s, s') = e^{-|s-s'|/\xi} = e^{-|s-s'|l/L}. \tag{15.263}$$

Starting point is the path integral representation with Neumann boundary conditions for the two-point correlation function

$$G(s, s') = \langle \mathbf{u}(s) \cdot \mathbf{u}(s') \rangle = \int_{\text{NBC}} \mathcal{D}'^{D-1} q(s) f(s, s') \exp \left\{ -\mathcal{A}_{\text{tot}}^{(0)}[q; \varepsilon] \right\}, \tag{15.264}$$

with the action of Eq. (15.249) for $n = 0$. The function in the integrand $f(s, s') \equiv f(q(s), q(s'))$ is an abbreviation for the scalar product $\mathbf{u}(s) \cdot \mathbf{u}(s')$ expressed in terms of independent coordinates $q^\mu(s)$:

$$f(q(s), q(s')) \equiv \mathbf{u}(s) \cdot \mathbf{u}(s') = \sqrt{1 - q^2(s)} \sqrt{1 - q^2(s')} + q(s) q(s'). \tag{15.265}$$

Rescaling the coordinates $q \rightarrow \sqrt{\varepsilon} q$, and expanding in powers of ε yields:

$$f(q(s), q(s')) = 1 + \varepsilon f_1(q(s), q(s')) + \varepsilon^2 f_2(q(s), q(s')) + \dots, \tag{15.266}$$

where

$$f_1(q(s), q(s')) = q(s) q(s') - \frac{1}{2} q^2(s) - \frac{1}{2} q^2(s'), \tag{15.267}$$

$$f_2(q(s), q(s')) = \frac{1}{4} q^2(s) q^2(s') - \frac{1}{8} [q^2(s)]^2 - \frac{1}{8} [q^2(s')]^2. \tag{15.268}$$

We shall attribute the integrand $f(q(s), q(s'))$ to an interaction $\mathcal{A}^f[q; \varepsilon]$ defined by

$$f(q(s), q(s')) \equiv e^{-\mathcal{A}^f[q; \varepsilon]}, \tag{15.269}$$

which has the ε -expansion

$$\begin{aligned} \mathcal{A}^f[q; \varepsilon] &= -\log f(q(s), q(s')) \\ &= -\varepsilon f_1(q(s), q(s')) + \varepsilon^2 \left[-f_2(q(s), q(s')) + \frac{1}{2} f_1^2(s, s') \right] - \dots, \end{aligned} \tag{15.270}$$

to be added to the interaction (15.253) with $n = 0$. Thus we obtain the perturbation expansion of the path integral (15.264)

$$G(s, s') = 1 - \left\langle (\mathcal{A}_0^{\text{int}}[q; \varepsilon] + \mathcal{A}^f[q; \varepsilon]) \right\rangle_0 + \frac{1}{2} \left\langle (\mathcal{A}_0^{\text{int}}[q; \varepsilon] + \mathcal{A}^f[q; \varepsilon])^2 \right\rangle_0 - \dots. \tag{15.271}$$

Inserting the interaction terms (15.253) and (15.271), we obtain

$$G(s, s') = 1 + \varepsilon \langle f_1(q(s), q(s')) \rangle_0 + \varepsilon^2 \left[\langle f_2(q(s), q(s')) \rangle_0 - \langle f_1(q(s), q(s')) \mathcal{A}_0^{\text{int}1}[q] \rangle_0 \right] + \dots, \tag{15.272}$$

and the expectation values can now be calculated using the propagator (15.260) with the Green function (15.246).

In going through this calculation we observe that because of translational invariance in the pseudotime, $s \rightarrow s + s_0$, the Green function $\Delta(s, s') + C$ is just as good a Green function satisfying Neumann boundary conditions as $\Delta(s, s')$. We may demonstrate this explicitly by setting $C =$

$L(a-1)/3$ with an arbitrary constant a , and calculating the expectation values in Eq. (15.272) using the modified Green function. Details are given in Appendix 15C [see Eq. (15C.1)], where we list various expressions and integrals appearing in the Wick contractions of the expansion Eq. (15.272). Using these results we find the a -independent terms up to second order in ε :

$$\langle f_1(q(s), q(s')) \rangle_0 = -\frac{(D-1)}{2} |s-s'|, \quad (15.273)$$

$$\begin{aligned} \langle f_2(q(s), q(s')) \rangle_0 - \langle f_1(q(s), q(s')) \rangle_0 \mathcal{A}_0^{\text{int}1}[q]_0 \\ = (D-1) \left[\frac{1}{2} D_1 - \frac{1}{8} (D+1) D_2^2 - K_1 - D K_2 - \frac{(D-1)}{L} K_3 + \frac{1}{2} K_4 + \frac{1}{2} K_5 \right] \\ = \frac{1}{8} (D-1)^2 (s-s')^2. \end{aligned} \quad (15.274)$$

This leads indeed to the correct large-stiffness expansion of the exact two-point correlation function (15.263):

$$G(s, s') = 1 - \varepsilon \frac{D-1}{2} |s-s'| + \varepsilon^2 \frac{(D-1)^2}{8} (s-s')^2 + \dots = 1 - \frac{|s-s'|}{\xi} + \frac{(s-s')^2}{2\xi^2} - \dots \quad (15.275)$$

Radial Distribution up to Four Loops

We now turn to the most important quantity characterizing a polymer, the radial distribution function. We eliminate the δ -function in Eq. (15.236) enforcing the end-to-end distance by considering the Fourier transform

$$P(k; L) = \int dr e^{ik(r-1)} P(r; L). \quad (15.276)$$

This is calculated from the path integral with Neumann boundary conditions

$$P(k; L) = \int_{\text{NBC}} \mathcal{D}'^{D-1} q(s) \exp \{ -\mathcal{A}_k^{\text{tot}}[q; \varepsilon] \}, \quad (15.277)$$

where the action $\mathcal{A}_k^{\text{tot}}[q; \varepsilon]$ reads, with the same rescaled coordinates as in (15.249),

$$\begin{aligned} \mathcal{A}_k^{\text{tot}}[q; \varepsilon] = \int_0^L ds \left\{ \frac{1}{2} \left[\dot{q}^2 + \varepsilon \frac{(q\dot{q})^2}{1-\varepsilon q^2} \right] + \frac{1}{2} \delta(0) \log(1-\varepsilon q^2) - \frac{ik}{L} \left(\sqrt{1-\varepsilon q^2} - 1 \right) \right\} \\ - \frac{1}{4} \varepsilon [q^2(0) + q^2(L)] - \varepsilon L \frac{R}{8} \equiv \mathcal{A}^0[q] + \mathcal{A}_k^{\text{int}}[q; \varepsilon]. \end{aligned} \quad (15.278)$$

As before in Eq. (15.253), we expand the interaction in powers of the coupling constant ε . The first term coincides with Eq. (15.255), except that σ_n is replaced by

$$\rho_k(s) = \delta_k + [\delta(s) + \delta(s-L)]/2, \quad \delta_k = \delta(0) - ik/L, \quad (15.279)$$

so that

$$\mathcal{A}_k^{\text{int}1}[q] = \int_0^L ds \frac{1}{2} \left\{ [q(s)\dot{q}(s)]^2 - \rho_k(s) q^2(s) \right\} - L \frac{R}{8}. \quad (15.280)$$

The second expansion term $\mathcal{A}_k^{\text{int}2}[q]$ is simpler than the previous (15.257) by not containing the last nonlocal term:

$$\mathcal{A}_k^{\text{int}2}[q] = \int_0^L ds \frac{1}{2} \left\{ [q(s)\dot{q}(s)]^2 - \frac{1}{2} \left(\delta(0) - \frac{ik}{2L} \right) q^2(s) \right\} q^2(s). \quad (15.281)$$

Apart from that, the perturbation expansion of (15.277) has the same general form as in (15.259):

$$P(k; L) = 1 - \varepsilon \langle \mathcal{A}_k^{\text{int}1}[q] \rangle_0 + \varepsilon^2 \left(-\langle \mathcal{A}_k^{\text{int}2}[q] \rangle_0 + \frac{1}{2} \langle \mathcal{A}_k^{\text{int}1}[q]^2 \rangle_0 \right) - \dots \quad (15.282)$$

The expectation values can be expressed in terms of the same integrals listed in Appendix 15A and Appendix 15B as follows:

$$\begin{aligned} \langle \mathcal{A}_{,k}^{\text{int}1}[q] \rangle_0 &= \frac{(D-1)}{2} \left[\frac{ik}{L} I_1 + DI_2 - \frac{1}{2} \Delta(0,0) - \frac{1}{2} \Delta(L,L) \right] - L \frac{R}{8} \\ &= -L \frac{(D-1)[(D-1) - ik]}{12}, \end{aligned} \quad (15.283)$$

$$\begin{aligned} \langle \mathcal{A}_{,k}^{\text{int}2}[q] \rangle_0 &= \frac{(D^2-1)}{4} \left[\left(\delta(0) + \frac{ik}{2L} \right) I_3 + 2(D+2)I_4 \right] \\ &= L^3 \frac{(D^2-1)}{120} \delta(0) + L^2 \frac{(D^2-1)[7(D+2) + 3ik]}{720}, \end{aligned} \quad (15.284)$$

$$\begin{aligned} \frac{1}{2} \langle \mathcal{A}_{,k}^{\text{int}1}[q]^2 \rangle_0 &= \frac{L^2}{2} \left\{ \frac{(D-1)L}{12} \left[\left(\delta(0) + \frac{D}{2L} \right) - \left(\delta_k + \frac{2}{L} \right) \right] - \frac{R}{8} \right\}^2 \\ &+ \frac{(D-1)}{4} [H_1^k - 2(H_2^k + H_3^k - H_5) + H_6 - 4D(H_4^k - H_7 - H_{10}) \\ &+ H_{11} + 2D^2(H_8 + H_9)] + \frac{(D-1)}{4} [DH_{12} + 2(D+2)H_{13} + DH_{14}] \\ &= L^2 \frac{(D-1)^2 [(D-1) - ik]^2}{2 \cdot 12^2} \\ &+ L^3 \frac{(D-1)}{120} \delta(0) + L^2 \frac{(D-1)}{1440} [(13D^2 - 6D + 21) + 4ik(2D + ik)] \\ &+ L^3 \frac{(D-1)D}{120} \delta(0) + L^2 \frac{(D-1)}{720} (29D - 1). \end{aligned} \quad (15.285)$$

In this way we find the large-stiffness expansion up to order ε^2 :

$$\begin{aligned} P(k; L) &= 1 + \varepsilon L \frac{(D-1)}{12} [(D-1) - ik] + \varepsilon^2 L^2 \frac{(D-1)}{1440} \\ &\times [(ik)^2(5D-1) - 2ik(5D^2 - 11D + 8) + (D-1)(5D^2 - 11D + 14)] + \mathcal{O}(\varepsilon^3). \end{aligned} \quad (15.286)$$

This can also be rewritten as

$$P(k; L) = P_{1\text{loop}}(k; L) \left\{ 1 + \frac{(D-1)}{6} l + \left[\frac{(D-3)}{180(D-1)} ik + \frac{(5D^2 - 11D + 14)}{360} \right] l^2 + \mathcal{O}(l^3) \right\}, \quad (15.287)$$

where the prefactor $P_{1\text{loop}}(k; L)$ has the expansion

$$P_{1\text{loop}}(k; L) = 1 - \varepsilon L \frac{(D-1)}{2^2 \cdot 3} (ik) + \varepsilon^2 L^2 \frac{(D-1)(5D-1)}{2^5 \cdot 3^2 \cdot 5} (ik)^2 - \dots \quad (15.288)$$

With the identification $\bar{\omega}^2 = ik\varepsilon L$, this is the expansion of *one-loop* functional determinant in (15.227). By Fourier-transforming (15.286), we obtain the radial distribution function

$$\begin{aligned} P(r; l) &= \delta(r-1) + \frac{l}{6} [\delta'(r-1) + (d-1)\delta(r-1)] + \frac{l^2}{360(d-1)} [(5d-1)\delta''(r-1) \\ &+ 2(5d^2 - 11d + 8)\delta'(r-1) + (d-1)(5d^2 - 11d + 14)\delta(r-1)] + \mathcal{O}(l^3). \end{aligned} \quad (15.289)$$

As a crosscheck, we can calculate from this expansion once more the even and odd moments

$$\langle R^n \rangle = L^n \int dr r^{n+(D-1)} P(r; l), \tag{15.290}$$

and find that they agree with Eq. (15.262).

Using the higher-order expansion of the moments in (15.198) we can easily extend the distribution (15.289) to arbitrarily high orders in l . Keeping only the terms up to order l^4 , we find that the one-loop end-to-end distribution function (15.212) receives a correction factor:

$$P(r; l) \propto \int_{-\infty}^{\infty} \frac{d\hat{\omega}^2}{2\pi} e^{-i\hat{\omega}^2(r-1)(D-1)/2l} \left(\frac{\bar{\omega}}{\sinh \bar{\omega}} \right)^{(D-1)/2} e^{-V(l, \hat{\omega}^2)}, \tag{15.291}$$

with

$$V(l, \hat{\omega}^2) \equiv V_0(l) + \bar{V}(l, \hat{\omega}^2) = V_0(l) + V_1(l) \frac{\hat{\omega}^2}{l} + V_2(l) \frac{\hat{\omega}^4}{l^2} + V_3(l) \frac{\hat{\omega}^6}{l^3} + \dots \tag{15.292}$$

The first term

$$V_0(l) = -\frac{d-1}{6}l + \frac{d-9}{360}l^2 + \frac{(d-1)(32-13d+5d^2)}{6480}l^3 - \frac{34-272d+259d^2-110d^3+25d^4}{259200}l^4 + \dots \tag{15.293}$$

contributes only to the normalization of $P(r; l)$, and can be omitted in (15.291). The remainder has the expansion coefficients

$$\begin{aligned} V_1(l) &= -\frac{d-3}{360}l^2 + \frac{(-5+9d)}{7560(-1+d)}l^3 + \frac{(-455+431d+91d^2+5d^3)}{907200(d-1)^2}l^4 + \dots, \\ V_2(l) &= -\frac{(5-3d)l^3}{7560} - \frac{(-31+42d+25d^2)l^4}{907200(d-1)} + \dots, \\ V_3(l) &= -\frac{(d-1)l^4}{18900} + \dots \end{aligned} \tag{15.294}$$

In the physical most interesting case of three dimensions, the first nonzero correction arises to order l^3 . This explains the remarkable agreement of the moments in (15.234) and (15.234) up to order l^2 .

The correction terms $\bar{V}(l, \hat{\omega}^2)$ may be included perturbatively into the sum over k in Eq. (15.220) by noting that the expectation value of powers of $\hat{\omega}^2/l$ within the $\hat{\omega}$ -integral (15.221) are

$$\langle \hat{\omega}^2/l \rangle = a_k^2 \equiv \frac{2k+(D-1)/2}{(D-1)(1-r)}, \quad \langle \hat{\omega}^2/l \rangle^2 = 3a_k^4, \quad \langle \hat{\omega}^2/l \rangle^3 = 15a_k^6, \tag{15.295}$$

so that we obtain an extra factor e^{-f_k}

$$f_k = V_1(l)a_k^2 + [3V_2(l)-V_1^2(l)]a_k^4 + \left[15V_3(l)-12V_1(l)V_2(l)+\frac{4}{3}V_1^3(l) \right] a_k^6 + \dots, \tag{15.296}$$

where up to order l^4 :

$$\begin{aligned} 3V_2(l)-V_1^2(l) &= \frac{3D-5}{2520}l^3 + \frac{156-231D-26D^2-7D^3}{907200(D-1)}l^4 + \dots, \\ 15V_3(l)-12V_1(l)V_2(l)+\frac{4}{3}V_1^3(l) &= -\frac{D-1}{1260}l^4 + \dots \end{aligned} \tag{15.297}$$

15.10 Excluded-Volume Effects

A significant modification of these properties is brought about by the interactions between the chain elements. If two of them come close to each other, the molecular forces prevent them from occupying the same place. This is called the *excluded-volume effect*. In less than four dimensions, it gives rise to a scaling law for the expectation value $\langle R^2 \rangle$ as a function of L :

$$\langle R^2 \rangle \propto L^{2\nu}, \quad (15.298)$$

as stated in (15.38). The critical exponent ν is a number between the random-chain value $\nu = 1/2$ and the stiff-chain value $\nu = 1$.

To derive this behavior we consider the polymer in the limiting path integral approximation (15.80) to a random chain which was derived for $R^2/La \ll 1$ and which is very accurate whenever the probability distribution is sizable. Thus we start with the time-sliced expression

$$P_N(\mathbf{R}) = \frac{1}{\sqrt{2\pi a/M}^D} \prod_{n=1}^{N-1} \left[\int \frac{d^D x_n}{\sqrt{2\pi a/M}^D} \right] \exp(-\mathcal{A}^N/\hbar), \quad (15.299)$$

with the action

$$\mathcal{A}^N = a \sum_{n=1}^N \frac{M}{2} \frac{(\Delta \mathbf{x}_n)^2}{a^2}, \quad (15.300)$$

and the mass parameter (15.79). In the sequel we use natural units in which energies are measured in units of $k_B T$, and write down all expressions in the continuum limit. The probability (15.299) is then written as

$$P_L(\mathbf{R}) = \int \mathcal{D}^D x e^{-\mathcal{A}^L[\mathbf{x}]}, \quad (15.301)$$

where we have used the label $L = Na$ rather than N . From the discussion in the previous section we know that although this path integral represents an ideal random chain, we can also account for a finite stiffness by interpreting the number a as an effective length parameter a_{eff} given by (15.158). The total Euclidean time in the path integral $\tau_b - \tau_a = \hbar/k_B T$ corresponds to the total length of the polymer L .

We now assume that the molecules of the polymer repel each other with a two-body potential $V(\mathbf{x}, \mathbf{x}')$. Then the action in the path integral (15.301) has to be supplemented by an interaction

$$\mathcal{A}_{\text{int}} = \frac{1}{2} \int_0^L d\tau \int_0^L d\tau' V(\mathbf{x}(\tau), \mathbf{x}(\tau')). \quad (15.302)$$

Note that the interaction is of a purely spatial nature and does not depend on the parameters τ, τ' , i.e., it does not matter which two molecules in the chain come close to each other.

The effects of an interaction of this type are most elegantly calculated by making use of a Hubbard-Stratonovich transformation. Generalizing the procedure in Subsection ??, we introduce an auxiliary fluctuating field variable $\varphi(\mathbf{x})$ at every space point \mathbf{x} and replace \mathcal{A}_{int} by

$$\mathcal{A}_{\text{int}}^{\varphi} = \int_0^L d\tau \varphi(\mathbf{x}(\tau)) - \frac{1}{2} \int d^D x d^D x' \varphi(\mathbf{x}) V^{-1}(\mathbf{x}, \mathbf{x}') \varphi(\mathbf{x}'). \quad (15.303)$$

Here $V^{-1}(\mathbf{x}, \mathbf{x}')$ denotes the inverse of $V(\mathbf{x}, \mathbf{x}')$ under functional multiplication, defined by the integral equation

$$\int d^D x' V^{-1}(\mathbf{x}, \mathbf{x}') V(\mathbf{x}', \mathbf{x}'') = \delta^{(D)}(\mathbf{x} - \mathbf{x}''). \quad (15.304)$$

To see the equivalence of the action (15.303) with (15.302), we rewrite (15.303) as

$$\mathcal{A}_{\text{int}}^{\varphi} = \int d^D x \rho(\mathbf{x}) \varphi(\mathbf{x}) - \frac{1}{2} \int d^D x d^D x' \varphi(\mathbf{x}) V^{-1}(\mathbf{x}, \mathbf{x}') \varphi(\mathbf{x}'), \quad (15.305)$$

where $\rho(\mathbf{x})$ is the particle density

$$\rho(\mathbf{x}) \equiv \int_0^L d\tau \delta^{(D)}(\mathbf{x} - \mathbf{x}(\tau)). \quad (15.306)$$

Then we perform a quadratic completion to

$$\mathcal{A}_{\text{int}}^{\varphi} = -\frac{1}{2} \int d^D x d^D x' \left[\varphi'(\mathbf{x}) V^{-1}(\mathbf{x}, \mathbf{x}') \varphi'(\mathbf{x}') - \rho(\mathbf{x}) V(\mathbf{x}, \mathbf{x}') \rho(\mathbf{x}') \right], \quad (15.307)$$

with the shifted field

$$\varphi'(\mathbf{x}) \equiv \varphi(\mathbf{x}) - \int d^D x' V(\mathbf{x}, \mathbf{x}') \rho(\mathbf{x}'). \quad (15.308)$$

Now we perform the functional integral

$$\int \mathcal{D}\varphi(\mathbf{x}) e^{-\mathcal{A}_{\text{int}}^{\varphi}} \quad (15.309)$$

integrating $\varphi(\mathbf{x})$ at each point \mathbf{x} from $-i\infty$ to $i\infty$ along the imaginary field axis. The result is a constant functional determinant $[\det V^{-1}(\mathbf{x}, \mathbf{x}')]^{-1/2}$. This can be ignored since we shall ultimately normalize the end-to-end distribution to unity. Inserting (15.306) into the surviving second term in (15.307), we obtain precisely the original interaction (15.302).

Thus we may study the excluded-volume problem by means of the equivalent path integral

$$P_L(\mathbf{R}) \propto \int \mathcal{D}^D x(\tau) \int \mathcal{D}\varphi(\mathbf{x}) e^{-\mathcal{A}}, \quad (15.310)$$

where the action \mathcal{A} is given by the sum

$$\mathcal{A} = \mathcal{A}^L[\mathbf{x}, \dot{\mathbf{x}}, \varphi] + \mathcal{A}[\varphi], \quad (15.311)$$

of the line and field actions

$$\mathcal{A}^L[\mathbf{x}, \varphi] \equiv \int_0^L d\tau \left[\frac{M}{2} \dot{\mathbf{x}}^2 + \varphi(\mathbf{x}(\tau)) \right], \quad (15.312)$$

$$\mathcal{A}[\varphi] \equiv -\frac{1}{2} \int d^D x d^D x' \varphi(\mathbf{x}) V^{-1}(\mathbf{x}, \mathbf{x}') \varphi(\mathbf{x}'), \quad (15.313)$$

respectively. The path integral (15.310) over $\mathbf{x}(\tau)$ and $\varphi(\mathbf{x})$ has the following physical interpretation. The line action (15.312) describes the orbit of a particle in a space-dependent random potential $\varphi(\mathbf{x})$. The path integral over $\mathbf{x}(\tau)$ yields the end-to-end distribution of the fluctuating polymer in this potential. The path integral over all potentials $\varphi(\mathbf{x})$ with the weight $e^{-\mathcal{A}[\varphi]}$ accounts for the repulsive cloud of the fluctuating chain elements. To be convergent, all $\varphi(\mathbf{x})$ integrations in (15.310) have to run along the imaginary field axis.

To evaluate the path integrals (15.310), it is useful to separate $\mathbf{x}(\tau)$ - and $\varphi(\mathbf{x})$ -integrations and to write end-to-end distributions as an average over φ -fluctuations

$$P_L(\mathbf{R}) \propto \int \mathcal{D}\varphi(\mathbf{x}) e^{-\mathcal{A}[\varphi]} P_L^\varphi(\mathbf{R}, \mathbf{0}), \quad (15.314)$$

where

$$P_L^\varphi(\mathbf{R}, \mathbf{0}) = \int \mathcal{D}^D x(\tau) e^{-\mathcal{A}^L[\mathbf{x}, \varphi]} \quad (15.315)$$

is the end-to-end distribution of a random chain moving in a *fixed* external potential $\varphi(\mathbf{x})$. The presence of this potential destroys the translational invariance of P_L^φ . This is why we have recorded the initial and final points $\mathbf{0}$ and \mathbf{R} . In the final distribution $P_L(\mathbf{R})$ of (15.314), the invariance is of course restored by the integration over all $\varphi(\mathbf{x})$.

It is possible to express the distribution $P_L^\varphi(\mathbf{R}, \mathbf{0})$ in terms of solutions of an associated Schrödinger equation. With the action (15.312), this equation is obviously

$$\left[\frac{\partial}{\partial L} - \frac{1}{2M} \partial_{\mathbf{R}}^2 + \varphi(\mathbf{R}) \right] P_L^\varphi(\mathbf{R}, \mathbf{0}) = \delta^{(D)}(\mathbf{R} - \mathbf{0}) \delta(L). \quad (15.316)$$

If $\psi_E^\varphi(R)$ denotes the time-independent solutions of the Hamiltonian operator

$$\hat{H}^\varphi = -\frac{1}{2M} \partial_{\mathbf{R}}^2 + \varphi(\mathbf{R}), \quad (15.317)$$

the probability $P_L^\varphi(\mathbf{R})$ has a spectral representation of the form

$$P_L^\varphi(\mathbf{R}, \mathbf{0}) = \int dE e^{-EL} \psi_E^\varphi(\mathbf{R}) \psi_E^{\varphi*}(\mathbf{0}), \quad L > 0. \quad (15.318)$$

From now on, we assume the interaction to be dominated by the simplest possible repulsive potential proportional to a δ -function:

$$V(\mathbf{x}, \mathbf{x}') = v a^D \delta^{(D)}(\mathbf{x} - \mathbf{x}'). \quad (15.319)$$

Then the functional inverse is

$$V^{-1}(\mathbf{x}, \mathbf{x}') = v^{-1} a^{-D} \delta^{(D)}(\mathbf{x} - \mathbf{x}'), \quad (15.320)$$

and the φ -action (15.312) reduces to

$$\mathcal{A}[\varphi] = -\frac{v^{-1} a^{-D}}{2} \int d^D x \varphi^2(\mathbf{x}). \quad (15.321)$$

The path integrals (15.314), (15.315) can be solved approximately by applying the semiclassical methods of Chapter 4 to both the $\mathbf{x}(\tau)$ - and the $\varphi(\mathbf{x})$ -path integrals. These are dominated by the extrema of the action and evaluated via the leading saddle point approximation. In the $\varphi(\mathbf{x})$ -integral, the saddle point is given by the equation

$$v^{-1} a^{-D} \varphi(\mathbf{x}) = \frac{\delta}{\delta \varphi(\mathbf{x})} \log P_L^\varphi(\mathbf{R}, \mathbf{0}). \quad (15.322)$$

This is the semiclassical approximation to the exact equation

$$v^{-1} a^{-D} \langle \varphi(\mathbf{x}) \rangle = \langle \rho(\mathbf{x}) \rangle \equiv \left\langle \int_0^L d\tau \delta^{(D)}(\mathbf{x} - \mathbf{x}(\tau)) \right\rangle_{\mathbf{x}}, \quad (15.323)$$

where $\langle \dots \rangle_{\mathbf{x}}$ is the average over all line fluctuations calculated with the help of the probability distribution (15.315).

The exact equation (15.323) follows from a functional differentiation of the path integral for P_L^φ with respect to $\varphi(\mathbf{x})$:

$$\frac{\delta}{\delta \varphi(\mathbf{x})} P_L^\varphi(\mathbf{R}) = \int \mathcal{D}\varphi \frac{\delta}{\delta \varphi(\mathbf{x})} \int \mathcal{D}^D x e^{-\mathcal{A}^L[\mathbf{x}, \varphi] - \mathcal{A}[\varphi]} = 0. \quad (15.324)$$

By anchoring one end of the polymer at the origin and carrying the path integral from there to $\mathbf{x}(\tau)$, and further on to \mathbf{R} , the right-hand side of (15.323) can be expressed as a convolution integral over two end-to-end distributions:

$$\left\langle \int_0^L d\tau \delta^{(D)}(\mathbf{x} - \mathbf{x}(\tau)) \right\rangle_{\mathbf{x}} = \int_0^L dL' P_{L'}^\varphi(\mathbf{x}) P_{L-L'}^\varphi(\mathbf{R} - \mathbf{x}). \quad (15.325)$$

With (15.323), this becomes

$$v^{-1} a^{-D} \langle \varphi(\mathbf{x}) \rangle_{\mathbf{x}} = \int_0^L dL' P_{L'}^\varphi(\mathbf{x}) P_{L-L'}^\varphi(\mathbf{R} - \mathbf{x}), \quad (15.326)$$

which is the same as (15.323).

According to Eq. (15.322), the extremal $\varphi(\mathbf{x})$ depends really on two variables, \mathbf{x} and \mathbf{R} . This makes the solution difficult, even at the semiclassical level. It becomes simple only for $\mathbf{R} = 0$, i.e., for a closed polymer. Then only the variable \mathbf{x} remains and, by rotational symmetry, $\varphi(\mathbf{x})$ can depend only on $r = |\mathbf{x}|$. For $\mathbf{R} \neq 0$, on the

other hand, the rotational symmetry is distorted to an ellipsoidal geometry, in which a closed-form solution of the problem is hard to find. As an approximation, we may use a rotationally symmetric ansatz $\varphi(\mathbf{x}) \approx \varphi(r)$ also for $\mathbf{R} \neq 0$ and calculate the end-to-end probability distribution $P_L(\mathbf{R})$ via the semiclassical approximation to the two path integrals in Eq. (15.310).

The saddle point in the path integral over $\varphi(\mathbf{x})$ gives the formula [compare (15.314)]

$$P_L(\mathbf{R}) \sim P_L^\varphi(\mathbf{R}, \mathbf{0}) = \int \mathcal{D}^D x \exp \left\{ - \int_0^L d\tau \left[\frac{M}{2} \dot{\mathbf{x}}^2 + \varphi(r(\tau)) \right] \right\}. \quad (15.327)$$

Thereby it is hoped that for moderate \mathbf{R} , the error is small enough to justify this approximation. Anyhow, the analytic results supply a convenient starting point for better approximations.

Neglecting the ellipsoidal distortion, it is easy to calculate the path integral over $\mathbf{x}(\tau)$ for $P_L^\varphi(\mathbf{R}, \mathbf{0})$ in the saddle point approximation. At an arbitrary given $\varphi(r)$, we must find the classical orbits. The Euler-Lagrange equation has the first integral of motion

$$\frac{M}{2} \dot{\mathbf{x}}^2 - \varphi(r) = E = \text{const.} \quad (15.328)$$

At fixed L , we have to find the classical solutions for all energies E and all angular momenta l . The path integral reduces an ordinary double integral over E and l which, in turn, is evaluated in the saddle point approximation. In a rotationally symmetric potential $\varphi(r)$, the leading saddle point has the angular momentum $l = 0$ corresponding to a symmetric polymer distribution. Then Eq. (15.328) turns into a purely radial differential equation

$$d\tau = \frac{dr}{\sqrt{2[E + \varphi(r)]/M}}. \quad (15.329)$$

For a polymer running from the origin to \mathbf{R} we calculate

$$L = \int_0^R \frac{dr}{\sqrt{2[E + \varphi(r)]/M}}. \quad (15.330)$$

This determines the energy E as a function of L . It is a functional of the yet unknown field $\varphi(r)$:

$$E = E_L[\varphi]. \quad (15.331)$$

The classical action for such an orbit can be expressed in the form

$$\begin{aligned} \mathcal{A}_{\text{cl}}[\mathbf{x}, \varphi] &= \int_0^L d\tau \left[\frac{M}{2} \dot{\mathbf{x}}^2 + \varphi(r(\tau)) \right] \\ &= - \int_0^L d\tau \left[\frac{M}{2} \dot{\mathbf{x}}^2 - \varphi(r(\tau)) \right] + \int_0^L d\tau M \dot{\mathbf{x}}^2 \\ &= -EL + \int_0^R dr \sqrt{2M[E + \varphi(r)]}. \end{aligned} \quad (15.332)$$

In this expression, we may consider E as an *independent* variational parameter. The relation (15.330) between $E, L, R, \varphi(r)$, by which E is fixed, reemerges when extremizing the classical expression $\mathcal{A}_{\text{cl}}[\mathbf{x}, \varphi]$:

$$\frac{\partial}{\partial E} \mathcal{A}_{\text{cl}}[\mathbf{x}, \dot{\mathbf{x}}, \varphi] = 0. \quad (15.333)$$

The classical approximation to the entire action $\mathcal{A}[\mathbf{x}, \varphi] + \mathcal{A}[\varphi]$ is then

$$\mathcal{A}_{\text{cl}} = -EL + \int_0^r dr' \sqrt{2M[E + \varphi(r')]} - \frac{1}{2} v^{-1} a^{-D} \int d^D x \varphi^2(r). \quad (15.334)$$

This action is now extremized independently in $\varphi(r), E$. The extremum in $\varphi(r)$ is obviously given by the algebraic equation

$$\varphi(r') = \begin{cases} 0 & \text{for } r' > r, \\ Mva^D S_D^{-1} r'^{1-D} / \sqrt{2M[E + \varphi(r')]} & \text{for } r' < r, \end{cases} \quad (15.335)$$

which is easily solved. We rewrite it as

$$E + \varphi(r) = \xi^3 \varphi^{-2}(r), \quad (15.336)$$

with the abbreviation

$$\xi^3 = \alpha r^{-2\delta}, \quad (15.337)$$

where

$$\delta \equiv D - 1 > 0 \quad (15.338)$$

and

$$\alpha \equiv \frac{M}{2} v^2 a^{2D} S_D^{-2}. \quad (15.339)$$

For large $\xi \gg 1/E$, i.e., small $r \ll \alpha^{2/\delta} E^{-6/\delta}$, we expand the solution as follows

$$\varphi(r) = \xi - \frac{E}{3} + \frac{E^2}{9} + \dots \quad (15.340)$$

This expansion is reinserted into the classical action (15.334), making it a power series in E . A further extremization in E yields $E = E(L, r)$. The extremal value of the action yields an approximate distribution function of a monomer in the closed polymer (which runs through the origin):

$$P_L(\mathbf{R}) \propto e^{-\mathcal{A}_{\text{cl}}(L, R)}. \quad (15.341)$$

To see how this happens consider first the noninteracting limit where $v = 0$. Then the solution of (15.335) is $\varphi(r) \equiv 0$, and the classical action (15.334) becomes

$$\mathcal{A}_{\text{cl}} = -EL + \sqrt{2MER}. \quad (15.342)$$

The extremization in E gives

$$E = \frac{M R^2}{2 L^2}, \quad (15.343)$$

yielding the extremal action

$$\mathcal{A}_{\text{cl}} = \frac{M R^2}{2 L}. \quad (15.344)$$

The approximate distribution is therefore

$$P_N(\mathbf{R}) \propto e^{-\mathcal{A}_{\text{cl}}} = e^{-MR^2/2L}. \quad (15.345)$$

The interacting case is now treated in the same way. Using (15.336), the classical action (15.334) can be written as

$$\mathcal{A}_{\text{cl}} = -EL + \sqrt{\frac{M}{2}} \int_0^R dr' \left[\sqrt{\varphi + E} - \frac{1}{2} \xi^{3/2} \frac{1}{\varphi + E} \right]. \quad (15.346)$$

By expanding this action in a power series in E [after having inserted (15.340) for φ], we obtain with $\epsilon(r) \equiv E/\xi = E\alpha^{-1/3}r^{2\delta/3}$

$$\mathcal{A}_{\text{cl}} = -EL + \sqrt{\frac{M}{2}} \alpha^{1/6} \int_0^R dr' r'^{-\delta/3} \left[\frac{3}{2} + \epsilon(r') - \frac{1}{6} \epsilon^2(r') + \dots \right]. \quad (15.347)$$

As long as $\delta < 3$, i.e., for

$$D < 4, \quad (15.348)$$

the integral exists and yields an expansion

$$\mathcal{A}_{\text{cl}} = -EL + a_0(R) + a_1(R)E - \frac{1}{2}a_2(R)E^2 + \dots, \quad (15.349)$$

with the coefficients

$$\begin{aligned} a_0(R) &= -\frac{M}{2} \sqrt{\frac{9}{2}} R^{1-\delta/3} \alpha^{1/6} \frac{1}{\delta-3}, \\ a_1(R) &= 3 \sqrt{\frac{M}{2}} R^{1+\delta/3} \alpha^{-1/6} \frac{1}{\delta+3}, \\ a_2(R) &= \frac{1}{3} \sqrt{\frac{M}{2}} R^{1+\delta} \alpha^{-1/2} \frac{1}{\delta+1}. \end{aligned} \quad (15.350)$$

Extremizing \mathcal{A}_{cl} in E gives the action

$$\mathcal{A}_{\text{cl}} = a_0(R) + \frac{1}{2a_2(R)} [L - a_1(R)]^2 + \dots. \quad (15.351)$$

The approximate end-to-end distribution function is therefore

$$P_L(\mathbf{R}) \approx \mathcal{N} \exp \left\{ -a_0(R) - \frac{1}{2a_2(R)} [L - a_1(R)]^2 \right\}, \quad (15.352)$$

where \mathcal{N} is an appropriate normalization factor. The distribution is peaked around

$$L = 3\sqrt{\frac{M}{2}} R^{1+\delta/3} \alpha^{-1/6} \frac{1}{\delta+3}. \quad (15.353)$$

This shows the most important consequence of the excluded-volume effect: The average value of R^2 grows like

$$\langle R^2 \rangle \approx \alpha^{1/(D+2)} \left(\frac{D+2}{3} \sqrt{\frac{2}{M}} L \right)^{6/(D+2)}. \quad (15.354)$$

Thus we have found a scaling law of the form (15.298) with the critical exponent

$$\nu = \frac{3}{D+2}. \quad (15.355)$$

The repulsion between the chain elements makes the excluded-volume chain reach out further into space than a random chain [although less than a completely stiff chain, which is always reached by the solution (15.354) for $D = 1$].

The restriction $D < 4$ in (15.348) is quite important. The value

$$D^{\text{uc}} = 4 \quad (15.356)$$

is called the *upper critical dimension*. Above it, the set of all possible intersections of a random chain has the measure zero and any short-range repulsion becomes irrelevant. In fact, for $D > D^{\text{uc}}$ it is possible to show that the polymer behaves like a random chain without any excluded-volume effect satisfying $\langle R^2 \rangle \propto L$.

15.11 Flory's Argument

Once we expect a power-like scaling law of the form

$$\langle R^2 \rangle \propto L^{2\nu}, \quad (15.357)$$

the critical exponent (15.355) can be derived from a very simple dimensional argument due to Flory. We take the action

$$\mathcal{A} = \int_0^L d\tau \frac{M}{2} \dot{\mathbf{x}}^2 - \frac{va^D}{2} \int_0^L d\tau \int_0^L d\tau' \delta^{(D)}(\mathbf{x}(\tau) - \mathbf{x}(\tau')), \quad (15.358)$$

with $M = D/a$, and replace the two terms by their dimensional content, L for the τ -variable and R - for each x -component. Then

$$\mathcal{A} \sim \frac{M}{2} L \frac{R^2}{L^2} - \frac{va^D}{2} \frac{L^2}{R^D}. \quad (15.359)$$

Extremizing this expression in R at fixed L gives

$$\frac{R}{L} \sim R^{-D-1} L^2, \quad (15.360)$$

implying

$$R^2 \sim L^{6/(D+2)}, \quad (15.361)$$

and thus the critical exponent (15.355).

15.12 Polymer Field Theory

There exists an alternative approach to finding the power laws caused by the excluded-volume effects in polymers which is superior to the previous one. It is based on an intimate relationship of polymer fluctuations with field fluctuations in a certain somewhat artificial and unphysical limit. This limit happens to be accessible to approximate analytic methods developed in recent years in quantum field theory. According to Chapter 7, the statistical mechanics of a many-particle ensemble can be described by a single fluctuating field. Each particle in such an ensemble moves through spacetime along a fluctuating orbit in the same way as a random chain does in the approximation (15.80) to a polymer in Section 15.6. Thus we can immediately conclude that *ensembles* of polymers may also be described by a single fluctuating field. But how about a single polymer? Is it possible to project out a single polymer of the ensemble in the field-theoretic description? The answer is positive. We start with the result of the last section. The end-to-end distribution of the polymer in the excluded-volume problem is rewritten as an integral over the fluctuating field $\varphi(\mathbf{x})$:

$$P_L(\mathbf{x}_b, \mathbf{x}_a) = \int \mathcal{D}\varphi e^{-\mathcal{A}[\varphi]} P_L^\varphi(\mathbf{x}_b, \mathbf{x}_a), \quad (15.362)$$

with an action for the auxiliary $\varphi(\mathbf{x})$ field [see (15.312)]

$$\mathcal{A}[\varphi] = -\frac{1}{2} \int d^D x d^D x' \varphi(\mathbf{x}) V^{-1}(\mathbf{x}, \mathbf{x}') \varphi(\mathbf{x}'), \quad (15.363)$$

and an end-to-end distribution [see (15.315)]

$$P_L^\varphi(\mathbf{x}_b, \mathbf{x}_a) = \int \mathcal{D}x \exp \left\{ - \int_0^L d\tau \left[\frac{M}{2} \dot{\mathbf{x}}^2 + \varphi(\mathbf{x}(\tau)) \right] \right\}, \quad (15.364)$$

which satisfies the Schrödinger equation [see (15.316)]

$$\left[\frac{\partial}{\partial L} - \frac{1}{2M} \nabla^2 + \varphi(\mathbf{x}) \right] P_L^\varphi(\mathbf{x}, \mathbf{x}') = \delta^{(3)}(\mathbf{x} - \mathbf{x}') \delta(L). \quad (15.365)$$

Since P_L and P_L^φ vanish for $L < 0$, it is convenient to go over to the Laplace transforms

$$P_{m^2}(\mathbf{x}, \mathbf{x}') = \frac{1}{2M} \int_0^\infty dL e^{-Lm^2/2M} P_L(\mathbf{x}, \mathbf{x}'), \quad (15.366)$$

$$P_{m^2}^\varphi(\mathbf{x}, \mathbf{x}') = \frac{1}{2M} \int_0^\infty dL e^{-Lm^2/2M} P_L^\varphi(\mathbf{x}, \mathbf{x}'). \quad (15.367)$$

The latter satisfies the L -independent equation

$$[-\nabla^2 + m^2 + 2M\varphi(\mathbf{x})]P_{m^2}^\varphi(\mathbf{x}, \mathbf{x}') = \delta^{(3)}(\mathbf{x} - \mathbf{x}'). \quad (15.368)$$

The quantity $m^2/2M$ is, of course, just the negative energy variable $-E$ in (15.332):

$$-E \equiv \frac{m^2}{2M}. \quad (15.369)$$

The distributions $P_{m^2}^\varphi(\mathbf{x}, \mathbf{x}')$ describe the probability of a polymer of any length running from \mathbf{x}' to \mathbf{x} , with a Boltzmann-like factor $e^{-Lm^2/2M}$ governing the distribution of lengths. Thus $m^2/2M$ plays the role of a chemical potential.

We now observe that the solution of Eq. (15.368) can be considered as the correlation function of an auxiliary fluctuating complex field $\psi(\mathbf{x})$:

$$\begin{aligned} P_{m^2}^\varphi(\mathbf{x}, \mathbf{x}') &= G_0^\varphi(\mathbf{x}, \mathbf{x}') = \langle \psi^*(\mathbf{x})\psi(\mathbf{x}') \rangle_\varphi \\ &\equiv \frac{\int \mathcal{D}\psi^*(\mathbf{x})\mathcal{D}\psi(\mathbf{x}) \psi^*(\mathbf{x})\psi(\mathbf{x}') \exp\{-\mathcal{A}[\psi^*, \psi, \varphi]\}}{\int \mathcal{D}\psi^*(\mathbf{x})\mathcal{D}\psi(\mathbf{x}) \exp\{-\mathcal{A}[\psi^*, \psi, \varphi]\}}, \end{aligned} \quad (15.370)$$

with a field action

$$\mathcal{A}[\psi^*, \psi, \varphi] = \int d^Dx \left\{ \nabla\psi^*(\mathbf{x})\nabla\psi(\mathbf{x}) + m^2\psi^*(\mathbf{x})\psi(\mathbf{x}) + 2M\varphi(\mathbf{x})\psi^*(\mathbf{x})\psi(\mathbf{x}) \right\}. \quad (15.371)$$

The second part of Eq. (15.370) defines the expectations $\langle \dots \rangle_\psi$. In this way, we express the Laplace-transformed distribution $P_{m^2}(\mathbf{x}_b, \mathbf{x}_a)$ in (15.366) in the purely field-theoretic form

$$\begin{aligned} P_{m^2}(\mathbf{x}, \mathbf{x}') &= \int \mathcal{D}\varphi \exp\{-\mathcal{A}[\varphi]\} \langle \psi^*(\mathbf{x})\psi(\mathbf{x}') \rangle_\varphi \\ &= \int \mathcal{D}\varphi \exp\left\{ \frac{1}{2} \int d^D\mathbf{y} d^D\mathbf{y}' \varphi(\mathbf{y}) V^{-1}(\mathbf{y}, \mathbf{y}') \varphi(\mathbf{y}') \right\} \\ &\quad \times \frac{\int \mathcal{D}\psi^*\mathcal{D}\psi \psi^*(\mathbf{x})\psi(\mathbf{x}') \exp\{-\mathcal{A}[\psi^*, \psi, \varphi]\}}{\int \mathcal{D}\psi^* \int \mathcal{D}\psi \exp\{-\mathcal{A}[\psi^*, \psi, \varphi]\}}. \end{aligned} \quad (15.372)$$

It involves only a fluctuating field which contains all information on the path fluctuations. The field $\psi(\mathbf{x})$ is, of course, the analog of the second-quantized field in Chapter 7.

Consider now the probability distribution of a single monomer in a closed polymer chain. Inserting the polymer density function

$$\rho(\mathbf{R}) \equiv \int_0^L d\tau \delta^{(D)}(\mathbf{R} - \mathbf{x}(\tau)) \quad (15.373)$$

into the original path integral for a closed polymer

$$P_L(\mathbf{R}) = \int_0^L d\tau \int \mathcal{D}^D x \int \mathcal{D}\varphi \exp \{-\mathcal{A}_L - \mathcal{A}[\varphi]\} \delta^{(D)}(\mathbf{R} - \mathbf{x}(\tau)), \quad (15.374)$$

the δ -function splits the path integral into two parts

$$P_L(\mathbf{R}) = \int \mathcal{D}\varphi \exp \{-\mathcal{A}[\varphi]\} \int_0^L d\tau P_{L-\tau}^\varphi(\mathbf{0}, \mathbf{R}) P_\tau^\varphi(\mathbf{R}, \mathbf{0}). \quad (15.375)$$

When going to the Laplace transform, the convolution integral factorizes, yielding

$$P_{m^2}(\mathbf{R}) = \int \mathcal{D}\varphi(\mathbf{x}) \exp \{-\mathcal{A}[\varphi]\} P_{m^2}^\varphi(\mathbf{0}, \mathbf{R}) P_{m^2}^\varphi(\mathbf{R}, \mathbf{0}). \quad (15.376)$$

With the help of the field-theoretic expression for $P_{m^2}(\mathbf{R})$ in Eq. (15.370), the product of the correlation functions can be rewritten as

$$P_{m^2}^\varphi(\mathbf{0}, \mathbf{R}) P_{m^2}^\varphi(\mathbf{0}, \mathbf{R}) = \langle \psi^*(\mathbf{R}) \psi(\mathbf{0}) \rangle_\varphi \langle \psi^*(\mathbf{0}) \psi(\mathbf{R}) \rangle_\varphi. \quad (15.377)$$

We now observe that the field ψ appears only quadratically in the action $\mathcal{A}[\psi^*, \psi, \varphi]$. The product of correlation functions in (15.377) can therefore be viewed as a term in the Wick expansion (recall Section 3.10) of the four-field correlation function

$$\langle \psi^*(\mathbf{R}) \psi(\mathbf{R}) \psi^*(\mathbf{0}) \psi(\mathbf{0}) \rangle_\varphi. \quad (15.378)$$

This would be equal to the sum of pair contractions

$$\langle \psi^*(\mathbf{R}) \psi(\mathbf{R}) \rangle_\varphi \langle \psi^*(\mathbf{0}) \psi(\mathbf{0}) \rangle_\varphi + \langle \psi^*(\mathbf{R}) \psi(\mathbf{0}) \rangle_\varphi \langle \psi^*(\mathbf{0}) \psi(\mathbf{R}) \rangle_\varphi. \quad (15.379)$$

There are no contributions containing expectations of two ψ or two ψ^* fields which could, in general, appear in this expansion. This allows the right-hand side of (15.377) to be expressed as a difference between (15.378) and the first term of (15.379):

$$P_{m^2}^\varphi(\mathbf{0}, \mathbf{R}) P_{m^2}^\varphi(\mathbf{0}, \mathbf{R}) = \langle \psi^*(\mathbf{R}) \psi(\mathbf{R}) \psi^*(\mathbf{0}) \psi(\mathbf{0}) \rangle_\varphi - \langle \psi^*(\mathbf{R}) \psi(\mathbf{R}) \rangle_\varphi \langle \psi^*(\mathbf{0}) \psi(\mathbf{0}) \rangle_\varphi. \quad (15.380)$$

The right-hand side only contains correlation functions of a collective field, the *density field* [8]

$$\rho(\mathbf{R}) = \psi^*(\mathbf{R}) \psi(\mathbf{R}), \quad (15.381)$$

in terms of which

$$P_{m^2}^\varphi(\mathbf{0}, \mathbf{R}) P_{m^2}^\varphi(\mathbf{0}, \mathbf{R}) = \langle \rho(\mathbf{R}) \rho(\mathbf{0}) \rangle_\varphi - \langle \rho(\mathbf{R}) \rangle_\varphi \langle \rho(\mathbf{0}) \rangle_\varphi. \quad (15.382)$$

Now, the right-hand side is the *connected* correlation function of the density field $\rho(\mathbf{R})$:

$$\langle \rho(\mathbf{R}) \rho(\mathbf{0}) \rangle_{\varphi,c} \equiv \langle \rho(\mathbf{R}) \rho(\mathbf{0}) \rangle_\varphi - \langle \rho(\mathbf{R}) \rangle_\varphi \langle \rho(\mathbf{0}) \rangle_\varphi. \quad (15.383)$$

In Section 3.10 we have shown how to generate all connected correlation functions: The action $\mathcal{A}[\psi, \psi^*, \varphi]$ is extended by a source term in the density field $\rho(\mathbf{x})$

$$\mathcal{A}_{\text{source}}[\psi^*, \psi, K] = - \int d^D x K(\mathbf{x}) \rho(\mathbf{x}) = \int d^D x K(\mathbf{x}) \psi^*(\mathbf{x}) \psi(\mathbf{x}), \quad (15.384)$$

and one considers the partition function

$$Z[K, \varphi] \equiv \int \mathcal{D}\psi \mathcal{D}\psi^* \exp \{ -\mathcal{A}[\psi^*, \psi, \varphi] - \mathcal{A}_{\text{source}}[\psi^*, \psi, K] \}. \quad (15.385)$$

This is the generating functional of all correlation functions of the density field $\rho(\mathbf{R}) = \psi^*(\mathbf{R})\psi(\mathbf{R})$ at a fixed $\varphi(\mathbf{x})$. They are obtained from the functional derivatives

$$\langle \rho(\mathbf{x}_1) \cdots \rho(\mathbf{x}_n) \rangle_{\varphi} = Z[K, \varphi]^{-1} \frac{\delta}{\delta K(\mathbf{x}_1)} \cdots \frac{\delta}{\delta K(\mathbf{x}_n)} Z[K, \varphi] \Big|_{K=0}. \quad (15.386)$$

Recalling Eq. (3.559), the connected correlation functions of $\rho(\mathbf{x})$ are obtained similarly from the logarithm of $Z[K, \varphi]$:

$$\langle \rho(\mathbf{x}_1) \cdots \rho(\mathbf{x}_n) \rangle_{\varphi, c} = \frac{\delta}{\delta K(\mathbf{x}_1)} \cdots \frac{\delta}{\delta K(\mathbf{x}_n)} \log Z[K, \varphi] \Big|_{K=0}. \quad (15.387)$$

For $n = 2$, the connectedness is seen directly by performing the differentiations according to the chain rule:

$$\begin{aligned} \langle \rho(\mathbf{R}) \rho(\mathbf{0}) \rangle_{\varphi, c} &= \frac{\delta}{\delta K(\mathbf{R})} \frac{\delta}{\delta K(\mathbf{0})} \log Z[K, \varphi] \Big|_{K=0} \\ &= \frac{\delta}{\delta K(\mathbf{R})} Z^{-1}[K, \varphi] \frac{\delta}{\delta K(\mathbf{0})} Z[K, \varphi] \Big|_{K=0} \\ &= \langle \rho(\mathbf{R}) \rho(\mathbf{0}) \rangle_{\varphi} - \langle \rho(\mathbf{R}) \rangle_{\varphi} \langle \rho(\mathbf{0}) \rangle_{\varphi}. \end{aligned} \quad (15.388)$$

This agrees indeed with (15.383). We can therefore rewrite the product of Laplace-transformed distributions (15.382) at a fixed $\varphi(\mathbf{x})$ as

$$P_{m^2}^{\varphi}(\mathbf{0}, \mathbf{R}) P_{m^2}^{\varphi}(\mathbf{0}, \mathbf{R}) = \frac{\delta}{\delta K(\mathbf{R})} \frac{\delta}{\delta K(\mathbf{0})} \log Z[K, \varphi] \Big|_{K=0}. \quad (15.389)$$

The Laplace-transformed monomer distribution (15.376) is then obtained by averaging over $\varphi(\mathbf{x})$, i.e., by the path integral

$$P_{m^2}(\mathbf{R}) = \frac{\delta}{\delta K(\mathbf{R})} \frac{\delta}{\delta K(\mathbf{0})} \int \mathcal{D}\varphi(\mathbf{x}) \exp \{ -\mathcal{A}[\varphi] \} \log Z[K, \varphi] \Big|_{K=0}. \quad (15.390)$$

Were it not for the logarithm in front of Z , this would be a standard calculation of correlation functions within the combined ψ, φ field theory whose action is

$$\begin{aligned} \mathcal{A}_{\text{tot}}[\psi^*, \psi, \varphi] &= \mathcal{A}[\psi^*, \psi, \varphi] + \mathcal{A}[\varphi] \\ &= \int d^D x \left(\nabla \psi^* \nabla \psi + m^2 \psi^* \psi + 2M \varphi \psi^* \psi \right) \\ &\quad - \frac{1}{2} \int d^D x d^D x' \varphi(\mathbf{x}) V^{-1}(\mathbf{x}, \mathbf{x}') \varphi(\mathbf{x}'). \end{aligned} \quad (15.391)$$

To account for the logarithm we introduce a simple mathematical device called the *replica trick* [9]. We consider $\log Z[K, \varphi]$ in (15.388)–(15.390) as the limit

$$\log Z = \lim_{n \rightarrow 0} \frac{1}{n} (Z^n - 1), \quad (15.392)$$

and observe that the n th power of the generating functional, Z^n , can be thought of as arising from a field theory in which every field ψ occurs n times, i.e., with n identical replica. Thus we add an extra internal symmetry label $\alpha = 1, \dots, n$ to the fields $\psi(\mathbf{x})$ and calculate Z^n formally as

$$Z^n[K, \varphi] = \int \mathcal{D}\psi_\alpha^* \mathcal{D}\psi_\alpha \exp \left\{ -\mathcal{A}[\psi_\alpha^*, \psi_\alpha, \varphi] - \mathcal{A}[\varphi] - \mathcal{A}_{\text{source}}[\psi_\alpha^*, \psi_\alpha, K] \right\}, \quad (15.393)$$

with the replica field action

$$\mathcal{A}[\psi_\alpha, \psi_\alpha^*, \varphi] = \int d^D x \left(\nabla \psi_\alpha^* \nabla \psi_\alpha + m^2 \psi_\alpha^* \psi_\alpha + 2M \varphi \psi_\alpha^* \psi_\alpha \right), \quad (15.394)$$

and the source term

$$\mathcal{A}_{\text{source}}[\psi_\alpha^*, \psi_\alpha, K] = - \int d^D x \psi_\alpha^*(\mathbf{x}) \psi_\alpha(\mathbf{x}) K(\mathbf{x}). \quad (15.395)$$

A sum is implied over repeated indices α . By construction, the action is symmetric under the group $U(n)$ of all unitary transformations of the replica fields ψ_α .

In the partition function (15.393), it is now easy to integrate out the $\varphi(\mathbf{x})$ -fluctuations. This gives

$$Z^n[K, \varphi] = \int \mathcal{D}\psi_\alpha^* \mathcal{D}\psi_\alpha \exp \left\{ -\mathcal{A}^n[\psi_\alpha^*, \psi_\alpha] - \mathcal{A}_{\text{source}}[\psi_\alpha^*, \psi_\alpha, K] \right\}, \quad (15.396)$$

with the action

$$\begin{aligned} \mathcal{A}^n[\psi_\alpha^*, \psi_\alpha] &= \int d^D x \left(\nabla \psi_\alpha^* \nabla \psi_\alpha + m^2 \psi_\alpha^* \psi_\alpha \right) \\ &\quad + \frac{1}{2} (2M)^2 \int d^D x d^D x' \psi_\alpha^*(\mathbf{x}) \psi_\alpha(\mathbf{x}) V(\mathbf{x}, \mathbf{x}') \psi_\beta^*(\mathbf{x}') \psi_\beta(\mathbf{x}'). \end{aligned} \quad (15.397)$$

It describes a self-interacting field theory with an additional $U(n)$ symmetry.

In the special case of a local repulsive potential $V(\mathbf{x}, \mathbf{x}')$ of Eq. (15.319), the second term becomes simply

$$\mathcal{A}_{\text{int}}[\psi_\alpha^*, \psi_\alpha] = \frac{1}{2}(2M)^2 v a^D \int d^D x [\psi_\alpha^*(\mathbf{x})\psi_\alpha(\mathbf{x})]^2. \quad (15.398)$$

Using this action, we can find $\log Z[K, \varphi]$ via (15.392) from the functional integral

$$\log Z[K, \varphi] \equiv \lim_{n \rightarrow 0} \frac{1}{n} \left(\int \mathcal{D}\psi_\alpha^* \mathcal{D}\psi_\alpha \exp \{ -\mathcal{A}^n[\psi_\alpha^*, \psi_\alpha] - \mathcal{A}_{\text{source}}[\psi_\alpha^*, \psi_\alpha, K] \} - 1 \right). \quad (15.399)$$

This is the generating functional of the Laplace-transformed distribution (15.390) which we wanted to calculate.

A polymer can run along the same line in two orientations. In the above description with complex replica fields it was assumed that the two orientations can be distinguished. If they are indistinguishable, the polymer fields $\Psi_\alpha(\mathbf{x})$ have to be taken as real.

Such a field-theoretic description of a fluctuating polymer has an important advantage over the initial path integral formulation based on the analogy with a particle orbit. It allows us to establish contact with the well-developed theory of critical phenomena in field theory. The end-to-end distribution of long polymers at large L is determined by the small- E regime in Eqs. (15.330)–(15.349), which corresponds to the small- m^2 limit of the system here [see (15.369)]. This is precisely the regime studied in the quantum field-theoretic approach to critical phenomena in many-body systems [10, 11]. It can be shown that for D larger than the upper critical dimension $D^{\text{uc}} = 4$, the behavior for $m^2 \rightarrow 0$ of all Green functions coincides with the free-field behavior. For $D = D^{\text{uc}}$, this behavior can be deduced from scale invariance arguments of the action, using naive dimensional counting arguments. The fluctuations turn out to cause only logarithmic corrections to the scale-invariant power laws. One of the main developments in quantum field theory in recent years was the discovery that the scaling powers for $D < D^{\text{uc}}$ can be calculated via an expansion of all quantities in powers of

$$\epsilon = D^{\text{uc}} - D, \quad (15.400)$$

the so-called ϵ -expansion. The ϵ -expansion for the critical exponent ν which rules the relation between R^2 and the length of a polymer L , $\langle R^2 \rangle \propto L^{2\nu}$, can be derived from a real ϕ^4 -theory with n replica as follows [12]:

$$\begin{aligned} \nu^{-1} &= 2 + \frac{(n+2)\epsilon}{n+8} \left\{ -1 - \frac{\epsilon}{2(n+8)^2} (13n + 44) \right. \\ &\quad \left. + \frac{\epsilon^2}{8(n+8)^4} [3n^3 - 452n^2 - 2672n - 5312 \right. \\ &\quad \left. + \zeta(3)(n+8) \cdot 96(5n+22)] \right. \\ &\quad \left. + \frac{\epsilon^3}{32(n+8)^6} [3n^5 + 398n^4 - 12900n^3 - 81552n^2 - 219968n - 357120 \right. \\ &\quad \left. + \zeta(3)(n+8) \cdot 16(3n^4 - 194n^3 + 148n^2 + 9472n + 19488) \right. \\ &\quad \left. + \zeta(4)(n+8)^3 \cdot 288(5n+22) \right\} \end{aligned}$$

$$\begin{aligned}
& -\zeta(5)(n+8)^2 \cdot 1280(2n^2 + 55n + 186)] \\
& + \frac{\epsilon^4}{128(n+8)^8} [3n^7 - 1198n^6 - 27484n^5 - 1055344n^4 \\
& - 5242112n^3 - 5256704n^2 + 6999040n - 626688 \\
& - \zeta(3)(n+8) \cdot 16(13n^6 - 310n^5 + 19004n^4 + 102400n^3 \\
& - 381536n^2 - 2792576n - 4240640) \\
& - \zeta^2(3)(n+8)^2 \cdot 1024(2n^4 + 18n^3 + 981n^2 + 6994n + 11688) \\
& + \zeta(4)(n+8)^3 \cdot 48(3n^4 - 194n^3 + 148n^2 + 9472n + 19488) \\
& + \zeta(5)(n+8)^2 \cdot 256(155n^4 + 3026n^3 + 989n^2 - 66018n - 130608) \\
& - \zeta(6)(n+8)^4 \cdot 6400(2n^2 + 55n + 186) \\
& + \zeta(7)(n+8)^3 \cdot 56448(14n^2 + 189n + 526)] \}, \tag{15.401}
\end{aligned}$$

where $\zeta(x)$ is Riemann's zeta function (2.521). As shown above, the single-polymer properties must emerge in the limit $n \rightarrow 0$. There, ν^{-1} has the ϵ -expansion

$$\nu^{-1} = 2 - \frac{\epsilon}{4} - \frac{11}{128}\epsilon^2 + 0.114\,425\,\epsilon^3 - 0.287\,512\,\epsilon^4 + 0.956\,133\,\epsilon^5. \tag{15.402}$$

This is to be compared with the much simpler result of the last section

$$\nu^{-1} = \frac{D+2}{3} = 2 - \frac{\epsilon}{3}. \tag{15.403}$$

A term-by-term comparison is meaningless since the field-theoretic ϵ -expansion has a grave problem: The coefficients of the ϵ^n -terms grow, for large n , like $n!$, so that the series does not converge anywhere! Fortunately, the signs are alternating and the series can be resummed [13]. A simple first approximation used in ϵ -expansions is to re-express the series (15.402) as a ratio of two polynomials of roughly equal degree

$$\nu^{-1}|_{\text{rat}} = \frac{2. + 1.023\,606\,\epsilon - 0.225\,661\,\epsilon^2}{1. + 0.636\,803\,\epsilon - 0.011\,746\,\epsilon^2 + 0.002\,677\,\epsilon^3}, \tag{15.404}$$

called a *Padé approximation*. Its Taylor coefficients up to ϵ^5 coincide with those of the initial series (15.402). It can be shown that this approximation would converge with increasing orders in ϵ towards the exact function represented by the divergent series. In Fig. 15.7, we plot the three functions (15.403), (15.402), and (15.404), the last one giving the most reliable approximation

$$\nu^{-1} \approx 0.585. \tag{15.405}$$

Note that the simple Flory curve lies very close to the Padé curve whose calculation requires a great amount of work.

There exists a general scaling relation between the exponent ν and another exponent appearing in the total number of polymer configurations of length L which behaves like

$$S = L^{\alpha-2}. \tag{15.406}$$

Figure 15.7 Comparison of critical exponent ν in Flory approximation (dashed line) with result of divergent ϵ -expansion obtained from quantum field theory (dotted line) and its Padé resummation (solid line). The value of the latter gives the best approximation $\nu \approx 0.585$ at $\epsilon = 1$.

The relation is

$$\alpha = 2 - D\nu. \quad (15.407)$$

Direct enumeration studies of random chains on a computer suggest a number

$$\alpha \sim \frac{1}{4}, \quad (15.408)$$

corresponding to $\nu = 7/12 \approx 0.583$, very close to (15.405).

The Flory estimate for the exponent α reads, incidentally,

$$\alpha = \frac{4 - D}{D + 2}. \quad (15.409)$$

In three dimensions, this yields $\alpha = 1/5$, not too far from (15.408).

The discrepancies arise from inaccuracies in both treatments. In the first treatment, they are due to the use of the saddle point approximation and the fact that the δ -function does not completely rule out the crossing of the lines, as required by the true self-avoidance of the polymer. The field theoretic ϵ -expansion, on the other hand, which in principle can give arbitrarily accurate results, has the problem of being divergent for any ϵ . Resummation procedures are needed and the order of the expansion must be quite large ($\approx \epsilon^5$) to extract reliable numbers.

15.13 Fermi Fields for Self-Avoiding Lines

There exists another way of enforcing the self-avoiding property of random lines [14]. It is based on the observation that for a polymer field theory with n fluctuating complex fields Ψ_α and a $U(n)$ -symmetric fourth-order self-interaction as in the action

(15.397), the symmetric incorporation of a set of m anticommuting Grassmann fields removes the effect of m of the Bose fields. For free fields this observation is trivial since the functional determinant of Bose and Fermi fields are inverse to one-another. In the presence of a fourth-order self-interaction, where the replica action has the form (15.397), we can always go back, by a Hubbard-Stratonovich transformation, to the action involving the auxiliary field $\varphi(\mathbf{x})$ in the exponent of (15.393). This exponent is purely quadratic in the replica field, and each path integral over a Fermi field cancels a functional determinant coming from the Bose field.

This boson-destructive effect of fermions allows us to study theories with a negative number of replica. We simply have to use more Fermi than Bose fields. Moreover, we may conclude that a theory with $n = -2$ has necessarily trivial critical exponents. From the above arguments it is equivalent to a single complex Fermi field theory with fourth-order self-interaction. However, for anticommuting Grassmann fields, such an interaction vanishes:

$$(\theta^\dagger \theta)^2 = [(\theta_1 - i\theta_2)(\theta_1 + i\theta_2)]^2 = [2i\theta_1\theta_2]^2 = 0. \quad (15.410)$$

Looking back at the ϵ -expansion for the critical exponent ν in Eq. (15.401) we can verify that up to the power ϵ^5 all powers in ϵ do indeed vanish and ν takes the mean-field value $1/2$.

Appendix 15A Basic Integrals

$$\Delta(0,0) = \Delta(L,L) = L/3, \quad (15A.1)$$

$$I_1 = \int_0^L ds \Delta(s,s) = L^2/6, \quad (15A.2)$$

$$I_2 = \int_0^L ds \dot{\Delta}^2(s,s) = L/12, \quad (15A.3)$$

$$I_3 = \int_0^L ds \Delta^2(s,s) = L^3/30, \quad (15A.4)$$

$$I_4 = \int_0^L ds \Delta(s,s) \dot{\Delta}^2(s,s) = 7L^2/360, \quad (15A.5)$$

$$I_5 = \int_0^L ds \int_0^L ds' \Delta^2(s,s') = L^4/90, \quad (15A.6)$$

$$\Delta(0,L) = \Delta(L,0) = -L/6, \quad (15A.7)$$

$$I_6 = \int_0^L ds [\Delta^2(s,0) + \Delta^2(s,L)] = 2L^3/45, \quad (15A.8)$$

$$I_7 = \int_0^L ds \int_0^L ds' \Delta(s,s) \dot{\Delta}^2(s,s') = L^3/45, \quad (15A.9)$$

$$I_8 = \int_0^L ds \int_0^L ds' \dot{\Delta}(s,s) \Delta(s,s') \dot{\Delta}(s,s') = L^3/180, \quad (15A.10)$$

$$I_9 = \int_0^L ds \Delta(s,s) [\dot{\Delta}^2(s,0) + \dot{\Delta}^2(s,L)] = 11L^2/90, \quad (15A.11)$$

$$I_{10} = \int_0^L ds \dot{\Delta}(s,s) [\Delta(s,0) \dot{\Delta}(s,0) + \Delta(s,L) \dot{\Delta}(s,L)] = 17L^2/360, \quad (15A.12)$$

$$\Delta(0,0) = -\Delta(L,L) = -1/2, \quad (15A.13)$$

$$I_{11} = \int_0^L ds \int_0^L ds' \Delta(s,s) \Delta(s,s') \Delta(s',s') = L^3/360, \quad (15A.14)$$

$$I_{12} = \int_0^L ds \int_0^L ds' \Delta(s,s') \Delta^2(s,s') = L^3/90. \quad (15A.15)$$

Appendix 15B Loop Integrals

We list here the Feynman integrals evaluated with dimensional regularization rules whenever necessary. Depending whether they occur in the calculation of the moments from the expectations (15.261)–(15.261) of from the expectations (15.283)–(15.285) we encounter the integrals depending on $\rho_n(s) \equiv \delta_n + [\delta(s) + \delta(s-L)]/2$ with $\delta_n = \delta(0) - \sigma_n/L$ or $\rho_k(s) = \delta_k + [\delta(s) + \delta(s-L)]/2$ with $\delta_k = \delta(0) - ik/L$:

$$\begin{aligned} H_1^{n(k)} &= \int_0^L ds \int_0^L ds' \rho_{n(k)}(s) \rho_{n(k)}(s') \Delta^2(s,s'), \\ &= \delta_{n(k)}^2 I_5 + \delta_{n(k)} I_6 + \frac{1}{2} [\Delta^2(0,0) + \Delta^2(0,L)], \end{aligned} \quad (15B.1)$$

$$H_2^{n(k)} = \int_0^L ds \int_0^L ds' \rho_{n(k)}(s') \Delta(s,s) \Delta^2(s,s') = \delta_{n(k)} I_7 + \frac{I_9}{2}, \quad (15B.2)$$

$$H_3^{n(k)} = \int_0^L ds \int_0^L ds' \rho_{n(k)}(s') \Delta d(s,s) \Delta^2(s,s') = \left[\delta_{n(k)} I_5 + \frac{I_6}{2} \right] \delta(0), \quad (15B.3)$$

$$H_4^{n(k)} = \int_0^L ds \int_0^L ds' \rho_{n(k)}(s') \Delta(s,s) \Delta(s,s') \Delta(s,s') = \delta_{n(k)} I_8 + \frac{I_{10}}{2}. \quad (15B.4)$$

When calculating $\langle R^n \rangle$, we need to insert here $\delta_n = \delta(0) - \sigma_n/L$, thus obtaining

$$H_1^n = \frac{L^4}{90} \delta^2(0) + \frac{L^3}{45} (3-D-n) \delta(0) + \frac{L^2}{360} [(45-24D+4D^2) - 4n(6-2D-n)], \quad (15B.5)$$

$$H_2^n = \frac{L^3}{45} \delta(0) + \frac{L^2}{180} (15-4D-4n), \quad (15B.6)$$

$$H_3^n = \frac{L^4}{90} \delta^2(0) + \frac{L^3}{90} (3-D-n) \delta(0), \quad (15B.7)$$

$$H_4^n = \frac{L^3}{180} \delta(0) + \frac{L^2}{720} (21-4D-4n), \quad (15B.8)$$

where the values for $n = 0$ correspond to the partition function $Z = \langle R^0 \rangle$. The substitution $\delta_k = \delta(0) - ik/L$ required for the calculation of $P(k;L)$ yields

$$H_1^k = \frac{L^4}{90} \delta^2(0) + \frac{L^3}{45} [2 + (-ik)] \delta(0) + \frac{L^2}{90} (-ik) [4 + (-ik)] + \frac{5L^2}{72}, \quad (15B.9)$$

$$H_2^k = \frac{L^3}{45} \delta(0) + \frac{L^2}{180} [11 + 4(-ik)], \quad (15B.10)$$

$$H_3^k = \frac{L^4}{90} \delta^2(0) + \frac{L^3}{90} [2 + (-ik)] \delta(0), \quad (15B.11)$$

$$H_4^k = \frac{L^3}{180} \delta(0) + \frac{L^2}{720} [17 + 4(-ik)]. \quad (15B.12)$$

The other loop integrals are

$$H_5 = \int_0^L ds \int_0^L ds' \Delta(s,s) \Delta^2(s,s') \Delta d(s',s') = \delta(0) I_7 = \frac{L^3}{45} \delta(0), \quad (15B.13)$$

$$H_6 = \int_0^L ds \int_0^L ds' \Delta d(s, s) \Delta^2(s, s') \Delta d(s', s') = \delta^2(0) I_5 = \frac{L^4}{90} \delta^2(0), \quad (15B.14)$$

$$H_7 = \int_0^L ds \int_0^L ds' \Delta(s, s) \Delta(s, s') \Delta(s, s') \Delta d(s', s') = \delta(0) I_8 = \frac{L^3}{180} \delta(0), \quad (15B.15)$$

$$H_8 = \int_0^L ds \int_0^L ds' \Delta(s, s) \Delta(s, s') \Delta(s, s') \Delta(s', s') = -\frac{L^2}{720}, \quad (15B.16)$$

$$H_9 = \int_0^L ds \int_0^L ds' \Delta(s, s) \Delta(s, s') \Delta d(s, s') \Delta(s', s') = \frac{I_{10}}{2} - \frac{I_8}{L} - H_8 = \frac{7L^2}{360}, \quad (15B.17)$$

$$H_{10} = \int_0^L ds \int_0^L ds' \Delta(s, s) \Delta(s, s') \Delta d(s, s') \Delta(s', s') = \frac{I_9}{4} - \frac{I_7}{2L} = \frac{7L^2}{360}, \quad (15B.18)$$

$$H_{11} = \int_0^L ds \int_0^L ds' \Delta(s, s) \Delta^2(s, s') \Delta(s', s') = \delta(0) I_3 + \left(\frac{I_1}{L}\right)^2 - \frac{2(I_3 - I_{11})}{L} - 2I_4, \\ + 2 [\Delta^2(L, L) \Delta(L, L) - \Delta^2(0, 0) \Delta(0, 0)] - 2H_{10} = \frac{L^3}{30} \delta(0) + \frac{L^2}{9}, \quad (15B.19)$$

$$H_{12} = \int_0^L ds \int_0^L ds' \Delta^2(s, s') \Delta^2(s, s') = \frac{L^2}{90}, \quad (15B.20)$$

$$H_{13} = \int_0^L ds \int_0^L ds' \Delta(s, s') \Delta(s, s') \Delta(s, s') \Delta d(s', s) = \frac{I_4}{2} - \frac{I_{12}}{2L} - \frac{H_{12}}{2} = -\frac{L^2}{720}, \quad (15B.21)$$

$$H_{14} = \int_0^L ds \int_0^L ds' \Delta^2(s, s') \Delta^2(s, s') = \delta(0) I_3 - \frac{2(I_3 - I_{12})}{L} - 2I_4 + \frac{I_5}{L^2}, \\ + 2 [\Delta^2(L, L) \Delta(L, L) - \Delta^2(0, 0) \Delta(0, 0)] - 2H_{13} = \frac{L^3}{30} \delta(0) + \frac{11L^2}{72}. \quad (15B.22)$$

Appendix 15C Integrals Involving Modified Green Function

To demonstrate the translational invariance of results showed in the main text we use the slightly modified Green function

$$\Delta(s, s') = \frac{L}{3} a - \frac{|s - s'|}{2} - \frac{(s + s')}{2} + \frac{(s^2 + s'^2)}{2L}, \quad (15C.1)$$

containing an arbitrary constant a . The following combination yields the standard Feynman propagator for the infinite interval [compare (3.249)]

$$\Delta_F(s, s') = \Delta_F(s - s') = \Delta(s, s') - \frac{1}{2} \Delta(s, s) - \frac{1}{2} \Delta(s', s') = -\frac{1}{2} (s - s'). \quad (15C.2)$$

Other useful relations fulfilled by the Green function (15C.1) are, assuming $s \geq s'$,

$$D_1(s, s') = \Delta^2(s, s') - \Delta(s, s) \Delta(s', s') = (s - s') \left[\frac{s(L - s)}{L} + \frac{(s - s')(s + s')^2}{4L^2} - \frac{La}{3} \right], \quad (15C.3)$$

$$D_2(s, s') = \Delta(s, s) - \Delta(s', s') = \frac{(s - s')(s + s' - L)}{L}. \quad (15C.4)$$

The following integrals are needed:

$$J_1(s, s') = \int_0^L dt \Delta(t, t) \Delta(t, s) \Delta(t, s') = \frac{(s^4 + s'^4)}{4L^2} - \frac{(2s^3 + s'^3)}{3L}, \\ + \frac{((a+3)s^2 + as'^2)}{6} - \frac{sa}{3} L + \frac{(20a-9)}{180} L^2, \quad (15C.5)$$

$$J_2(s, s') = \int_0^L dt \Delta(t, t) \Delta(t, s) \Delta(t, s') = \frac{(-2s^4 + 6s^2s'^2 + 3s'^4)}{24L^2},$$

$$+ \frac{(3s^3 - 3s^2s' - 6ss'^2 - s'^3)}{12L} - \frac{(5s^2 - 12ss' - 4as'^2)}{24} - \frac{s'a}{6}L + \frac{(20a-3)}{720}L^2, \quad (15C.6)$$

$$J_3(s, s') = \int_0^L dt \Delta(t, s) \Delta(t, s') = -\frac{(s^4 + 6s^2s'^2 + s'^4)}{60L} + \frac{(s^2 + 3s'^2)s}{6},$$

$$- \frac{(s^2 + s'^2)}{6}L + \frac{(5a^2 - 10a + 6)}{45}L^3. \quad (15C.7)$$

These are the building blocks for other relations:

$$\langle f_2(q(s), q(s')) \rangle = \frac{(d-1)}{2} \left[D_1(s, s') - \frac{(d+1)}{4} D_2^2(s, s') \right] = -\frac{(d-1)(s-s')}{4}$$

$$\times \left[\frac{2La}{3} + \frac{(d-3)s - (d+1)s'}{2} - \frac{(d-1)s^2 - (d+1)s'^2}{L} + \frac{d(s-s')(s+s')^2}{2L^2} \right], \quad (15C.8)$$

and

$$K_1(s, s') = J_1(s, s') - \frac{1}{2}J_1(s, s) - \frac{1}{2}J_1(s', s'),$$

$$= -(s-s') \left[\frac{La}{6} - \frac{(s+s')}{4} + \frac{(s^2 + ss' + s'^2)}{6L} \right], \quad (15C.9)$$

$$K_2(s, s') = J_2(s, s') + J_2(s', s) - J_2(s, s) - J_2(s', s'),$$

$$= -(s-s')^2 \left[\frac{1}{4} - \frac{(5s+7s')}{12L} + \frac{(s+s')^2}{4L^2} \right], \quad (15C.10)$$

$$K_3(s, s') = J_3(s, s') - \frac{1}{2}J_3(s, s) - \frac{1}{2}J_3(s', s') = -(s-s')^2 \left[\frac{(s+2s')}{6} - \frac{(s+s')^2}{8L} \right], \quad (15C.11)$$

$$K_4(s, s') = \Delta(0, s)\Delta(0, s') - \frac{1}{2}\Delta^2(0, s) - \frac{1}{2}\Delta^2(0, s') = -\frac{(s-s')^2(s+s'-2L)^2}{8L^2}, \quad (15C.12)$$

$$K_5(s, s') = \Delta(L, s)\Delta(L, s') - \frac{1}{2}\Delta^2(L, s) - \frac{1}{2}\Delta^2(L, s') = -\frac{(s^2 - s'^2)^2}{8L^2}. \quad (15C.13)$$

Polymers and Particle Orbits in Multiply Connected Spaces

In the previous chapter, the binary interaction potential between the polymer elements was approximated by a δ -function. Quantum-mechanically, this potential is not completely impenetrable. Correspondingly, a polymer with such an interaction has a finite probability of self-intersections. This is only a rough approximation to the situation in nature where the atomic potential is of the hard-core type and self-intersections are extremely rare. In a grand-canonical ensemble, a polymer is often entangled with itself and with others. It can be disentangled only if it has open ends. Macroscopic fluctuations are required to achieve this in the form of worm-like creeping processes. Compared with local fluctuations, these take a very long time. For closed polymers, disentangling is impossible without breaking bonds at the cost of large activation energies. In order to study such entanglement phenomena in their purest form, it is useful to idealize the strongly repulsive interaction potential, as in Section 15.10, to a topological constraint of the type discussed in Chapter 6.

Entanglement phenomena play an important role also in quantum mechanics. Fluctuating particle orbits may get entangled with magnetic flux tubes or with other particle orbits. In fact, the statistical properties of Bose and Fermi particles may be viewed as entanglement phenomena, as will be shown in this chapter.

16.1 Simple Model for Entangled Polymers

Consider the simplest model system with a topological constraint producing entanglement phenomena: a fixed polymer stretched out along the z -axis and a fluctuating second polymer. Arbitrary entanglements with the straight polymer may occur. The possible entanglements of the fluctuating polymer with itself are ignored, for simplicity. Let us study the end-to-end distribution of the fluctuating second polymer. At first we neglect the third dimension, which can be trivially included at a later stage, imagining the movement to be confined entirely to the xy -plane. If the polymer along the z -axis is infinitely thin, the total end-to-end distribution of

the fluctuating polymer in the plane is certainly independent of the presence of the central polymer. In the random-chain approximation it reads for not too large R

$$P_N(\mathbf{x}_b - \mathbf{x}_a) = \sqrt{\frac{2}{2\pi La}} e^{-(\mathbf{x}_b - \mathbf{x}_a)^2/2La}, \quad (16.1)$$

where \mathbf{x} is a planar vector.

In the presence of the central polymer, an interesting new problem arises: How does the end-to-end distribution decompose with respect to the number of times by which the fluctuating polymer is wrapped around the central polymer? To define this number, we choose an arbitrary reference line from the origin to infinity, say the x -axis. For each path from \mathbf{x}_a to \mathbf{x}_b , we count how often it crosses this line, including a minus sign for opposite directions of the crossings. In this way, each path receives an integer-valued label n which depends on the position of the reference line.

A property independent of the choice of the reference line exists for the pairs of paths with fixed ends. The difference path is closed. The number n of times by which a closed path encircles the origin is a topological invariant called the *winding number*. Let us find the decomposition of the probability distribution of a closed polymer $P_N(\mathbf{x}_b - \mathbf{x}_a)$ with respect to n :

$$P_N(\mathbf{x}_b - \mathbf{x}_a) = \sum_{n=-\infty}^{\infty} P_N^n(\mathbf{x}_b, \mathbf{x}_a). \quad (16.2)$$

The topological constraint destroys the translational invariance of the total distribution on the left-hand side, so that the different fixed- n distributions on the right-hand side depend separately on both \mathbf{x}_b and \mathbf{x}_a .

In a path integral it is easy to keep track of the number of crossings n . The angular difference between initial and final points \mathbf{x}_b and \mathbf{x}_a is given by the integral

$$\varphi_b - \varphi_a = \int_{t_a}^{t_b} dt \dot{\varphi}(t) = \int_{t_a}^{t_b} dt \frac{x_1 \dot{x}_2 - x_2 \dot{x}_1}{x_1^2 + x_2^2} = \int_{\mathbf{x}_a}^{\mathbf{x}_b} \frac{\mathbf{x} \times d\mathbf{x}}{\mathbf{x}^2}. \quad (16.3)$$

Given two paths C_1 and C_2 connecting \mathbf{x}_a and \mathbf{x}_b , this integral differs by an integer multiple of 2π . The winding number is therefore given by the contour integral over the closed difference path C :

$$n = \frac{1}{2\pi} \oint_C \frac{\mathbf{x} \times d\mathbf{x}}{\mathbf{x}^2}. \quad (16.4)$$

In order to decompose the end-to-end distribution (16.2) with respect to the winding number, we recall the angular decomposition of the imaginary-time evolution amplitude in Eqs. (8.9) and (8.17) of a free particle in two dimensions

$$P_L(\mathbf{x}_b - \mathbf{x}_a) = \sum_m \frac{1}{\sqrt{r_b r_a}} (r_b \tau_b | r_a \tau_a)_m \frac{1}{2\pi} e^{im(\varphi_b - \varphi_a)}, \quad (16.5)$$

with the radial amplitude

$$(r_b \tau_b | r_a \tau_a)_m = 2 \frac{\sqrt{r_b r_a}}{La} e^{-(r_b^2 + r_a^2)/La} I_m \left(2 \frac{r_b r_a}{La} \right). \quad (16.6)$$

We have inserted the polymer parameters following the rules of Section 15.6, replacing $M/2\hbar(\tau_b - \tau_a)$ by $1/La$, and using the label $L = Na$ in P_L rather than N , as in Eq. (15.301).

We now recall that according to Section 6.1, an angular path integral consisting of a product of integrals

$$\prod_{n=1}^N \int_{-\pi}^{\pi} \frac{d\varphi_n}{2\pi}, \quad (16.7)$$

whose conjugate momenta are integer-valued, can be converted into a product of ordinary integrals

$$\prod_{n=1}^N \int_{-\infty}^{\infty} \frac{d\varphi_n}{2\pi}, \quad (16.8)$$

whose conjugate momenta are continuous. These become independent of the time slice n by momentum conservation, and the common momentum is eventually restricted to its proper integer values by a final sum over an integer number n occurring in the Poisson formula [see (6.9)]

$$\sum_n e^{ik(\varphi_b + 2\pi n - \varphi_a)} = \sum_{m=-\infty}^{\infty} \delta(k - m) e^{im(\varphi_b - \varphi_a)}. \quad (16.9)$$

Obviously, the number n on the left-hand side is precisely the winding number by which we want to sort the end-to-end distribution. The desired restricted probability $P_L^n(\mathbf{x}_b, \mathbf{x}_a)$ for a given winding number n is therefore obtained by converting the sum over m in Eq. (16.5) into an integral over μ and another sum over n as in Eq. (1.205), and by omitting the sum over n . The result is:

$$P_L^n(\mathbf{x}_b, \mathbf{x}_a) = \frac{2}{La} \int_{-\infty}^{\infty} d\mu e^{-(r_b^2 + r_a^2)/La} I_{|\mu|} \left(2 \frac{r_b r_a}{La} \right) \frac{1}{2\pi} e^{i\mu(\varphi_b - \varphi_a + 2\pi n)}. \quad (16.10)$$

From this we find the desired probability of a closed polymer running through a point \mathbf{x} with various winding numbers n around the central polymer:

$$P_L^n(\mathbf{x}, \mathbf{x}) = \frac{2}{La} \int_{-\infty}^{\infty} d\mu e^{-2r^2/La} I_{|\mu|} \left(2 \frac{r^2}{La} \right) \frac{1}{2\pi} e^{i2\pi\mu n}. \quad (16.11)$$

Let us also calculate the partition function of a closed polymer with a given winding number n . To make the partition function finite, we change the system by

adding a harmonic oscillator potential centered at the origin.¹ If ω is measured in units 1/length, the above probability becomes

$$P_L^n(\mathbf{x}, \mathbf{x}) = \frac{2}{a} \frac{\omega}{\sinh \omega L} \int_{-\infty}^{\infty} d\mu e^{-2(r^2/a)\omega \coth \omega L} I_{|\mu|} \left(\frac{2}{a} \frac{r^2 \omega}{\sinh \omega L} \right) \frac{1}{2\pi} e^{i2\pi\mu n}. \quad (16.12)$$

This can be integrated over the entire space using the formula (2.475). The result is

$$P_L^n \equiv \int d^2x P_L^n(\mathbf{x}, \mathbf{x}) = \frac{1}{2 \sinh \omega L} \int_{-\infty}^{\infty} d\mu e^{-|\mu|\omega L} e^{2\pi i \mu n}. \quad (16.13)$$

To check this formula, we sum both sides over all n . Then the integral over μ is reduced, via Poisson's formula, to a sum over integers $\mu = m = 0, \pm 1, \pm 2, \dots$, and we find

$$\begin{aligned} P_L &\equiv \int d^2x P_L(\mathbf{x}, \mathbf{x}) = \sum_{n=-\infty}^{\infty} P_L^n \\ &= \frac{1}{2 \sinh \omega L} \left(\frac{2}{1 - e^{-\omega L}} - 1 \right) = \frac{1}{[2 \sinh(\omega L/2)]^2}. \end{aligned} \quad (16.14)$$

As we should have expected, this is the partition function of the two-dimensional harmonic oscillator.

To find the contribution of the various winding numbers, we perform the integral over μ and obtain

$$P_L^n = \frac{\omega L}{\sinh \omega L} \frac{1}{4\pi^2 n^2 + \omega^2 L^2}. \quad (16.15)$$

The right-hand factor is recognized as a term arising in the expansion

$$\begin{aligned} \frac{1}{2\omega L} \coth(\omega L/2) &= \sum_{n=-\infty}^{\infty} \frac{1}{4\pi^2 n^2 + (\omega L)^2} \\ &= \frac{1}{L^2} \sum_{n=-\infty}^{\infty} \frac{1}{\omega_n^2 + \omega^2}. \end{aligned} \quad (16.16)$$

The quantities $\omega_n \equiv 2\pi n/L$ are the polymer analogs of the Matsubara frequencies. Thus we may write

$$P_L^n = P_L \cdot \alpha_n, \quad (16.17)$$

where α_n is the relative probability of finding the winding number n (with the normalization $\sum_n \alpha_n = 1$),

$$\begin{aligned} \alpha_n &= \frac{1}{\omega_n^2 + \omega^2} \left[\sum_{n=-\infty}^{\infty} \frac{1}{\omega_n^2 + \omega^2} \right]^{-1} \\ &= \frac{1}{L^2} \frac{1}{\omega_n^2 + \omega^2} \left[\frac{1}{2\omega L} \coth \frac{\omega L}{2} \right]^{-1}. \end{aligned} \quad (16.18)$$

¹Alternatively, we may add a magnetic field with the Landau frequency $\omega = -eB/Mc$, as done in (16.33). Then the amplitude contains $\omega/2$ instead of ω , and an extra factor $e^{m\omega L/2}$.

16.2 Entangled Fluctuating Particle Orbit: Aharonov-Bohm Effect

The entanglement of a fluctuating polymer around a straight central polymer has an interesting quantum-mechanical counterpart known as the *Aharonov-Bohm effect*. Consider a free nonrelativistic charged particle moving through a space containing an infinitely thin tube of finite magnetic flux along the z -direction:

$$B_3 = \frac{g}{2\pi} \epsilon_{3jk} \partial_j \partial_k \varphi = g \delta^{(2)}(\mathbf{x}_\perp), \quad (16.19)$$

where \mathbf{x}_\perp is the transverse vector $\mathbf{x}_\perp \equiv (x_1, x_2)$. Let us study the associated path integral. The magnetic interaction is given by [recall Eq. (2.635)]

$$\mathcal{A}_{\text{mag}} = \frac{e}{c} \int_{t_a}^{t_b} dt \dot{\mathbf{x}} \cdot \mathbf{A}, \quad (16.20)$$

where e is the charge and \mathbf{A} the vector potential. The flux tube (16.19) is obtained from the components in the xy -plane.

$$A_i = \frac{g}{2\pi} \partial_i \varphi, \quad (i = 1, 2), \quad (16.21)$$

where φ is the azimuthal angle around the tube:

$$\varphi(\mathbf{x}) \equiv \arctan(x_2/x_1). \quad (16.22)$$

Note that the derivatives in front of φ in (16.19) commute everywhere, except at the origin where Stokes' theorem yields

$$\int d^2x (\partial_1 \partial_2 - \partial_2 \partial_1) \varphi = \oint d\varphi = 2\pi. \quad (16.23)$$

The total magnetic flux through the tube is defined by the integral

$$\Phi = \int d^2x B_3. \quad (16.24)$$

Inserting (16.19) we see that the total flux is equal to g :

$$\Phi = g. \quad (16.25)$$

With the vector potential (16.21), the interaction (16.20) takes the form

$$\mathcal{A}_{\text{mag}} = -\hbar\mu_0 \int_{t_a}^{t_b} dt \dot{\varphi}, \quad (16.26)$$

where μ_0 is the dimensionless number

$$\mu_0 \equiv -\frac{eg}{2\pi\hbar c}. \quad (16.27)$$

The minus sign is a matter of convention.

Since the particle orbits are present at all times, their worldlines in spacetime can be considered as being closed at infinity, and the integral

$$n = \frac{1}{2\pi} \int_{t_a}^{t_b} dt \dot{\varphi} \quad (16.28)$$

is the topological invariant (16.4) with integer values of the winding number n . The magnetic interaction (16.26) is therefore a purely topological one, its value being

$$\mathcal{A}_{\text{mag}} = -\hbar\mu_0 2\pi n. \quad (16.29)$$

After adding this to the action of a free particle in the radial decomposition (8.9) of the quantum-mechanical path integral, we rewrite the sum over the azimuthal quantum numbers m via Poisson's summation formula as in (16.10), and obtain

$$\begin{aligned} (\mathbf{x}_b\tau_b|\mathbf{x}_a\tau_a) &= \int_{-\infty}^{\infty} d\mu \frac{1}{\sqrt{r_b r_a}} (r_b\tau_b|r_a\tau_a)_\mu \\ &\times \sum_{n=-\infty}^{\infty} \frac{1}{2\pi} e^{i(\mu-\mu_0)(\varphi_b+2\pi n-\varphi_a)}. \end{aligned} \quad (16.30)$$

Since the winding number n is often not easy to measure experimentally, let us extract observable consequences which are independent of n . The sum over all n forces μ to be equal to μ_0 modulo an arbitrary integer number $m = 0, \pm 1, \pm 2, \dots$. The result is

$$(\mathbf{x}_b\tau_b|\mathbf{x}_a\tau_a) = \sum_{m=-\infty}^{\infty} \frac{1}{\sqrt{r_b r_a}} (r_b\tau_b|r_a\tau_a)_{m+\mu_0} \frac{1}{2\pi} e^{im(\varphi_b-\varphi_a)}, \quad (16.31)$$

with the radial amplitude

$$(r_b\tau_b|r_a\tau_a)_{m+\mu_0} = \sqrt{r_b r_a} \frac{M}{\hbar} \frac{1}{(\tau_b - \tau_a)} \exp \left\{ -\frac{M}{2\hbar} \frac{r_b^2 + r_a^2}{\tau_b - \tau_a} \right\} I_{|m+\mu_0|} \left(\frac{M}{\hbar} \frac{r_b r_a}{\tau_b - \tau_a} \right). \quad (16.32)$$

For the sake of generality, we allow for the presence of a homogeneous magnetic field B whose Landau frequency is $\omega = -eB/Mc$. In analogy with the parameter μ_0 in (16.27), it is defined with a minus sign. Using the radial amplitude (9.105), we see that (16.32) is simply generalized to

$$\begin{aligned} (r_b\tau_b|r_a\tau_a)_{m+\mu_0} &= \sqrt{r_b r_a} \frac{M\omega}{2\hbar\eta} \frac{\eta}{\sinh \eta} \exp \left[-\frac{M\omega}{2\hbar} \frac{1}{2} \coth \eta (r_b^2 + r_a^2) \right] \\ &\times I_{|m+\mu_0|} \left(\frac{M\omega r_b r_a}{2\hbar \sinh \eta} \right) e^{(m+\mu_0)\eta}, \end{aligned} \quad (16.33)$$

where $\eta \equiv \omega(\tau_b - \tau_a)/2$.

At this point we can make an interesting observation: If μ_0 is an integer number, i.e., if

$$\frac{eg}{2\pi\hbar c} = \text{integer}, \quad (16.34)$$

the quantum-mechanical particle distribution function $(\mathbf{x} t_b | \mathbf{x} t_a)$ in (16.31) becomes *independent* of the magnetic flux tube along the z -axis. The condition implies that the magnetic flux is an integer multiple of the fundamental flux quantum

$$\Phi_0 \equiv g_0 \equiv \frac{2\pi\hbar c}{e} = \frac{hc}{e}. \quad (16.35)$$

We recognize this infinitely thin tube as a *Dirac string*. Such undetectable strings were used in Sections 8.12, Appendix 10A.3, and Section 14.6 to import the magnetic flux of a magnetic monopole from infinity to a certain point where the magnetic field lines emerge radially. In Appendix 10A.3 we have made the string invisible mathematically imposing monopole gauge invariance. The present discussion shows explicitly that the flux quantization makes Dirac strings indeed undetectable by any charged particle. This observation inspired Dirac his speculation on the existence of magnetic monopoles.

In low-temperature physics, a quantization of magnetic flux is observable in type-II superconductors. Superconductors are perfect diamagnets which expel magnetic fields. Those of type II have the property that above a certain critical external field called H_{c1} , the expulsion is not perfect but they admit quantized magnetic tubes of flux Φ_0 (*Shubnikov phase*). For increasing fields, there are more and more such flux tubes. They are squeezed together and can form a periodically arranged bundle. When cut across in the xy -plane, the bundle looks like a hexagonal planar flux lattice [4]. If the central magnetic flux tube in (16.19) carries an amount of flux that is not an integer multiple of Φ_0 , the amplitude of particles passing the tube displays an interesting interference pattern. This was initially a surprise since the space is free of magnetic fields. To calculate this pattern we consider the fixed-energy amplitude of a free particle in two dimensions (9.12), decomposed into partial waves via the addition theorem (9.14) for Bessel functions as in (9.15):

$$(\mathbf{x}_b | \mathbf{x}_a)_E = -\frac{2iM}{\hbar} \sum_{m=-\infty}^{\infty} I_m(\kappa r_{<}) K_m(\kappa r_{>}) \frac{1}{2\pi} e^{im(\varphi_b - \varphi_a)}. \quad (16.36)$$

Comparing this with (16.30) and repeating the arguments leading to (16.31), (16.32), we can immediately write down the fixed-energy amplitude in the presence of a flux Φ_0 :

$$(\mathbf{x}_b | \mathbf{x}_a)_E = -\frac{2iM}{\hbar} \sum_{m=-\infty}^{\infty} I_{|m+\mu_0|}(\kappa r_{<}) K_{|m+\mu_0|}(\kappa r_{>}) \frac{1}{2\pi} e^{im(\varphi_b - \varphi_a)}. \quad (16.37)$$

The wave functions are now easily extracted. In the complex E -plane, the right-hand side has a discontinuity across the positive real axis. By going through the same steps as in (9.15)–(9.22), we derive for the discontinuity

$$\int_{-\infty}^{\infty} \frac{dE}{2\pi\hbar} \text{disc}(\mathbf{x}_b | \mathbf{x}_a)_E = \sum_{m=-\infty}^{\infty} \int_0^{\infty} dk k J_{|m+\mu_0|}(kr_b) J_{|m+\mu_0|}(kr_a) \frac{1}{2\pi} e^{im(\varphi_b - \varphi_a)}. \quad (16.38)$$

The integration measure $\int (dE/2\pi\hbar)(2\pi M/\hbar)$ has been replaced by $\int_0^\infty dk k$ according to Eq. (9.23).

In the absence of the flux tube, the amplitude (16.38) reduces to that of a free particle, which has the decomposition

$$\begin{aligned} \int_{-\infty}^{\infty} \frac{dE}{2\pi\hbar} \text{disc}(\mathbf{x}_b|\mathbf{x}_a)_E &= \int \frac{d^2k}{(2\pi)^2} e^{i\mathbf{k}(\mathbf{x}_b-\mathbf{x}_a)} = \frac{1}{2\pi} \int_0^\infty dk k J_0(k|\mathbf{x}_b-\mathbf{x}_a|) \\ &= \sum_{m=-\infty}^{\infty} \int_0^\infty dk k J_m(kr_b) J_m(kr_a) \frac{1}{2\pi} e^{im(\varphi_b-\varphi_a)}. \end{aligned} \quad (16.39)$$

If a flux tube is present, a beam of incoming charged particles is deflected even though the space around the z -axis contains no magnetic field. Let us calculate the scattering amplitude and the ensuing cross section from the fixed-energy amplitude (16.37). Recall the results of the quantum-mechanical scattering theory due to Lippmann and Schwinger. In this theory one studies the effect of an interaction upon an incoming free-particle state $\varphi_{\mathbf{k}}$ of wave vector \mathbf{k} . The result is the scattering state $\psi_{\mathbf{k}}$ obtained from the *Lippmann-Schwinger* integral equation

$$\begin{aligned} \psi_{\mathbf{k}} &= \varphi_{\mathbf{k}} + \frac{1}{E - \hat{H}_0 + i\eta} \hat{V} \psi_{\mathbf{k}} \\ &= \varphi_{\mathbf{k}} - \frac{i}{\hbar} \hat{R}(E) \hat{V} \varphi_{\mathbf{k}}, \end{aligned} \quad (16.40)$$

where E is the energy of the incoming particle, \hat{V} the potential, and $\hat{R}(E)$ the resolvent operator (1.319). The scattering states $\psi_{\mathbf{k}}$ are solutions of the Schrödinger equation

$$\hat{H} \psi_{\mathbf{k}} = (\hat{H}_0 + \hat{V}) \psi_{\mathbf{k}} = E \psi_{\mathbf{k}}. \quad (16.41)$$

In \mathbf{x} -space, the Lippmann-Schwinger equation reads

$$\psi_{\mathbf{k}}(\mathbf{x}) = \varphi_{\mathbf{k}}(\mathbf{x}) - \frac{i}{\hbar} \int d^D x' (\mathbf{x}|\mathbf{x}')_E V(\mathbf{x}') \varphi_{\mathbf{k}}(\mathbf{x}'). \quad (16.42)$$

The first term describes the impinging particles, the second the scattered ones. For the scattering amplitude, only the large- \mathbf{x} behavior of the second term matters. One usually normalizes $\varphi_{\mathbf{k}}(\mathbf{x})$ to $e^{i\mathbf{k}\mathbf{x}}$ and factorizes the second term asymptotically into a product of an outgoing spherical wave times a scattering amplitude. In three dimensions, the asymptotic behavior far away from the scattering center is

$$\psi_{\mathbf{k}}(\mathbf{x}) \xrightarrow{|\mathbf{x}| \rightarrow \infty} e^{i\mathbf{k}\mathbf{x}} + \frac{e^{i|\mathbf{k}||\mathbf{x}|}}{|\mathbf{x}|} f(\theta, \varphi) + \dots, \quad (16.43)$$

where θ and φ are the scattering angles of the outgoing beam and f is the scattering amplitude. Its square gives directly the differential cross section

$$\frac{d\sigma}{d\Omega} = |f(\theta, \varphi)|^2. \quad (16.44)$$

In two dimensions, the corresponding splitting is

$$\psi_{\mathbf{k}}(\mathbf{x}) \xrightarrow{|\mathbf{x}| \rightarrow \infty} e^{i\mathbf{k}\mathbf{x}} + \frac{e^{i|\mathbf{k}||\mathbf{x}|}}{\sqrt{|\mathbf{x}|}} f(\varphi) + \dots \quad (16.45)$$

The scattering amplitude $f(\varphi)$ which depends only on the azimuthal angle $\varphi = \arctan(x_2/x_1)$ yields the differential cross section

$$\frac{d\sigma}{d\varphi} = |f(\varphi)|^2. \quad (16.46)$$

To calculate $f(\varphi)$, we observe that the most general solution $\Psi(\mathbf{x})$ of the Schrödinger equation (16.41) is obtained by forming the convolution integral of the discontinuity of the resolvent with an arbitrary wave function $\phi(\mathbf{x})$:

$$\psi(\mathbf{x}) = \int d^D x' \text{disc}(\mathbf{x}|\mathbf{x}')_E \phi(\mathbf{x}'). \quad (16.47)$$

Using (16.38), this becomes some linear combination of wave functions $J_{|m+\mu_0|}(kr)$

$$\psi(\mathbf{x}) = \sum_{m=-\infty}^{\infty} a_m J_{|m+\mu_0|}(kr) e^{im\varphi}, \quad (16.48)$$

which certainly satisfies the Schrödinger equation (16.41). The coefficients a_m have to be chosen to satisfy the scattering boundary condition at spatial infinity. Suppose that the incident particles carry a wave vector $\mathbf{k} = (-k, 0)$. In the incoming region $x \rightarrow \infty$, they are described by a wave function

$$\lim_{x \rightarrow \infty} \psi(\mathbf{x}) = e^{-ikx} e^{-i\mu_0\varphi}. \quad (16.49)$$

The extra phase factor is necessary for the correct wave vector since in the presence of the gauge field

$$eA_i = -\hbar c \mu_0 \partial_i \varphi, \quad (16.50)$$

the physical momentum $\mathbf{p} = \hbar\mathbf{k}$ is not given by the usual derivative operator $-i\hbar\nabla$ but by the gauge-invariant momentum operator

$$\hat{\mathbf{P}} = -i\hbar\nabla - \frac{e}{c}\mathbf{A} = -i\hbar(\nabla + i\mu_0\nabla\varphi). \quad (16.51)$$

The corresponding incident gauge-invariant particle current is

$$\mathbf{j}(\mathbf{x}) = -i\frac{\hbar}{2M}\psi^\dagger \overleftrightarrow{\nabla} \psi(\mathbf{x}) - \frac{e}{Mc}\mathbf{A}(\mathbf{x})\psi^\dagger\psi(\mathbf{x}). \quad (16.52)$$

We demonstrate below that the correct choice for the coefficients a_m is

$$a_m = (-i)^{|m+\mu_0|}, \quad (16.53)$$

leading to the scattering amplitude

$$f(\varphi) = \frac{1}{\sqrt{2\pi}} e^{-i\pi/4} \sin \pi \mu_0 \frac{e^{-i\varphi/2}}{\cos(\varphi/2)}, \quad (16.54)$$

i.e., to the cross section

$$\frac{d\sigma}{d\varphi} = \frac{1}{2\pi} \sin^2 \pi \mu_0 \frac{1}{\cos^2(\varphi/2)}. \quad (16.55)$$

It has a strong peak near the forward direction $\varphi \approx \pi$. For $\mu_0 =$ integer, there is no scattering at all and the flux tube becomes an invisible Dirac string.

To derive (16.53) and (16.54) we may assume that $\mu_0 \in (0, 1)$. Otherwise, we could simply shift the sum over m in (16.37) by an integer Δm , and this would merely produce an overall factor $e^{i\Delta m(\varphi_b - \varphi_a)}$ in $\text{disc}(\mathbf{x}_b | \mathbf{x}_a)_E$. This would wind up as a factor $e^{i\Delta m \varphi}$ in $\psi(\mathbf{x})$. For $\mu_0 \in (0, 1)$, we split the wave function (16.48) into three parts:

$$\psi_{\mathbf{k}} = \psi^{(1)} + \psi^{(2)} + \psi^{(3)}. \quad (16.56)$$

The first collects the terms with positive m ,

$$\psi^{(1)} = \sum_{m=1}^{\infty} (-i)^{m+\mu_0} J_{m+\mu_0} e^{im\varphi}, \quad (16.57)$$

the second those with negative m ,

$$\begin{aligned} \psi^{(2)} &= \sum_{m=-\infty}^{-1} (-i)^{m+\mu_0} J_{|m+\mu_0|} e^{im\varphi} \\ &= \sum_{m=1}^{\infty} (-i)^{m-\mu_0} J_{m-\mu_0} e^{-im\varphi}, \end{aligned} \quad (16.58)$$

and the third contains only the term $m = 0$,

$$\psi^{(3)} = (-i)^{|\mu_0|} J_{|\mu_0|}. \quad (16.59)$$

Obviously, $\psi^{(2)}$ may be obtained from $\psi^{(1)}$ via the identity

$$\psi^{(2)}(r, \varphi, \mu_0) = \psi^{(1)}(r, -\varphi, -\mu_0). \quad (16.60)$$

Thus, the wave function (16.56) requires only a calculation of $\psi^{(1)}$.

As a first step we observe that the sum (16.57) has an integral representation

$$\psi^{(1)} = \frac{1}{2} (-i)^{\mu_0} e^{-i\rho \cos \varphi} I(\rho), \quad (16.61)$$

with $I(\rho)$ being the integral

$$I(\rho) \equiv \int_0^\rho d\rho' e^{i\rho' \cos \varphi} (J_{1+\mu_0} - iJ_{\mu_0} e^{i\varphi}). \quad (16.62)$$

We have set $kr \equiv \rho$ such that $\mathbf{kx} \equiv \rho \cos \varphi$. To prove the integral representation, we differentiate (16.61) and find the differential equation

$$\partial_\rho \psi^{(1)} = -i \cos \varphi \psi^{(1)} + \frac{1}{2}(-i)^{\mu_0} (J_{1+\mu_0} - iJ_{\mu_0} e^{i\varphi}), \quad (16.63)$$

with all functions depending only on $kr \equiv \rho$. Precisely the same equation is obeyed by the sum (16.57):

$$\begin{aligned} \partial_\rho \psi^{(1)} &= \sum_{m=1}^{\infty} (-i)^{m+\mu_0} \partial_\rho J_{m+\mu_0} e^{im\varphi} \\ &= \sum_{m=1}^{\infty} (-i)^{m+\mu_0} \frac{1}{2} (J_{m+\mu_0-1} - J_{m+\mu_0+1}) e^{im\varphi} \\ &= -\frac{i}{2} \sum_{m=1}^{\infty} (-i)^{m+\mu_0} J_{m+\mu_0} e^{im\varphi} (e^{i\varphi} + e^{-i\varphi}) + \frac{1}{2}(-i)^{\mu_0} (J_{1+\mu_0} - iJ_{\mu_0} e^{ie}). \end{aligned} \quad (16.64)$$

Thus, the two expressions (16.57) and (16.61) for $\psi^{(1)}$ can differ at most by an integration constant. However, the constant must be zero since both expressions vanish at $\rho = 0$. This proves the integral representation (16.61).

In order to derive the scattering amplitude for the magnetic flux tube, we have to find the asymptotic of the wave function. This is done by splitting $\psi_\infty^{(1)}$ into two terms, a contribution $\psi_\infty^{(1)}$ in which the integral I is carried all the way to infinity, to be denoted by I_∞ , and a remainder $\Delta\psi^{(1)}$ which vanishes for $r \rightarrow \infty$. The integral I_∞ can be calculated analytically using the formula

$$\int_0^\infty d\rho e^{i\beta\rho} J_\alpha(k\rho) = \frac{1}{(k^2 - \beta^2)^{1/2}} e^{i\alpha \arcsin(\beta/k)}, \quad 0 < \beta < k, \quad \alpha > -2. \quad (16.65)$$

This gives

$$\begin{aligned} I_\infty &\equiv \int_0^\infty d\rho' e^{i\rho' \cos \varphi} (J_{1+\mu_0} - iJ_{\mu_0} e^{i\varphi}) = \frac{1}{|\sin \varphi|} [e^{i\mu_0(\pi/2-|\varphi|)} - ie^{i\varphi} e^{i(1+\mu_0)(\pi/2-|\varphi|)}] \\ &= \frac{i}{|\sin \varphi|} e^{i\mu_0(\pi/2-|\varphi|)} (e^{-i|\varphi|} - e^{i\varphi}) = \begin{cases} 0, & \varphi < 0, \\ e^{-i\mu_0\varphi} 2i^{\mu_0}, & \varphi > 0, \end{cases} \end{aligned} \quad (16.66)$$

with $\varphi \in (-\pi, \pi)$. Hence we have

$$\psi_\infty^{(1)} = \begin{cases} 0, & \varphi < 0, \\ e^{-ikx} e^{-i\mu_0\varphi}, & \varphi > 0. \end{cases} \quad (16.67)$$

Using (16.60), we find

$$\psi_\infty^{(2)} = \begin{cases} e^{-ikx} e^{-i\mu_0\varphi}, & \varphi < 0, \\ 0, & \varphi > 0. \end{cases} \quad (16.68)$$

The sum $\psi_\infty^{(1)} + \psi_\infty^{(2)}$ represents the incoming wave (16.49). The scattered wave must therefore reside in the remainder

$$\psi_{sc} = \Delta\psi^{(1)} + \Delta\psi^{(2)} + \psi^{(3)}. \quad (16.69)$$

For the scattering amplitude, only the leading $1/\sqrt{r}$ -behavior of the three terms is relevant. To find it for $\Delta\psi^{(1)}$, we take (16.61) and write the remainder of the integral (16.62) as

$$\Delta I(\rho) \equiv I(\rho) - I_\infty = \int_\rho^\infty d\rho' e^{i\rho' \cos \varphi} (J_{1+\mu_0} - ie^{i\varphi} J_{\mu_0}). \quad (16.70)$$

At large ρ , the asymptotic expansion

$$J_\alpha(\rho) \sim \sqrt{2/\pi\rho} \cos(\rho - \alpha/2 - \pi/4) \quad (16.71)$$

renders

$$\Delta I(\rho) = \sqrt{\frac{2}{\pi}} [A(\rho) + B(\rho)], \quad (16.72)$$

with the integrals

$$\begin{aligned} A(\rho) &= \int_\rho^\infty \frac{d\rho'}{\sqrt{\rho'}} e^{i\rho' \cos \varphi} \cos[\rho' - (1 + \mu_0)/2 - \pi/4], \\ B(\rho) &= -ie^{i\varphi} \int_\rho^\infty \frac{d\rho'}{\sqrt{\rho'}} e^{i\rho' \cos \varphi} \cos[\rho' - \mu_0/2 - \pi/4]. \end{aligned} \quad (16.73)$$

Separating the cosine into exponentials and changing the variable ρ' in the two terms to $\rho' = t^2/(1 \pm \cos \varphi)$, we find

$$A(\rho) = \left[\frac{(-i)^{1/2+\mu_0}}{\sqrt{1 + \cos \theta}} \int_{\sqrt{\rho(1+\cos \varphi)}}^\infty dt e^{it^2} + \frac{i^{3/2+\mu_0}}{\sqrt{1 - \cos \theta}} \int_{\sqrt{\rho(1-\cos \varphi)}}^\infty dt e^{-it^2} \right], \quad (16.74)$$

and a corresponding expression for $B(\rho)$. The asymptotic expansion of the error function

$$\int_x^\infty dt e^{\pm it^2} = \pm \frac{i \exp(\pm ix^2)}{x} + \dots \quad (16.75)$$

leads to

$$\begin{aligned} A(\rho) &= \frac{1}{2} \left[(-i)^{\frac{1}{2}+\mu_0} \frac{e^{i\rho}}{\sqrt{\rho(1 + \cos \varphi)^2}} + i^{\frac{1}{2}+\mu_0} \frac{e^{-i\rho}}{\sqrt{\rho(1 - \cos \varphi)^2}} \right] e^{i\rho \cos \varphi}, \\ B(\rho) &= (-i) \frac{e^{i\varphi}}{2} \\ &\quad \times \left[(-i)^{-\frac{1}{2}+\mu_0} \frac{e^{i\rho}}{\sqrt{\rho(1 + \cos \varphi)^2}} + i^{-\frac{1}{2}+\mu_0} \frac{e^{-i\rho}}{\sqrt{\rho(1 - \cos \varphi)^2}} \right] e^{i\rho \cos \varphi}. \end{aligned} \quad (16.76)$$

Adding the two terms together in (16.72) and inserting everything into (16.61) gives the asymptotic behavior

$$\Delta\psi^{(1)} = \frac{\sqrt{-i}}{2\sqrt{2\pi\rho}} \left[(-1)^{\mu_0} e^{i\rho} \frac{1 + e^{i\varphi}}{1 + \cos \varphi} + ie^{-i\rho} \frac{1 - e^{i\varphi}}{1 - \cos \varphi} \right]. \quad (16.77)$$

Together with $\Delta\psi^{(2)}$ found via (16.60), we obtain

$$\Delta\psi^{(1)} + \Delta\psi^{(2)} = \frac{\sqrt{-i}}{\sqrt{2\pi\rho}} \left[e^{i\rho} \frac{\cos(\pi\mu_0 - \varphi/2)}{\cos(\varphi/2)} + ie^{-i\rho} \right] + e^{-i(\rho \cos \varphi + \mu_0 \varphi)}. \quad (16.78)$$

Adding further $\psi^{(3)}$ from (16.59) with the asymptotic limit given by (16.71), the total wave function is seen to behave like

$$\psi(\mathbf{x}) \rightarrow e^{-i(\rho \cos \varphi + \mu_0 \varphi)} + \psi_{\text{sc}}(\mathbf{x}), \quad (16.79)$$

with the scattered wave

$$\psi_{\text{sc}} = \frac{1}{\sqrt{2\pi i \rho}} e^{i\rho} \frac{\sin \pi \mu_0}{\cos(\varphi/2)} e^{-i\varphi/2}. \quad (16.80)$$

This corresponds precisely to the scattering amplitude (16.54) with the cross section (16.55).

Let us mention that for half-integer values of μ_0 , the solution of the Schrödinger equation has the simple integral representation

$$\psi(\mathbf{x}) = \sqrt{\frac{i}{2}} e^{-i(\varphi/2 + \rho \cos \varphi)} \int_0^{\sqrt{\rho(1+\cos \varphi)}} dt e^{it^2}. \quad (16.81)$$

It vanishes on the line $\varphi = \pi$, i.e., directly behind the flux tube and is manifestly single-valued.

16.3 Aharonov-Bohm Effect and Fractional Statistics

It was noted in Section 7.5 and it is worth mentioning once more in this context that the amplitude for the relative motion of two fermion orbits can be obtained from the amplitude of the Aharonov-Bohm effect.

For this, we take the amplitude with $\mu_0 = 1$ and sum it over the final states with $\varphi_b, \varphi_b + \pi$, to account for particle identity. The result is

$$\begin{aligned} (\mathbf{x}_b|\mathbf{x}_a)_E + (-\mathbf{x}_b|\mathbf{x}_a)_E &= -\frac{2iM}{\hbar} \sum_m I_{|m+1|}(\kappa r_<) K_{|m+1|}(\kappa r_>) \\ &\quad \times \frac{1}{2\pi} \left[e^{im(\varphi_b - \varphi_a)} + (-)^m e^{im(\varphi_b - \varphi_a)} \right] \\ &= -\frac{4iM}{\hbar} e^{-i(\varphi_b - \varphi_a)} \sum_{m=\text{odd}} I_{|m|}(\kappa r_<) K_{|m|}(\kappa r_>) \frac{1}{2\pi} e^{im(\varphi_b - \varphi_a)}. \end{aligned} \quad (16.82)$$

The sum over the two identical final states selects only the odd wave functions, as in (7.267)–(7.268). When calculating observable quantities such as particle densities or partition functions which involve only the trace of the amplitude, the phase factor $e^{-i(\varphi_b - \varphi_a)}$ has no observable consequences and can be omitted.

For $\mu_0 \neq 1$, the resulting amplitudes may be interpreted as describing particles in two dimensions obeying an unusual fractional statistics. This interpretation has recently come to enjoy great popularity,² since it has led to an understanding of the experimental data of the fractional quantum Hall effect. The data can be explained by the following assumption: The excitations of a gas of electrons with Coulomb interactions in a quasi-two-dimensional material traversed by a strong magnetic field can be viewed, to lowest approximation, as a gas of quasi-particles which has *no* Coulomb interactions, but a new effective pair interaction. Each pair behaves as if one partner were accompanied by a thin magnetic flux tube of a certain value of μ_0 . While the quasi-particles of the ground state carry an integer-valued μ_0 and act statistically like ordinary electrons, the elementary excitations carry a fractional value of μ_0 and display fractional statistics (more in Section 16.11).

To study the fundamental thermodynamic properties of an ensemble of such particles, we calculate the partition function of a particle running around a thin flux tube along the z -axis. For finiteness, we assume the presence of an additional homogeneous magnetic field in the z -direction. Ignoring the third dimension, we take the amplitude (16.33), integrate it over all space, and find

$$\begin{aligned} Z &= \int d^2x (\mathbf{x}_b \tau_b | \mathbf{x}_a \tau_a) \\ &= \frac{1}{2} e^{\mu_0 \eta} \sum_{m=-\infty}^{\infty} e^{m\eta} \int_0^{\infty} d\xi e^{-\xi \cosh \eta} I_{|m+\mu_0|}(\xi), \end{aligned} \quad (16.83)$$

where

$$\xi \equiv M\omega r^2 / 2\hbar \sinh \eta \quad (16.84)$$

[recall that $\omega = -eB/Mc$ and $\eta = \omega(\tau_b - \tau_a)/2$]. To calculate the partition function, the difference between the Euclidean times τ_b, τ_a is set equal to $\tau_b - \tau_a = \hbar/k_\beta T = \hbar\beta$, so that $\eta = \omega\hbar\beta/2$.

To deal with two identical particles, we also need the integral in which \mathbf{x}_b is exchanged by $-\mathbf{x}_b$:

$$Z_{\text{ex}} = \int d^2x (-\mathbf{x}_b \tau_b | \mathbf{x}_a \tau_a) = \frac{1}{2} e^{\mu_0 \eta} \sum_{m=-\infty}^{\infty} (-)^m e^{m\eta} \int_0^{\infty} d\xi e^{-\xi \cosh \eta} I_{|m+\mu_0|}(\xi). \quad (16.85)$$

In order to facilitate writing joint equations for both expansions, let us denote Z and Z_{ex} by Z_1 and $Z_{1,\text{ex}}$, respectively. The integrals are performed with the help of formula (2.474), yielding the sums

$$Z_{1,1,\text{ex}} = \frac{1}{2} \sum_{m=-\infty}^{\infty} (\pm)^m e^{\eta(m+\mu_0)} \frac{1}{\sinh \eta} e^{-\eta|m+\mu_0|}. \quad (16.86)$$

These sums are obviously periodic under $\mu_0 \rightarrow \mu_0 + 2$. Because of translational invariance, the partition function $Z \equiv Z_1$ diverges with the total area $V = \int d^2x$ as

²See Notes and References at the end of Chapter 7.

an overall factor. To enforce convergence, we multiply the volume elements d^2x with an exponential regulating factor $e^{-\epsilon\xi}$. Then the area integrals can be extended over all space. In terms of the variable ξ of (16.84), the measure in the above rotationally symmetric integrals can be written as

$$d^2x = l_e^2(T) \frac{\sinh \eta}{\eta} d\xi, \quad (16.87)$$

with the thermal length $l_e(T) \equiv \sqrt{2\pi\hbar^2/k_B TM}$ introduced in Eq. (2.354). The role of the total area $V = \int d^2x$ is now played by the finite quantity

$$V \equiv \int d^2x e^{-\epsilon\xi} = \frac{l_e^2(T) \sinh \eta}{\epsilon \eta}. \quad (16.88)$$

Inserting the factor $e^{-\epsilon\xi}$ into the integrals in Eqs. (16.83) and (16.85), and defining a variable η' slightly different from η by

$$\cosh \eta' \equiv \epsilon + \cosh \eta, \quad (16.89)$$

which has the expansion

$$\begin{aligned} e^{\eta'} &= \cosh \eta' + \sqrt{\cosh^2 \eta' - 1} \\ &= e^\eta \left(1 + \frac{\epsilon}{\sinh \eta} - \frac{1}{2} e^{-\eta} \frac{\epsilon^2}{\sinh^3 \eta} + \dots \right), \quad \eta > 0, \end{aligned} \quad (16.90)$$

the regulated sums (16.86) for Z_1 and $Z_{1\text{ex}}$ look almost the same as before:

$$Z_{1,1\text{ex}} = \frac{1}{2} \sum_{m=-\infty}^{\infty} (\pm)^m e^{\eta(m+\mu_0)} \frac{1}{\sinh \eta'} e^{-\eta'|m+\mu_0|}. \quad (16.91)$$

Separating positive and negative values of $m + \mu_0$, the two sums can be done for $\mu_0 \in (0, 1)$ and for $\mu_0 \in (-1, 0)$. In the combined interval $\mu_0 \in (-1, 1)$, we find

$$Z_{1,1\text{ex}} = \frac{1}{2} e^{\eta\mu_0} \frac{1}{\sinh \eta'} \left\{ \frac{e^{-\eta'\mu_0}}{1 \mp a} + \frac{e^{\eta'\mu_0}}{1 \mp b} - e^{\eta'|\mu_0|} \right\}, \quad (16.92)$$

where

$$a \equiv e^{\eta-\eta'}, \quad b \equiv e^{-\eta-\eta'}.$$

Two identical particles have the partition function

$$Z = \frac{1}{2} (Z_1 + Z_{1\text{ex}}) = \frac{1}{2} e^{\eta\mu_0} \frac{1}{\sinh \eta'} \left\{ \frac{e^{-\eta'\mu_0}}{1 - a^2} + \frac{e^{\eta'\mu_0}}{1 - b^2} - e^{\eta'|\mu_0|} \right\}. \quad (16.93)$$

It is symmetric under the simultaneous exchange $\mu_0 \rightarrow -\mu_0$, $\eta \rightarrow -\eta$. Outside the interval $\mu_0 \in (-1, 1)$, it is defined by periodic extension.

In the absence of the thin flux tube we may take $Z_{1,1\text{ex}}$ directly from the amplitude (2.668). For $\mathbf{x}_b = \mathbf{x}_a$ and $\mathbf{x}_b = -\mathbf{x}_a$, this yields with the present variables

$$(\mathbf{x}_a\tau_b|\mathbf{x}_a\tau_a) = l_e^{-2}(T)\frac{\eta}{\sinh\eta}, \quad (-\mathbf{x}_a\tau_b|\mathbf{x}_a\tau_a) = l_e^{-2}(T)\frac{\eta}{\sinh\eta}e^{-2\cosh\eta\xi}. \quad (16.94)$$

Their regulated spatial integrals are

$$\begin{aligned} Z_{1,0} &= \frac{1}{2} \int_0^\infty d\xi e^{-\epsilon\xi} = \frac{1}{2\epsilon}, \\ Z_{1\text{ex},0} &= \frac{1}{2} \int_0^\infty d\xi e^{-(\epsilon+2\cosh\eta)\xi} = \frac{1}{2(\epsilon+2\cosh\eta)}. \end{aligned} \quad (16.95)$$

The subtracted partition functions $\Delta Z_{1,1\text{ex}} \equiv Z_{1,1\text{ex}} - \frac{1}{2}Z_{1,0}$ have a finite $\epsilon \rightarrow 0$ -limit, and $\Delta Z = Z - \frac{1}{2}Z_{1,0}$ becomes for $\mu_0 \in (0, 2)$

$$\Delta Z = -\frac{1}{8\sinh\eta} \left[\coth\eta + 2(\mu_0 - 1) - 2e^{2(\mu_0+1)\eta} \frac{1}{\sinh 2\eta} + 4e^{2\eta\mu_0} \right]. \quad (16.96)$$

These results can be used to calculate the second coefficient appearing in a *virial expansion* of the equation of state. For a dilute gas of particles with the above magnetic interactions it reads

$$\frac{pV}{Nk_B T} = 1 + \sum_{r=2}^{\infty} B_r n^{r-1}. \quad (16.97)$$

Here n is the number density of the particles N/V . In many-body theory it is shown that the coefficient B_2 depends on the two-body partition function Z_2 as follows:

$$B_2 = V \left(\frac{1}{2} - \frac{Z_2}{Z_1^2} \right), \quad (16.98)$$

where Z_1 is the two-dimensional single particle partition function of mass M . In the presence of the homogeneous magnetic field, Z_1 is given by $Z_{1,0}$ of Eq. (16.95). Without the regulating factor, the spatial integral over the imaginary-time amplitude in (16.94) gives directly

$$Z_1 = V \frac{\eta}{l_e^2(T) \sinh\eta}. \quad (16.99)$$

Separating the center of mass from the relative motion, we see that $Z_2 = 2Z_1 Z_{\text{rel}}$ and obtain

$$B_2 = \frac{V}{Z_1} (Z_1/2 - 2Z_{\text{rel}}) = \frac{l_e^2(T) \sinh\eta}{2\eta} (Z_1 - 4Z_{\text{rel}}). \quad (16.100)$$

The difference on the right-hand side is convergent for $V \rightarrow \infty$. It can be evaluated using *any* regulator for the area integration, in particular the exponential regulator of Eq. (16.88).

Figure 16.1 Second virial coefficient B_2 as function of flux μ_0 for various external magnetic field strengths parametrized by $\eta = -(eB/2Mc)\hbar\beta$. For a better comparison, each curve has been normalized to unity at $\mu_0 = 0$.

The partition function for the relative motion of two identical particles is obtained from Z by replacing M by the reduced mass, i.e., $M \rightarrow M/2$. This renders a factor $1/2$ via $l_e^{-2}(T)$. Hence $Z_1/2 - 2Z_{\text{rel}}$ becomes equal to $-\Delta Z$ and (16.100) yields [5]

$$B_2 = \frac{l_e^2(T)}{4\eta} \left[\coth\eta + 2(\mu_0 - 1) - 2e^{2(\mu_0+1)\eta} \frac{1}{\sinh(2\eta)} + 4e^{2\eta\mu_0} \right]. \quad (16.101)$$

The behavior of B_2 as a function of μ_0 is shown in Fig. 16.1. In the absence of a magnetic field, it reduces to

$$B_2 = \frac{l_e^2(T)}{4} \left[1 - 2(1 - |\mu_0|^2)^2 \right], \quad \mu_0 \in (-1, 1). \quad (16.102)$$

As μ_0 grows from zero to infinity, B_2 oscillates with a period 2 between $B_2 = -l_e^2(T)/4$ for even values of μ_0 , and $B_2 = l_e^2(T)/4$ for odd values. These are the well-known second *virial coefficients* of free bosons and fermions. They can, of course, be obtained in a simpler and more direct way from the symmetric and antisymmetric combinations of (16.95), $Z_0 = (1/2)(Z_{1,0} \pm Z_{1_{\text{ex}},0})$. Subtracting $Z_{1,0}$ leaves $\pm Z_{1_{\text{ex}},0}/2$ which reduces for $\eta = 0$ to $\pm 1/8$. Accounting for the factor 2 in the reduced mass, this yields $B_2 = \mp l_e^2(T)/4$.

The expression (16.102) can be interpreted as the *virial coefficient* of particles which are neither bosons nor fermions, but obey the laws of fractional statistics. These particles are the *anyons* introduced in Section 7.5. Unfortunately, there are at present no experimental data for the virial coefficients to which the theoretical expressions (16.102) [or (16.101)] could be compared.

At this point we should mention older, meanwhile discarded speculations that the phenomenon of high-temperature superconductivity might be explained by fractional statistics of some elementary excitations. Indeed, the change in statistics can

Figure 16.2 Lefthanded trefoil knot in polymer.

be derived from the electromagnetic interaction between the electrons in a quasi-two-dimensional layer of material moving in a strong magnetic field. Also, it is possible to construct a model of anyonic two-dimensional superconductivity in which topological effects lead to a Meissner screening of magnetic fields (see Section 16.13). A closer investigation, however, shows that the currents in the model show dissipation after all.

It must be emphasized that the equality between electromagnetic and statistical interaction used in the above calculations is restricted to two-particle systems and cannot be extended to arbitrarily many particles as in Section 7.5. Although it is possible to distribute the magnetic flux in a many-particle system equally between the constituents producing the desired behavior under particle exchange, an equal distribution of the charges would create an unwanted additional Coulomb potential, and the purely topological character of the interaction would be destroyed. The problem does not arise for charged particles such as electrons. Nevertheless, there is a definite need for a better and universally applicable theoretical description of anyons. This will be presented in Section 16.7.

16.4 Self-Entanglement of Polymer

An interesting consequence of the excluded-volume properties of polymers is the possibility of a self-entanglement of a closed polymer. Since its line elements are forbidden to cross each other, the fluctuations are unable to explore all possible configurations. An initially circular polymer, for example, can never turn into a *trefoil knot* of the form shown in Fig. 16.2 without breaking a molecular bond.

In the chemical formation process of a large number of polymers, many

entangled configurations arise. It is an interesting problem to find the distribution of the various independent topology classes. Until recently, the lack of theoretical methods has made analytic work almost impossible, restricting it to classification questions. Only Monte Carlo methods have yielded quantitative insights. Since 1989, however, interesting new quantum field-theoretic methods have been developed promising significant progress in the near future. Here we survey these methods and indicate how to derive analytic results. First, we introduce the relevant topological concepts.

A closed polymer will in general form a knot. A circular polymer represents a trivial knot. Two knots are called *equivalent* if they can be deformed into each

Figure 16.3 Nonprime (compound) knot. The dashed line separates two pieces. After closing the open ends, the pieces form two prime knots.

Figure 16.4 Illustration of multiplication law $a_1 a_2 \approx a_3$ in knot group. The loops a_1 and a_2 are equivalent, $a_1 \approx a_2$, while $a_4 \approx a_1^{-1}$.

other without breaking any line. Such deformations are called *isotopic*. A first step towards the classification consists in separating the equivalence classes into irreducible and reducible ones, defining *prime* or *simple* knots and *nonprime* or *compound* knots, respectively. A *compound* knot is characterized by the existence of a plane which is intersected twice (after some isotopic deformation) (see Fig. 16.3). By closing the open ends on each side of the plane one obtains two new knots. These may or may not be reduced further in the same way until one arrives at simple knots. One important step towards distinguishing different equivalence classes of simple and compound knots is the *knot group* defined as follows. In the multiply connected space created by a certain knot, choose an arbitrary point P (see Fig. 16.4). Then consider all possible closed loops starting from P and ending again at P . Two such loops are said to be *equivalent* if they can be deformed into each other without crossing the lines of the knot under consideration. The loops are, however, allowed to have arbitrary self-intersections. The classes of equivalent knots form the knot group. Group multiplication is defined by running through any two loops of two equivalence classes successively. The class whose loops can be contracted into the

Figure 16.5 Inequivalent (compound) knots possessing isomorphic knot groups. The upper is the *granny knot*, the lower the *square knot*. They are stereoisomers characterized by the same Alexander polynomial $(t^2 - t + 1)^2$ but different HOMFLY polynomials [see (16.126)].

point P is defined as the unit element e . Changing the orientation of the loops in a class corresponds to inverting the associated group element.

In this way, the classification of knots can be related to the classification of all possible knot groups. Consider the trivial knot, the circle. Obviously, the closed loops through P fall into classes labeled by an integer number n . The associated knot group is the group of integers. Conversely, no nontrivial knot is associated with this group.

Although this trivial example might at first suggest a one-to-one correspondence between the simple knots and their knot groups, there is none. Many examples are known where inequivalent knots have isomorphic knot groups. In particular, all mirror-reflected knots which usually are inequivalent to the original ones (such as the right- and left-handed trefoil), have the same knot group. Thus, the knot groups necessarily yield an *incomplete* classification of knots. An example is shown in Fig. 16.5.

Fortunately, the degeneracies are quite rare. Only a small fraction of inequivalent knots cannot be distinguished by their knot groups.

The easiest way of picturing a knot in 3 dimensions is by drawing its projection onto the paper plane. The lines in the projection show a number of *crossings*, and the drawing must distinguish the top from the bottom line. The knot is then deformed isotopically until the projection has the minimal number of crossings. In the projection, all isotopic deformations can be decomposed into a succession of three elementary types, the so-called *Reidemeister moves* shown in Fig. 16.6.

A picture of all simple knots up to $n = 8$ is shown in Fig. 16.7. The numbers of inequivalent simple and compound knots with a given number n of minimal crossings are listed in Table 16.1.

The projected pictures can be used to construct an important algebraic quantity characterizing the knot group, called the *Alexander polynomial* discovered in 1928. It reduces the classification of knot groups to that of polynomials. This type of work is typical of the field of algebraic topology.

Figure 16.6 Reidemeister moves in projection image of knot which do not change its class of isotopy. They define the movements of *ambient isotopy*. For ribbons, only the second and third movements are allowed, defining the *regular isotopy*. The first movement is forbidden since it changes its writhe [for the definition see Eq. (16.110)].

Table 16.1 Numbers of simple and compound knots with n minimal crossings in a projected plane.

n	simple knots	compound knots
0	1	0
1	0	0
2	0	0
3	1	0
4	1	0
5	2	0
6	3	1
7	7	1
8	21	3
9	49	5
10	166	10
11	548	37
12	–	154
13	–	484
14	–	1115

We explain the construction for the trefoil knot. Attaching a directional arrow to the polymer and selecting an arbitrary starting point, we follow the arrow until we run into a first underpass. This point is denoted by 1. Now we continue to the next underpass denoted by 2, etc., up to n (see Fig. 16.8). The polymer sections between two successive underpasses i and $i + 1$ are named x_{i+1} . At each underpass from x_i to x_{i+1} , we record (see Table 16.2) whether the overpassing section x_k runs from right to left (type r) or from left to right (type l). We now set up a matrix A_{ij} . Each underpass with label i defines a row A_{ij} , $j = 1, 2, 3, \dots$ according to the

Figure 16.7 Simple knots with up to 8 minimal crossings. The number of crossings under each picture carries a subscript enumerating the equivalence classes.

Figure 16.8 Labeling of underpasses for construction of Alexander polynomial $t^2 - t + 1$ of the left-handed trefoil.

Table 16.2 Tables of underpasses (under) and directions (dir) r or l of overpassing lines (over), for trefoil knot 3_1 and knot 4_1 of Fig. 16.7.

$3_1 :$	under	over	dir
	x_1	x_3	r
	x_2	x_1	r
	x_3	x_2	r

$4_1 :$	under	over	dir
	x_1	x_4	r
	x_2	x_1	l
	x_3	x_2	r
x_4	x_3	l	

following rules: Let x_k be the overpassing section. If x_k coincides with x_i or x_{i+1} the underpass is called *trivial*. In this, case the i th row of the matrix A_{ij} has the elements

$$A_{ii} = -1, \quad A_{i,i+1} = 1. \tag{16.103}$$

All other row elements A_{ij} vanish. If the underpass is nontrivial, the nonvanishing row elements are

$$A_{ii} = 1, \quad A_{ii+1} = -t, \quad A_{ik} = t - 1, \quad \text{type } r \text{ (right to left),} \tag{16.104}$$

$$A_{ii} = -t, \quad A_{ii+1} = 1, \quad A_{ik} = t - 1, \quad \text{type } l \text{ (left to right).} \tag{16.105}$$

In this way, we find the matrix of the trefoil knot:

$$A_{ij} = \begin{pmatrix} 1 & -t & t-1 \\ t-1 & 1 & -t \\ -t & t-1 & 1 \end{pmatrix}. \tag{16.106}$$

As another example, the knot 4_1 in Fig. 16.7 has the matrix

$$A_{ij} = \begin{pmatrix} 1 & -t & 0 & t-1 \\ t-1 & -t & 1 & 0 \\ 0 & t-1 & 1 & -t \\ 1 & 0 & t-1 & -t \end{pmatrix}. \tag{16.107}$$

Table 16.3 Alexander, Jones, and HOMFLY polynomials for smallest simple knots up to 8 crossings. The numbers specify the coefficients; for instance, the knot 7_1 has the Alexander polynomial $A(t) = 1 - t + t^2 - t^3 + t^4 - t^5 + t^6$ and the knot 8_8 has the Jones polynomial $J(t) = t^{-3}(1 - t + 2t^2 - t^3 + t^4)$. For the HOMFLY polynomial $H(t, \alpha)$, see the explanation on p. 1125.

Figure 16.9 Exceptional knots found by Kinoshita and Terasaka (a), Conway (b), and Seifert (c), all with same Alexander polynomial as trivial knot [$A(t) \equiv 1$].

Having set up the $n \times n$ -matrix A_{ij} , we choose an arbitrary subdeterminant (minor) of order $n - 1$. It is a polynomial in t with integer coefficients. This polynomial is divided by a suitable power of t to make it start out with a constant. The result is the Alexander polynomial $A(t)$. It is independent of the choice of the subdeterminant.

For the left-handed trefoil, the matrix (16.106) yields

$$A(t) = t^2 - t + 1. \quad (16.108)$$

For the knot 4_1 , we find from (16.107)

$$A(t) = t^2 - 3t + 1. \quad (16.109)$$

The Alexander polynomials of the simple knots in Fig. 16.7 are shown in Table 16.3. Note that the replacement $t \rightarrow 1/t$ leaves the Alexander polynomial invariant (after renormalizing it back by some power of t to start out with a constant).

The Alexander polynomial of a composite knot factorizes into those of the simple knots it is composed of. If two knots are mirror images of each other, they have the same knot group and the same Alexander polynomials. Due to the factorization property, two composite knots whose simple parts differ by mirror reflection (*stereoisomers*; see Fig. 16.5) have the same polynomial. Thus the Alexander polynomial cannot render a complete classification of inequivalent knots. This is true even after removing degeneracies of the above type. In Fig. 16.9, we give the simplest examples of knots with an Alexander polynomial $A(t) \equiv \pm 1$ of the trivial knot. Up to 11 crossings, these are the only examples. Since the total number of simple knots up to $n = 11$ is 795, the exceptions are indeed very few.

Recent years have witnessed the development of simpler construction procedures and more efficient polynomials for the classification of knots and links of several

knots, the Jones and the *HOMFLY polynomials*³ and their generalizations. The former depend on one, the latter on two variables, one of which occurs also with inverse powers, i.e., in this variable the polynomials are of the Laurent type. Other polynomials found in the literature, such as *Conway*, *X-*, or *Kauffman's bracket polynomials*, are special cases of the HOMFLY polynomials. In addition, there exist a different type of *Kauffman polynomials* and of *BLM/Ho polynomials* $F(a, z)$ and $Q(x)$, respectively, which are capable of distinguishing some knots with accidentally degenerate HOMFLY polynomials. They will not be discussed here. For their definition see Appendix 16B.

The *X*-polynomial $X(a)$ is trivially related to the Jones polynomial $J(t)$, to which it reduces after a variable change $a = t^{1/4}$. The *X*-polynomial is closely related to the Kauffman polynomial $K(a)$ by

$$X(a) = (-a)^{-3w} K(a). \quad (16.110)$$

The number w is the *cotorsion*, also called *twist number*, *Tait number*, or *writhe* [6]. It is defined by giving the loop or link an orientation and attributing to each crossing a number 1 or -1 according to the following rule. At each crossing follows the overpass along the direction of orientation. If the underpass runs from right to left, the crossing carries the number 1, otherwise -1 . The sum of these numbers is the cotorsion w . In the trefoil knot in Fig. 16.2 each crossing carries a -1 so that $w = -3$.

The Kauffman polynomial is found by a very simple construction procedure. A set of n trivial loops is defined to have the Laurent polynomial

$$K_n(a) = -(a^2 + a^{-2})^{n-1}. \quad (16.111)$$

Every knot or link can be reduced to such loops by changing the crossings recursively into two new configurations according to the graphical rule shown in Fig. 16.10.

Figure 16.10 Graphical rule for removing crossing in generating Kauffman polynomial.

The first configuration is associated with a factor a , the second with a factor a^{-1} . The configuration receiving the factor a is most easily identified by approaching the crossing on the underpassing curve and taking a right turn. The two new

configurations are processed further in the same way and so on until one arrives only at trivial loops. By applying these rules to a trefoil knot, we obtain a knot and a link known as the *Hopf link*. These are decomposed further as shown in Fig. 16.11. The Kauffman polynomials of each part are listed in Table 16.4. The polynomial of the trefoil knot is

$$K(a) = a^7 - a^3 - a^{-5}. \tag{16.112}$$

Since $w = -3$, we obtain with the factor $(-a)^{-3w} = -a^9$ the X -polynomial

$$X(a) = -a^{16} + a^{12} + a^4. \quad (16.113)$$

This corresponds to a Jones polynomial $J(t) = t + t^3 - t^4$.

For the Jones polynomials, there exists a simple direct construction. According to J.H. Conway, any knot can be related to lower knots or links by performing the *skein operations* shown in Fig. 16.12 on any crossing in the projection plane. Either

Figure 16.12 Skein operations relating higher knots to lower ones.

a crossing L_+ is transformed into L_- and L_+ , or L_+ is transformed into L_- and L_0 . For knots related in this way one defines the Jones polynomial $J(t)$ recursively by the *skein relation*

$$\frac{1}{t}J_{L_+}(t) - tJ_{L_-}(t) = \left(\sqrt{t} - \frac{1}{\sqrt{t}}\right)J_{L_0}(t). \quad (16.114)$$

The circular loop is defined to have the trivial polynomial $J(t) \equiv 1$. By applying the skein operations to two disjoint unknotted loops in Fig. 16.13, one finds the Jones polynomial

$$J_2(t) = -(\sqrt{t} + 1/\sqrt{t}). \quad (16.115)$$

Upon carrying this procedure to n such loops, we find

$$J_n(t) = [-(\sqrt{t} + 1/\sqrt{t})]^{n-1}, \quad (16.116)$$

in agreement with (16.111). For the lowest knots, the Jones polynomials are listed in Table 16.3. Up to nine crossings, the Jones polynomials distinguish mirror-symmetric knots.

Conway discovered the first skein relation in 1970 when trying to develop a computer program for calculating Alexander polynomials. He found the Alexander polynomials to obey modulo the normalization convention, the skein relation

$$A_{L_+}(t) - A_{L_-}(t) = (\sqrt{t} - 1/\sqrt{t})A_{L_0}(t), \quad (16.117)$$

which eventually reduces the polynomials of all knots to the trivial one $A_1(t) = 1$. The skein relation simplifies the procedure so much that Conway was able to work out by hand all polynomials known at that time. Because of the simplicity of

Figure 16.13 Skein operations for calculating Jones polynomial of two disjoint unknotted loops.

Figure 16.14 Skein operation for calculating Jones polynomial of trefoil knot.

Figure 16.15 Skein operation for calculating Jones polynomial of Hopf link.

this procedure, the Alexander polynomials are now often referred to as *Alexander-Conway polynomials*.

Let us now calculate the Jones polynomial for the trefoil knot 3_1 of Fig. 16.7. First we apply the skein operation shown in Fig. 16.14. The loop L_- is unknotted and has a unit polynomial. Thus we obtain the polynomial relation

$$J_{\text{trefoil}}(t)J_{L_+}(t) = t^2 \cdot 1 + t(\sqrt{t} - 1/\sqrt{t})J_{L_0}(t). \tag{16.118}$$

The configuration L_0 is known as a *Hopf link*. It needs one more reduction⁴ via the operation shown in Fig. 16.15, resulting in the relation

$$\frac{1}{t}J_{L_0}(t) = tJ_2(t) + (\sqrt{t} - 1/\sqrt{t})J_1(t). \tag{16.119}$$

⁴The Kauffman bracket polynomial of the Hopf link is $K_{L_0}(a) = -a^4 - a^{-4}$. Together with the cotorson $w = -2$, this amounts to an X -polynomial $X(a) = -a^{10} - a^2$ and the Jones polynomial $J_{L_0}(t) = -\sqrt{t}(1 + t^2)$ as in (16.120).

Using (16.111), we find

$$J_{L_0}(t) = -\sqrt{t}(1+t^2). \quad (16.120)$$

Inserting this into (16.118) leads to the Jones polynomial of the trefoil knot

$$J_{\text{trefoil}} = t + t^3 - t^4. \quad (16.121)$$

It differs from the result found above for the left-handed trefoil by the substitution $t \rightarrow t^{-1}$.

The HOMFLY polynomials $H_L(t, \alpha)$ are obtained from a slight generalizations of the skein relation (16.114) of the Jones polynomials: The factor $(\sqrt{t} - 1/\sqrt{t})$ on the right-hand side is replaced by an arbitrary parameter α , leading to the skein relation

$$\frac{1}{t}H_{L_+}(t, \alpha) - tH_{L_-}(t, \alpha) = \alpha H_{L_0}(t, \alpha). \quad (16.122)$$

The trivial knot is defined to have the trivial polynomial $H_1(t, \alpha) = 1$. For two independent loops, the relation yields

$$H_2(t, \alpha) = (t^{-1} - t)\alpha^{-1}. \quad (16.123)$$

The HOMFLY polynomials $H(t, \alpha)$ transform under a mirror reflection of the knot into $H(-t^{-1}, \alpha)$. Note that $H_2(t, \alpha)$ is mirror-symmetric [$H_1(t, \alpha)$ is trivially so].⁵ In general, the HOMFLY polynomials give reliable information on a possible mirror symmetry. There are, however, a few exceptions, i.e., mirror-related pairs of knots possessing the same HOMFLY polynomial.⁶

Examples for HOMFLY polynomials are

$$\begin{aligned} H_{\text{trefoil(rh)}}(t, \alpha) &= -t^4 + 2t^2 + t^2\alpha^2, \\ H_{\text{trefoil(lh)}}(t, \alpha) &= -t^{-4} + 2t^{-2} + t^{-2}\alpha^2, \\ H_{\text{Hopf(rh)}}(t, \alpha) &= (t - t^3)\alpha^{-1} + t\alpha, \\ H_{\text{knot } 4_1}(t, \alpha) &= t^{-2} - 1 + t^2 - \alpha^2. \end{aligned} \quad (16.124)$$

Setting $\alpha = t^{1/2} - t^{-1/2}$ produces the Jones polynomials, while $t \rightarrow 1, \alpha \rightarrow t^{1/2} - t^{-1/2}$ leads, with appropriate powers of t as normalization factors, back to the Alexander-Conway polynomials.

In Table 16.3, the HOMFLY polynomials are listed for knots up to 8 crossings. For mirror-unsymmetric knots, only one partner is recorded. The reflected polynomial is obtained by the substitution $t \rightarrow -t^{-1}$. The meaning of the entries is best explained with an example: The knot 7_1 has an entry $([0]004 - 3)([0]00(10) - 4)([0]006 - 1)([0]001)$, which stands for the polynomial

⁵For the Kauffman polynomials $F(a, x)$ defined in Appendix 16B, mirror reflection implies $F(a, x) \rightarrow F(a^{-1}, x)$.

⁶The first degeneracy of this type occurs for a link of 3 loops with 8 crossings.

$H(t, \alpha) = (4t^6 - 3t^8) + (10t^6 - 4t^8)\alpha^2 + (6t^6 - t^8)\alpha^4 + t^6\alpha^6$. A bracket marks the position and coefficient of the zeroth power in t^2 ; the numbers to the right and the left of it specify the coefficients of the adjacent higher and lower powers of t^2 , respectively. Numbers with more than one digit are put in parentheses. The polynomial of the reflected knot is obtained by reflecting the numbers in parentheses on the associated bracket. The knots marked by an s are mirror-symmetric.

The Alexander-Conway polynomials are special cases of the HOMFLY polynomials. A comparison with the skein relation (16.117) shows that they are obtained from them by setting $t = 1$ and replacing α by $t^{1/2} - t^{-1/2}$:

$$A_L(t) = H_L(1, t^{1/2} - t^{-1/2}). \quad (16.125)$$

The reducible granny and square knots in Fig. 16.5 are distinguished by the Jones and the HOMFLY polynomials; the latter are

$$\begin{aligned} H_{\text{granny}}(t, \alpha) &= (2t^2 - t^4 + t^2\alpha^2)^2, \\ H_{\text{square}}(t, \alpha) &= (2t^2 - t^4 + t^2\alpha^2)(2t^{-2} - t^{-4} + t^2\alpha^2); \end{aligned} \quad (16.126)$$

the former are obtained by inserting $\alpha = t^{1/2} - t^{-1/2}$.

Up to now, there exists no complete algebraic classification scheme. For example, the Jones polynomials of the knots with 10 and 13 crossings shown in Fig. 16.16 are

Figure 16.16 Knots with 10 and 13 crossings, not distinguished by Jones polynomials.

the same.⁷ For further details, see the mathematical literature quoted at the end of the chapter.

Even with the incomplete classification of knots, it has until now been impossible to calculate the probability distribution of the various equivalence classes of knots. Modern computers allow us to enumerate the different topological configurations for not too long polymers and to simulate their distributions by Monte Carlo methods. In Fig. 16.17 we show the result of a simulation by Michels and Wiegel, where they measure the fraction f_N of unknotted polymers of N links. They fit their curve by a power law

$$f_N = C\mu^N N^\alpha, \quad (16.127)$$

⁷The HOMFLY polynomials have their first degeneracy for prime knots with 9 crossings. It was checked that up to 13 crossings (amounting to 12965 knots) no polynomial of a nontrivial knot is accidentally degenerate with the trivial polynomial of a circle.

Figure 16.17 Fraction f_N of unknotted closed polymers in ensemble of fixed length $L = Na$.

with the parameters $C \approx 1.026$, $\mu \approx 0.99640$, $\alpha \approx 0.0088$. Thus f_N falls off exponentially in N like μ^N with $\mu < 1$. The exponent α is extremely small. A more recent simulation by S. Windwer takes account of the fact that the line elements are self-avoiding. It yields the parameters⁸

$$C \approx 1.2325, \quad \mu \approx 0.9949, \quad \alpha \approx 0. \quad (16.128)$$

For a polymer enclosed in a sphere of radius R , the distribution has the finite-size dependence

$$f_N(R) = e^{-A(N^\beta l/R)^\gamma}, \quad (16.129)$$

where l is the length of a link. The “critical exponents” are $\beta \approx 0.76$ and $\gamma \approx 3$.

16.5 The Gauss Invariant of Two Curves

For any analytic calculation of topological properties one needs a functional of the polymer shape which is capable of distinguishing the different knot classes. Initially,

⁸A first theoretical determination of these parameters has recently been given by mapping the problem onto a four-state Potts model. A presentation of this method which does not involve path integrals would go beyond the scope of this book. See the papers by A. Kholodenko quoted at the end of the chapter.

a hopeful candidate was the one-loop version of the contour integral introduced almost two centuries ago by Gauss for a pair of closed curves C and C' :

$$G(C, C') = \frac{1}{4\pi} \oint_C \oint_{C'} [d\mathbf{x} \times d\mathbf{x}'] \cdot \frac{\mathbf{x} - \mathbf{x}'}{|\mathbf{x} - \mathbf{x}'|^3}. \quad (16.130)$$

Gauss proved this to be a topological invariant. In fact, we may rewrite (16.130) with the help of the δ -function (10A.8) as

$$\oint_C d\mathbf{x} \oint_{C'} \frac{d\mathbf{x}' \times (\mathbf{x} - \mathbf{x}')}{|\mathbf{x} - \mathbf{x}'|^3} = - \int d^3x \delta(\mathbf{x}; C) \cdot \left[\int d^3x' \delta(\mathbf{x}'; C') \times \frac{\mathbf{R}'}{R'^3} \right] \quad (16.131)$$

The second integral is recognized as the gradient of the multivalued field $\Omega(\mathbf{x}; C')$ defined by Eqs. (10A.18), which is the solid angle under which the contour C' is seen from the point \mathbf{x} , so that

$$G(C, C') = -\frac{1}{4\pi} \int d^3x \delta(\mathbf{x}; C) \cdot \nabla \Omega(\mathbf{x}; C'). \quad (16.132)$$

Inserting here Eq. (10A.27), where S' is any surface enclosed by the contour L' , and using the fact that

$$\int d^3x \delta(\mathbf{x}; C) \cdot \nabla \Omega(\mathbf{x}; S') = - \int d^3x \nabla \cdot \delta(\mathbf{x}; C) \Omega(\mathbf{x}; S') = 0, \quad (16.133)$$

due to (10A.9) and the fact that $\Omega(\mathbf{x}; S) = 0$ is single-valued, we obtain

$$G(C, C') = - \int d^3x \delta(\mathbf{x}; C) \cdot \delta(\mathbf{x}; S'). \quad (16.134)$$

This is a purely topological integral. By rewriting it as

$$G(C, C') = - \oint_C dx_i \delta_i(\mathbf{x}; S'), \quad (16.135)$$

we see that $G(C, C')$ gives the linking number of C and C' . It is defined as the number of times by which one of the curves, say C' , perforates the surface S spanned by the other.

Alternative expressions for the Gauss integral (16.134) are

$$G(C, C') = -\frac{1}{4\pi} \oint_{C'} d\Omega'(\mathbf{x}'; C) = -\frac{1}{4\pi} \oint_C d\Omega(\mathbf{x}, C'), \quad (16.136)$$

where where $\Omega'(\mathbf{x}'; S)$ is the solid angle under which the curve C is seen from the point \mathbf{x}' .

The values of the Gauss integral for various pairs of linked curves up to 8 crossings are given in the third column of Table 16.5. All the intertwined pairs of curves labeled by $2_1, 7_1, 7_2, 8_7$, for instance, have a Gauss integral $G(C, C') = \pm 1$.

Let us end this section by another interpretation of the Gauss integral. According to Section 10A.1, the solid angle Ω is equal to the magnetic potential of a current 4π running through the curve C' . Its gradient is the magnetic field

$$B_i = \partial_i \Omega. \quad (16.137)$$

Hence we can write

$$G(C, C') = - \oint_C dx_i B_i = - \oint_{C'} dx'_i B'_i. \quad (16.138)$$

According to this expression, $G(C, C')$ gives the total work required to move a unit magnetic charge around the closed orbit C in the presence of the magnetic field due to a unit electric current along C' .

Unfortunately, there exists no such topologically invariant integral for a single closed polymer. If we identify the curves C and C' , the Gauss integral ceases to be a topological invariant. It can, however, be used to classify self-entangled *ribbons*. These possess two separate edges identified with C and C' . Such ribbons play an important role in biophysics. The molecules of DNA, the carriers of genetic information on the structure of living organisms, can be considered as ribbons. They consist of two chains of molecules connected by weak hydrogen bridges. These can break up thermally or by means of enzymes decomposing the ribbon into two single chains.

16.6 Bound States of Polymers and Ribbons

Two or more polymers may line up parallel to each other and form a bound state. The most famous example is the molecule of DNA. It is a bound state of two long chains of molecules which may contain a few thousand up to several billion links. The distance d between the two chains is about 20\AA . In equilibrium, the two chains are twisted up in the form of a double helix, rising by about 20\AA (i.e., about 10 monomers) per turn (see Fig. 16.18). The DNA molecule may be idealized as an infinitesimally thin ribbon. The ribbon is always *two-sided* since the edges of the ribbon are made up of different phosphate groups whose chemical structure makes the binding unique. One-sided structures formed by a Möbius strip are excluded.

Circular DNA molecules have interesting topological properties. In the double helix, one edge passes through the other an integer number of times. This is the *linking number* L_k of the double helix. Being a topological invariant, it does not change if the two closed edges become unbound and distorted into an arbitrary shape.

If the total number of windings N_w in the DNA helix is different from the linking number L_k , a circular helix is always under mechanical stress. It can relax by forming a supercoil (see Fig. 16.19). The number of excess turns

$$\tau = L_k - N_w, \quad (16.139)$$

provides a measure for the *supercoiling density* which is defined by the ratio

$$\sigma \equiv \frac{\tau}{N_w}. \quad (16.140)$$

In natural DNA, the supercoiling density is usually $-\sigma \sim 0.03 - -0.1$. The negative sign implies that the natural twist of the double helix is slightly *decreased* by the supercoiling. The negative sign seems to be essential in the main biological process, the *replication*. It may be varied by an enzyme, called DNA gyrase. A cell has a large arsenal of enzymes which can break one of the chains in the helix and unwind the linking number L_k by one or more units, changing the topology. Such enzymes run under the name of *topoisomerases* of type I. There is also one of a type II which breaks *both* chains and can tie or untie knots in the double helix of DNA as a whole.

The biophysical importance of the supercoil derives from the fact that the stress carried by such a configuration can be relaxed by breaking a number of bonds between the two chains. In fact, a number $\theta = -\sigma$ of broken bonds leads to a complete relaxation. During a cell division, all bonds are broken. Note that this process would be energetically unfavorable if the supercoiling density were positive.

Figure 16.18 Small section and idealized view of circular DNA molecule. The link number L_k (defined as number of times one chain passes through arbitrary surface spanned by the other) is $L_k \approx 9$.

Figure 16.19 A supercoiled DNA molecule. This is the natural shape when carefully extracted from a cell. The supercoiling is negative.

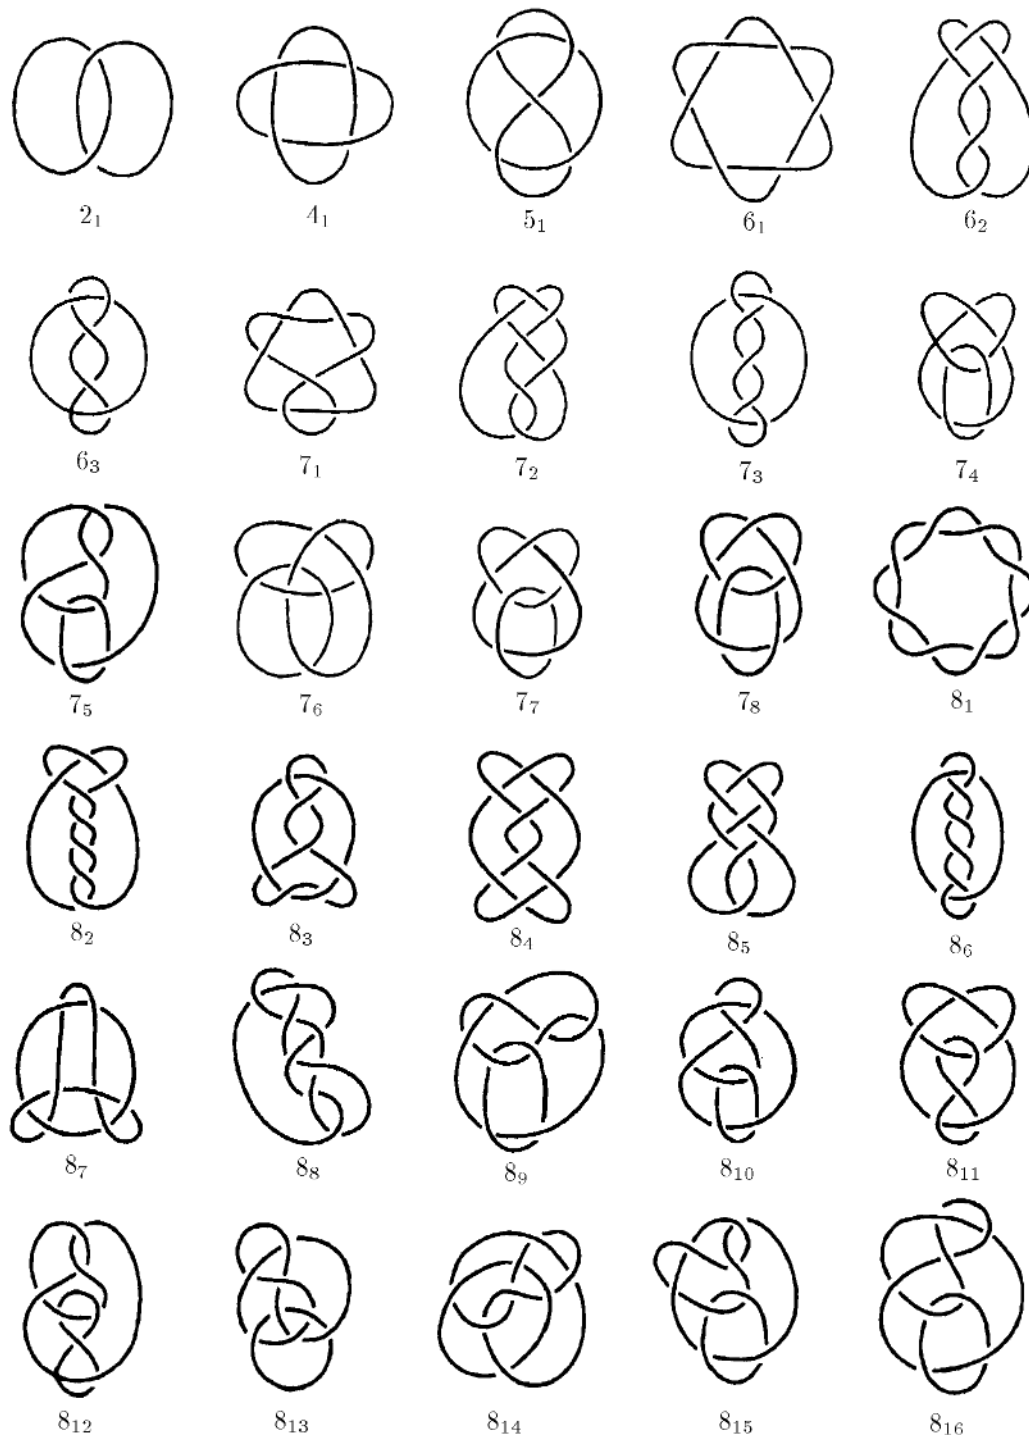

Figure 16.20 Simple links of two polymers up to 8 crossings.

Just as for knots, no complete topological invariants are known for such types of links of two (or more) closed polymers. Historically, generalized Alexander polynomials were used to achieve an approximate classification of links. They are polynomials of two variables. To construct them, we take one of the two polymers and label all underpasses in the same way as for knots. The same thing is done for the other polymer. For each underpass, a row of the Alexander matrix A_{ij} is written down with two variables s and t . The Alexander polynomial $A(s, t)$ is again given by any $(n-1) \times (n-1)$ -subdeterminant of the $n \times n$ -matrix A_{ij} . The links up to 8 crossings are shown in Fig. 16.20. The Alexander polynomials associated with these are listed in Table 16.5. Note that the replacements $s \rightarrow 1/s, t \rightarrow 1/t$, or both, leave the Alexander polynomial invariant (due to the prescription of renormalizing the lowest coefficients to an integer). For unlinked polymers one has $A(s, t) = 0$.

There is no need to go through the details of the procedure since the more recent and powerful Jones and HOMFLY polynomials can be constructed for arbitrary links without additional prescriptions. The latter are tabulated in the fourth column of Table 16.5. In many cases, a change in the orientation of the second loop gives rise to an inequivalent link. Then the table shows two entries underneath each other. For the knot 7_2 , the upper entry $\{-1\}(1 * -1)(1 * 0 - 11)(* - 1 - 1)$ indicates the polynomial $H(t, \alpha) = \alpha^{-1}(t^{-1} - t) + \alpha(t^{-1} - t^2 + t^3) + \alpha^3(-t - t^3)$. The curly bracket shows the lowest power of α and the star marks the position of the zeroth power of t . The coefficients of t, t^3, \dots stand to the right of it, those of \dots, t^{-3}, t^{-1} to the left of it.

For the special case of a circular ribbon such as a DNA molecule, the Gauss integral over the two edges, being a topological invariant, renders also a classification of the ribbon as a whole. As shown in Eq. (16.135), the Gauss integral yields precisely the linking number L_k .

It is useful to calculate $G(C, C')$ for a ribbon in the limit of a very small edge-to-edge distance d . This will also clarify why the Gauss integral $G(C, C')$ in which both C and C' run over the same single loop is not a topological invariant. We start with the Gauss integral for the two edges C, C' of the ribbon

$$G(C, C') = \frac{1}{4\pi} \oint_C \oint_{C'} [d\mathbf{x} \times d\mathbf{x}'] \cdot \frac{\mathbf{x} - \mathbf{x}'}{|\mathbf{x} - \mathbf{x}'|^3} \quad (16.141)$$

and shift the two neighboring integration contours C, C' both towards the ribbon axis called \bar{C} . Let ϵ measure the distance between the two edges, and let $\mathbf{n}(\tau)$ be the unit vector orthogonal to the axis pointing from C to C' . Then we write

$$G(C, C') = \frac{1}{4\pi} \oint_{\bar{C}} d\tau \oint_{\bar{C}} d\tau' [\dot{\mathbf{x}}(\tau) \times (\dot{\mathbf{x}}(\tau') + \epsilon \dot{\mathbf{n}}(\tau'))] \cdot \frac{\mathbf{x}(\tau) - \mathbf{x}(\tau') - \epsilon \mathbf{n}(\tau')}{|\mathbf{x}(\tau) - \mathbf{x}(\tau') - \epsilon \mathbf{n}(\tau')|^3}. \quad (16.142)$$

In the limit $\epsilon \rightarrow 0$, $G(C, C')$ does not just become equal to $G(\bar{C}, \bar{C})$ [which then would be the same as $G(C, C)$ or $G(C', C')$]. A careful limiting procedure performed below shows that there is a remainder T_w ,

$$L_k = G(\bar{C}, \bar{C}) + T_w. \quad (16.143)$$

Table 16.5 Alexander polynomials $A(s, t)$ and the coefficients of HOMFLY polynomials $H(t, \alpha)$ for simple links of two closed curves up to 8 minimal crossings, labeled as in Fig. 16.20. The value $|A(1, 1)|$ is equal to the absolute value of the Gauss integral $|G(C, C')|$ for the two curves. The entries in the last column are explained in the text.

The remainder is called the *twist* of the ribbon, defined by

$$T_w \equiv \frac{1}{2\pi} \oint_{\bar{C}} d\tau \dot{\mathbf{x}}(\tau) \cdot [\mathbf{n}(\tau) \times \dot{\mathbf{n}}(\tau)] / |\dot{\mathbf{x}}(\tau)|. \quad (16.144)$$

Incidentally, this integral makes sense also for a single curve if $\mathbf{n}(\tau)$ is taken to be the principal normal vector of the curve. Then T_w gives what is called the *total integrated torsion* of the single curve. The first term in (16.143), the Gauss integral for a single closed curve \bar{C} , is called in this context the *writhing number* of the curve

$$W_r \equiv G(\bar{C}, \bar{C}) = \frac{1}{4\pi} \oint_{\bar{C}} d\tau \oint_{\bar{C}} d\tau' [\dot{\mathbf{x}}(\tau) \times \dot{\mathbf{x}}(\tau')] \cdot \frac{\mathbf{x}(\tau) - \mathbf{x}(\tau')}{|\mathbf{x}(\tau) - \mathbf{x}(\tau')|^3}. \quad (16.145)$$

Thus one writes the relation (16.143) commonly in the form

$$L_k = W_r + T_w. \quad (16.146)$$

Only the sum $W_r + T_w$ is a topological invariant, with T_w containing the information on the ribbon structure of the closed loop \bar{C} . This formula was found by Calagareau in 1959 and generalized by White in 1969.

From what we have seen above in Eq. (16.136), the writhing number may also be written as an integral

$$W_r = -\frac{1}{4\pi} \oint_{\bar{C}} d\Omega(\mathbf{x}), \quad (16.147)$$

where $\Omega(\mathbf{x})$ is the solid angle under which the axis of the ribbon is seen from another point on the axis. When rewritten in the form (16.138), it has the magnetic interpretation stated there.

This interpretation is relevant for understanding the spacetime properties of the dionium atom which in turn may be viewed as a world ribbon whose two edges describe an electric and a magnetic charge. We have pointed out in Section 14.6 that for a half-integer charge parameter q , a dionium atom consisting of two bosons is a fermion. For this reason, a path integral over a fluctuating ribbon can be used to describe the quantum mechanics of a fermion in three spacetime dimensions [7].

Let us derive the relation (16.146). We split the integral (16.142) over τ into two parts: a small neighborhood of the point τ' , i.e.,

$$\tau \in (\tau' - \delta, \tau' + \delta) \quad (16.148)$$

and the remainder, for which the integrand is regular. In the regular part, we can set the distance ϵ between the curves C and C' equal to zero, and obtain the Gauss integral $G(\bar{C}, \bar{C})$, i.e., the writhing number W_r . In the singular part, we approximate $x(\tau)$ within the small neighborhood (16.148) by the straight line

$$\begin{aligned} \mathbf{x}(\tau) &\approx \mathbf{x}(\tau') + \dot{\mathbf{x}}(\tau')(\tau - \tau'), \\ \dot{\mathbf{x}}(\tau) &\approx \dot{\mathbf{x}}(\tau'). \end{aligned} \quad (16.149)$$

Figure 16.21 Illustration of Calagareau-White relation (16.146). The number of windings around the cylinder is $L_k = 2$, while $T_w = L_k - p/\sqrt{p^2 + R^2}$, where p is the pitch of the helix and R the radius of the cylinder.

Then the τ -integral can be performed. For $\epsilon \ll \delta \ll 1$, we find

$$\begin{aligned}
 T_w &= -\frac{1}{4\pi} \oint_{C'} d\tau' [\mathbf{n}(\tau') \times \dot{\mathbf{x}}(\tau')] \cdot \dot{\mathbf{n}}(\tau') \epsilon^2 \int_{\tau'-\delta}^{\tau'+\delta} d\tau \frac{1}{\sqrt{|\dot{\mathbf{x}}(\tau')|^2 (\tau - \tau')^2 + \epsilon^2}} \\
 &= \frac{1}{2\pi} \oint_{C'} d\tau' [\dot{\mathbf{x}}(\tau') \times \mathbf{n}(\tau')] \cdot \dot{\mathbf{n}}(\tau') / |\dot{\mathbf{x}}(\tau')|. \tag{16.150}
 \end{aligned}$$

It is worth emphasizing that in contrast to the Gauss integral for two curves C, C' , the value of the Gauss integral for \bar{C} is *not* an integer but a continuous number. It depends on the shape of the ribbon, changing continuously when the ribbon is deformed isotopically. If one section of the ribbon passes through the other, however, it changes by 2 units. The defining equation shows that W_r vanishes if the ribbon axis has a center or a plane of symmetry. To give an example for a circular closed ribbon with an integer number L_k and an *arbitrary writhing number* W_r we follow Brook-Fuller and Crick. A cylinder with a closed ribbon is wound flat around the surface of a cylinder, returning along the cylinder axis (see Fig. 16.21). While the two edges of the ribbon perforate each other an integer number of times such that $L_k = 2$, the ribbon axis has a noninteger Gauss integral W_r depending on the ratio between pitch and radius, $W_r = 2 - p/\sqrt{p^2 + R^2}$.

16.7 Chern-Simons Theory of Entanglements

The Gauss integral has a form very similar to the Biot-Savart law of magnetostatics found in 1820. That law supplies an action-at-a-distance formula for the interaction energy of two currents I, I' running along the curves C and C' :

$$E = -\frac{II'}{c^2} \oint_C \oint_{C'} d\mathbf{x} \cdot d\mathbf{x}' \frac{1}{|\mathbf{x} - \mathbf{x}'|}, \quad (16.151)$$

where c is the light velocity. It was a decisive conceptual advance of Maxwell's theory to explain formula (16.151) by means of a *local* field energy arising from a vector potential $\mathbf{A}(\mathbf{x})$. In view of the importance of the Gauss integral for the topological classification of entanglements, it is useful to derive a local field theory producing the Gauss integral as a topological action-at-a-distance. Imagine the two contours C and C' carrying stationary currents of some pseudo-charge which we normalize at first to unity. These currents are coupled to a vector potential $\mathbf{A}(\mathbf{x})$, which is now unrelated to magnetism and which will be called *statisto-magnetic vector potential*:

$$\mathcal{A}_{e,\text{curr}} = -i \oint_C d\mathbf{x} \mathbf{A}(\mathbf{x}) - i \oint_{C'} d\mathbf{x} \mathbf{A}(\mathbf{x}). \quad (16.152)$$

The action is of the Euclidean type as indicated by the subscript e (recall the relation with the ordinary action $\mathcal{A} = i\mathcal{A}_e$). We now construct a field action for $\mathbf{A}(\mathbf{x})$ so that the field equations render an interaction between the two currents which is precisely of the form of the Gauss integral. This field action reads

$$\mathcal{A}_{e,\text{CS}} = \frac{i}{2} \int d^3x \mathbf{A} \cdot (\nabla \times \mathbf{A}) \quad (16.153)$$

and is called the *Chern-Simons action*. It shares with the ordinary Euclidean magnetic field action the quadratic dependence on the vector potential $\mathbf{A}(\mathbf{x})$, as well as the invariance under local gauge transformations

$$\mathbf{A}(\mathbf{x}) \rightarrow \mathbf{A}(\mathbf{x}) + \nabla \Lambda(\mathbf{x}), \quad (16.154)$$

which is obvious when transforming the second vector potential in (16.153). The gauge transformation of the first vector potential produces no change after a partial integration. Also the coupling in (16.152) to the contours C and C' is gauge-invariant after a partial integration, since the contours are closed, satisfying

$$\nabla \cdot \oint d\mathbf{x} = 0. \quad (16.155)$$

In contrast to the magnetic field energy, however, the action (16.153) is purely imaginary. The factor i is important for the applications in which the Chern-Simons action will give rise to phase factors of the form $e^{i2\theta G(C,C')}$.

By extremizing the combined action, we obtain the field equation

$$\nabla \times \mathbf{A}(\mathbf{x}) = \left(\oint_C + \oint_{C'} \right) d\mathbf{x}. \quad (16.156)$$

Its solution is

$$A_i(\mathbf{x}) = \left(\oint_C + \oint_{C'} \right) G_{ij}(\mathbf{x}, \mathbf{x}') dx'_j, \quad (16.157)$$

where $G_{ij}(\mathbf{x}, \mathbf{x}')$ is a suitable Green function solving the inhomogeneous field equation (16.157) with a δ -function source instead of the current. Due to the gauge invariance of the left-hand side, however, there is no unique solution. Given a solution $G_{ij}(\mathbf{x}, \mathbf{x}')$, any gauge-transformed Green function

$$G_{ij}(\mathbf{x}, \mathbf{x}') \rightarrow G_{ij}(\mathbf{x}, \mathbf{x}') + \nabla_i \Lambda_j(\mathbf{x}, \mathbf{x}') + \nabla_j \Lambda_i(\mathbf{x}, \mathbf{x}')$$

will give the same curl $\nabla \times \mathbf{A}$. Only the transverse part of the vector potential (16.157) is physical, and the Green function has to satisfy

$$\epsilon_{ijk} \nabla_j G_{kl}(\mathbf{x}, \mathbf{x}') = \delta_{ij}^{(3)}(\mathbf{x} - \mathbf{x}')^T, \quad (16.158)$$

where

$$\delta_{ij}^{(3)}(\mathbf{x} - \mathbf{x}')^T = \left(\delta_{ij} - \frac{\nabla_i \nabla_j}{\nabla^2} \right) \delta^{(3)}(\mathbf{x} - \mathbf{x}') \quad (16.159)$$

is the transverse δ -function. The vector potential is then obtained from (16.157) in the transverse gauge with

$$\nabla \cdot \mathbf{A}(\mathbf{x}) = 0. \quad (16.160)$$

The solution of the differential equation (16.158) is easily found in the two-dimensional transverse subspace. The Fourier transform of Eq. (16.158) reads

$$i\epsilon_{ijk} p_j G_{kl}(\mathbf{p}) = \delta_{il} - \frac{p_j p_l}{\mathbf{p}^2}, \quad (16.161)$$

and this is obviously solved by

$$G_{ij}(\mathbf{p}) = i\epsilon_{ikj} p_k \frac{1}{\mathbf{p}^2}. \quad (16.162)$$

The transverse gauge (16.160) may be enforced in an action formalism by adding to the action (16.153) a *gauge-fixing term*

$$\mathcal{A}_{\text{GF}} = \frac{1}{2\alpha} (\nabla \cdot \mathbf{A})^2, \quad (16.163)$$

with an intermediate gauge parameter α which is taken to zero at the end. The field equation (16.158) is then changed to

$$\left(\epsilon_{ijk} \nabla_j + \frac{i}{\alpha} \nabla_i \nabla_k \right) G_{kl}(\mathbf{x}, \mathbf{x}') = \delta_{ik} \delta^{(3)}(\mathbf{x} - \mathbf{x}'), \quad (16.164)$$

which reads in momentum space

$$\left(i\epsilon_{ijk}p_j - \frac{i}{\alpha}p_i p_k\right) G_{kl}(\mathbf{p}) = \delta_{ik}. \quad (16.165)$$

This has the unique solution

$$G_{ik}(\mathbf{p}) = \left(i\epsilon_{ijk}p_j + i\alpha \frac{p_i p_k}{\mathbf{p}^2}\right) \frac{1}{\mathbf{p}^2}, \quad (16.166)$$

whose $\alpha \rightarrow 0$ -limit is (16.162).

Going back to configuration space, the Green function becomes

$$G_{ij}(\mathbf{x}, \mathbf{x}') = \int \frac{d^3p}{(2\pi)^3} e^{i\mathbf{p}(\mathbf{x}-\mathbf{x}')} \frac{i\epsilon_{ikj}p_k}{\mathbf{p}^2} = \frac{1}{4\pi} \epsilon_{ikj} \nabla_k \frac{1}{|\mathbf{x}-\mathbf{x}'|} = \frac{1}{4\pi} \epsilon_{ijk} \frac{(x-x')_k}{|\mathbf{x}-\mathbf{x}'|^3}. \quad (16.167)$$

Inserting this into $\mathcal{A}_{e,\text{curr}} + \mathcal{A}_{e,\text{CS}}$ yields the interaction between the currents⁹

$$\mathcal{A}_{e,\text{int}} = -i \oint_C \oint_{C'} dx_i dx'_j G_{ij}(\mathbf{x}, \mathbf{x}'). \quad (16.168)$$

Up to the prefactor $-i$, this is precisely the Gauss integral $G(C, C')$ of the two curves C, C' . In addition there are the self-interactions of the two curves

$$\mathcal{A}_{e,\text{int}} = -\frac{i}{2} \left(\oint_C \oint_C + \oint_{C'} \oint_{C'} \right) dx_i dx'_j G_{ij}(\mathbf{x}, \mathbf{x}'), \quad (16.169)$$

which are equal to $-(i/2)[G(C, C) + G(C', C')]$. Due to their nontopological nature discussed earlier, these have no quantized values and must be avoided.

Such unquantized self-interactions can be avoided by considering systems whose orbits are subject to appropriate restrictions. They may, for instance, contain only lines which are not entangled with themselves and run in a preferred direction from $-\infty$ to ∞ . Ensembles of nonrelativistic particles in two space dimensions have precisely this type of worldlines in three-dimensional spacetime. They are therefore an ideal field for the Chern-Simons theory, as we shall see below in more detail.

Another way of avoiding unquantized self-interactions is based on a suitable limiting procedure. If the lines C and C' coincide, the Gaussian integral $G(C, C')$ over $C = C'$ may be spread over a large number N of parallel running lines C_i ($i = 1, \dots, N$), each of which carries a topological charge $1/N$. The sum $(1/N^2) \sum_{ij} G(C_i, C_j)$ contains N -times the same self-interaction and $N(N-1)$ -times the same integer-valued linking number L_k of pairs of lines. In the limit $N \rightarrow \infty$, only the number L_k survives. The result coincides with the Gauss integral for the two frame lines C_1 and C_N of the ribbon. The number L_K may therefore be called the *frame linking number*. This number depends obviously on the choice of the framing. There is a preferred choice for which L_k vanishes. This eliminates the self-interaction trivially.

⁹Compare this with the derivation of Eq. (3.247).

Although the limiting procedure makes the self-interaction topological, the arbitrariness of the framing destroys all information on the knot classes. This information can be salvaged by means of a generalization of the above topological action leading to a nonabelian version of the Chern-Simons theory. That theory has the same arbitrariness in the choice of the framing. However, by choosing the framing to be the same as in the abelian case and calculating only ratios of observable quantities, it is possible to eliminate the framing freedom. This will enable us to distinguish the different knot classes after all.

16.8 Entangled Pair of Polymers

For a pair of polymers, the above problems with self-entanglement can be avoided by a slight modification of the Chern-Simons theory. This will allow us to study the entanglement of the pair. In particular, we shall be able to calculate the *second topological moment* of the entanglement, which is defined as the expectation value $\langle m^2 \rangle$ of the square of the linking number m [8]. The self-entanglements of the individual polymers will be ignored.

The result will apply approximately to a polymer in an ensemble of many others, since these may be considered roughly as a single very long effective polymer.

Consider two polymers running along the contours C_1 and C_2 which statistically can be linked with each other any number of times $m = 0, 1, 2, \dots$. The situation is illustrated in Fig. 16.22 for $m = 2$. The linking number (16.134) for these two polymers can be calculated with the help of

Figure 16.22 Closed polymers along the contours C_1, C_2 respectively.

a slight modification of the Chern-Simons action (16.153) and the couplings (16.152). We simply introduce two vector potentials and the Euclidean action

$$\mathcal{A}_e = \mathcal{A}_{e,CS12} + \mathcal{A}_{e,curr}, \quad (16.170)$$

where

$$\mathcal{A}_{e,CS12} = i \int d^3x \mathbf{A}_1 \cdot (\nabla \times \mathbf{A}_2) \quad (16.171)$$

and

$$\mathcal{A}_{e,curr} = -i \oint_{C_1} d\mathbf{x} \mathbf{A}_1(\mathbf{x}) - i \oint_{C_2} d\mathbf{x} \mathbf{A}_2(\mathbf{x}). \quad (16.172)$$

If we choose the gauge fields to be transverse, as in (16.160), we obtain with the same technique as before the correlation functions of the gauge fields

$$D_{ab}^{\mu\nu}(\mathbf{x}, \mathbf{x}') \equiv \langle A_a^\mu(\mathbf{x}) A_b^\nu(\mathbf{x}') \rangle, \quad a, b = 1, 2 \quad (16.173)$$

are

$$D_{11}^{ij}(\mathbf{x}, \mathbf{x}') = 0, \quad D_{22}^{ij}(\mathbf{x}, \mathbf{x}') = 0, \quad (16.174)$$

$$\begin{aligned} D_{12}^{ij}(\mathbf{x}, \mathbf{x}') &= D_{21}^{ij}(\mathbf{x}, \mathbf{x}') = \int \frac{d^3 p}{(2\pi)^3} e^{i\mathbf{p}(\mathbf{x}-\mathbf{x}')} \frac{i\epsilon_{ijk} k^k}{\mathbf{p}^2} = \frac{1}{4\pi} \epsilon_{ijk} \nabla_k \frac{1}{|\mathbf{x}-\mathbf{x}'|} \\ &= \frac{1}{4\pi} \epsilon_{ij\kappa} \frac{(x-x')^\kappa}{|\mathbf{x}-\mathbf{x}'|^3}. \end{aligned} \quad (16.175)$$

The transverse gauge is enforced by adding to the action (16.171) a gauge-fixing term

$$\mathcal{A}_{\text{GF}} = \frac{1}{2\alpha} [(\nabla \cdot \mathbf{A}_1)^2 + (\nabla \cdot \mathbf{A}_2)^2], \quad (16.176)$$

and taking the limit $\alpha \rightarrow 0$ at the end. Extremizing the extended action produces the Gaussian linking number $-iG(C_1, C_2)$ of Eq. (16.134). The calculation is completely analogous to that leading to Eq. (16.168).

The partition function of the two polymers and the gauge fields is given by the path integral

$$Z = \int_{C_1} \mathcal{D}\mathbf{x}_1 \int_{C_2} \mathcal{D}\mathbf{x}_2 \int \mathcal{D}\mathbf{A}_1 \mathcal{D}\mathbf{A}_2 e^{-\mathcal{A}_e - \mathcal{A}_{\text{GF}}}. \quad (16.177)$$

Performing the functional integral over the gauge fields, we obtain from the extremum

$$Z = \text{const} \times \int_{C_1} \mathcal{D}\mathbf{x}_1 \int_{C_2} \mathcal{D}\mathbf{x}_2 e^{iG(C_1, C_2)}, \quad (16.178)$$

where the constant is the trivial fluctuation factor of the vector potentials. The Gaussian integral $G(C_1, C_2)$ has the values $m = 0, \pm 1, \pm 2, \dots$ of the linking numbers.

In order to analyze the distribution of linking number in the two-polymer system we must be able to fix a certain linking number. This is possible by replacing the phase factor e^{im} in the path integral (16.178) by $e^{im\lambda}$, and calculating $Z(\lambda)$. An integral $\int d\kappa e^{-i\bar{m}\lambda} Z(\lambda)$ will then select any specific linking number \bar{m} . But a phase factor $e^{im\lambda}$ is simply produced in the partition function (16.178) by attaching to one of the current couplings in the interaction (16.172), say to that of C_2 , a factor λ , thus changing (16.172) to

$$\mathcal{A}_{e, \text{curr}, \lambda} = -i \oint_{C_1} d\mathbf{x} \mathbf{A}_1(\mathbf{x}) - i\lambda \oint_{C_2} d\mathbf{x} \mathbf{A}_2(\mathbf{x}). \quad (16.179)$$

The λ -dependent partition function is then

$$\begin{aligned} Z(\lambda) &= \int_{C_1} \mathcal{D}\mathbf{x}_1 \int_{C_2} \mathcal{D}\mathbf{x}_2 \int \mathcal{D}\mathbf{A}_1 \mathcal{D}\mathbf{A}_2 e^{-\mathcal{A}_e, \text{CS12} - \mathcal{A}_{e, \text{curr}, \lambda} - \mathcal{A}_{\text{GF}}} \\ &= \text{const} \times \int_{C_1} \mathcal{D}\mathbf{x}_1 \int_{C_2} \mathcal{D}\mathbf{x}_2 e^{im\lambda}. \end{aligned} \quad (16.180)$$

Ultimately, we want to find the probability distribution of the linking numbers m as a function of the lengths of C_1 and C_2 . The solution of this two-polymer problem may be considered as an approximation to a more interesting physical problem in which a particular polymer is linked to any number N of polymers, which are effectively replaced by a single long “effective” polymer [9]. Unfortunately, the full distribution of m is very hard to calculate. Only a calculation of the second topological moment is possible with limited effort. This quantity is given by the expectation value $\langle m^2 \rangle$ of the square of the linking number m .

Let $P_{L_1, L_2}(\mathbf{x}_1, \mathbf{x}_2; m)$ be the configurational probability to find the polymer C_1 of length L_1 with fixed coinciding endpoints at \mathbf{x}_1 and the polymer C_2 of length L_2 with fixed coinciding

endpoints at \mathbf{x}_2 , entangled with a Gaussian linking number m . The second moment $\langle m^2 \rangle$ is given by the ratio of integrals

$$\langle m^2 \rangle = \frac{\int d^3x_1 d^3x_2 \int_{-\infty}^{+\infty} dm m^2 P_{L_1, L_2}(\mathbf{x}_1, \mathbf{x}_2; m)}{\int d^3x_1 d^3x_2 \int_{-\infty}^{+\infty} dm P_{L_1, L_2}(\mathbf{x}_1, \mathbf{x}_2; m)}, \quad (16.181)$$

performed for either of the two probabilities. The integrations in $d^3\mathbf{x}_1 d^3\mathbf{x}_2$ covers all positions of the endpoints. The denominator plays the role of a partition function of the system:

$$Z \equiv \int d^3x_1 d^3x_2 \int_{-\infty}^{+\infty} dm P_{L_1, L_2}(\mathbf{x}_1, \mathbf{x}_2; m). \quad (16.182)$$

Due to translational invariance of the system, the probabilities depend only on the differences between the endpoint coordinates:

$$P_{L_1, L_2}(\mathbf{x}_1, \mathbf{x}_2; m) = P_{L_1, L_2}(\mathbf{x}_1 - \mathbf{x}_2; m). \quad (16.183)$$

Thus, after the shift of variables, the spatial double integrals in (16.181) can be rewritten as

$$\int d^3x_1 d^3x_2 P_{L_1, L_2}(\mathbf{x}_1, \mathbf{x}_2; m) = V \int d^3x P_{L_1, L_2}(\mathbf{x}; m), \quad (16.184)$$

where V denotes the total volume of the system.

16.8.1 Polymer Field Theory for Probabilities

The calculation of the path integral over all line configurations is conveniently done within the polymer field theory developed in Section 15.12. It permits us to rewrite the partition function (16.180) as a functional integral over two $\psi_1^{\alpha_1}(\mathbf{x}_1)$ and $\psi_2^{\alpha_2}(\mathbf{x}_2)$ with n_1 and n_2 replica ($\alpha_1 = 1, \dots, n_1$, $\alpha_2 = 1, \dots, n_2$). At the end we shall take $n_1, n_2 \rightarrow 0$ to ensure that these fields describe only one polymer each, as explained in Section 15.12. For these fields we define an auxiliary probability $P_{\vec{z}}(\vec{\mathbf{x}}_1, \vec{\mathbf{x}}_2; \lambda)$ to find the polymer C_1 with open ends at $\mathbf{x}_1, \mathbf{x}'_1$ and the polymer C_2 with open ends at $\mathbf{x}_2, \mathbf{x}'_2$. The double vectors $\vec{\mathbf{x}}_1 \equiv (\mathbf{x}_1, \mathbf{x}'_1)$ and $\vec{\mathbf{x}}_2 \equiv (\mathbf{x}_2, \mathbf{x}'_2)$ collect initial and final endpoints of the two polymers C_1 and C_2 . The auxiliary probability $P_{\vec{z}}(\vec{\mathbf{x}}_1, \vec{\mathbf{x}}_2; \lambda)$ is given by a functional integral

$$P_{\vec{z}}(\vec{\mathbf{x}}_1, \vec{\mathbf{x}}_2; \lambda) = \lim_{n_1, n_2 \rightarrow 0} \int \mathcal{D}(\text{fields}) \psi_1^{\alpha_1}(\mathbf{x}_1) \psi_1^{*\alpha_1}(\mathbf{x}'_1) \psi_2^{\alpha_2}(\mathbf{x}_2) \psi_2^{*\alpha_2}(\mathbf{x}'_2) e^{-\mathcal{A}}, \quad (16.185)$$

where $\mathcal{D}(\text{fields})$ indicates the measure of functional integration, and \mathcal{A} the total action (16.180) governing the fluctuations. The expectation value is calculated for any fixed pair (α_1, α_2) of replica labels, i.e., replica labels are not subject to Einstein's summation convention of repeated indices. The action \mathcal{A} consists of kinetic terms for the fields, a quartic interaction of the fields to account for the fact that two monomers of the polymers cannot occupy the same point, the so-called *excluded-volume effect*, and a Chern-Simons field to describe the linking number m . Neglecting at first the excluded-volume effect and focusing attention on the linking problem only, the action reads

$$\mathcal{A} = \mathcal{A}_{\text{CS12}} + \mathcal{A}_{\text{e,curr}} + \mathcal{A}_{\text{pol}} + \mathcal{A}_{\text{GF}}, \quad (16.186)$$

with a polymer field action

$$\mathcal{A}_{\text{pol}} = \sum_{i=1}^2 \int d^3\mathbf{x} [|\bar{\mathbf{D}}^i \psi_i|^2 + m_i^2 |\Psi_i|^2]. \quad (16.187)$$

They are coupled to the polymer fields by the covariant derivatives

$$\mathbf{D}^i = \nabla + i\gamma_i \mathbf{A}^i, \quad (16.188)$$

with the coupling constants $\gamma_{1,2}$ given by

$$\gamma_1 = 1, \quad \gamma_2 = \lambda. \quad (16.189)$$

The square masses of the polymer fields are given by

$$m_i^2 = 2Mz_i. \quad (16.190)$$

where $M = 3/a$, with a being the length of the polymer links [recall (15.79)], and z_i the chemical potentials of the polymers, measured in units of the temperature. The chemical potentials are conjugate variables to the length parameters L_1 and L_2 , respectively. The symbols Ψ_i collect the replica of the two polymer fields

$$\Psi_i = (\psi_i^1, \dots, \psi_i^{n_i}), \quad (16.191)$$

and their absolute squares contain the sums over the replica

$$|\mathbf{D}^i \bar{\Psi}_i|^2 = \sum_{\alpha_i=1}^{n_i} |\mathbf{D}^i \psi_i^{\alpha_i}|^2, \quad |\Psi_i|^2 = \sum_{\alpha_i=1}^{n_i} |\psi_i^{\alpha_i}|^2. \quad (16.192)$$

Having specified the fields, we can now write down the measure of functional integration in Eq. (16.185):

$$\mathcal{D}(\text{fields}) = \int \mathcal{D}A_1^i \mathcal{D}A_2^j \mathcal{D}\Psi_1 \mathcal{D}\Psi_1^* \mathcal{D}\Psi_2 \mathcal{D}\Psi_2^*. \quad (16.193)$$

By Eq. (16.180), the parameter λ is conjugate to the linking number m . We can therefore calculate the probability $P_{L_1, L_2}(\vec{\mathbf{x}}_1, \vec{\mathbf{x}}_2; m)$ in which the two polymers are open with different endpoints from the auxiliary one $P_{\vec{z}}(\vec{\mathbf{x}}_1, \vec{\mathbf{x}}_2; \lambda)$ by the following Laplace integral over $\vec{z} = (z_1, z_2)$:

$$P_{L_1, L_2}(\vec{\mathbf{x}}_1, \vec{\mathbf{x}}_2; m) = \lim_{\substack{\mathbf{x}'_1 - \mathbf{x}_1 \\ \mathbf{x}'_2 - \mathbf{x}_2}} \int_{c-i\infty}^{c+i\infty} \frac{Mdz_1}{2\pi i} \frac{Mdz_2}{2\pi i} e^{z_1 L_1 + z_2 L_2} \int_{-\infty}^{\infty} dk e^{-im\lambda} P_{\vec{z}}(\vec{\mathbf{x}}_1, \vec{\mathbf{x}}_2; \lambda). \quad (16.194)$$

16.8.2 Calculation of Partition Function

Let us use the polymer field theory to calculate the partition function (16.182). By Eq. (16.194), it is given by the integral over the auxiliary probabilities

$$Z = \int d^3x_1 d^3x_2 \lim_{\substack{\mathbf{x}'_1 - \mathbf{x}_1 \\ \mathbf{x}'_2 - \mathbf{x}_2}} \int_{c-i\infty}^{c+i\infty} \frac{Mdz_1}{2\pi i} \frac{Mdz_2}{2\pi i} e^{z_1 L_1 + z_2 L_2} \int_{-\infty}^{\infty} dm \int_{-\infty}^{+\infty} d\lambda e^{-im\lambda} P_{\vec{z}}(\vec{\mathbf{x}}_1, \vec{\mathbf{x}}_2; \lambda). \quad (16.195)$$

The integration over m is trivial and gives $2\pi\delta(\lambda)$, enforcing $\lambda = 0$, so that

$$Z = \int d^3x_1 d^3x_2 \lim_{\substack{\mathbf{x}'_1 - \mathbf{x}_1 \\ \mathbf{x}'_2 - \mathbf{x}_2}} \int_{c-i\infty}^{c+i\infty} \frac{Mdz_1 Mdz_2}{2\pi i} e^{z_1 L_1 + z_2 L_2} P_{\vec{z}}(\vec{\mathbf{x}}_1, \vec{\mathbf{x}}_2; 0). \quad (16.196)$$

To calculate $P_{\vec{z}}(\vec{\mathbf{x}}_1, \vec{\mathbf{x}}_2; 0)$, we observe that the action \mathcal{A} in Eq. (16.186) depends on λ only via the polymer part (16.187), and is quadratic in λ . Let us expand \mathcal{A} as

$$\mathcal{A} = \mathcal{A}_0 + \lambda \mathcal{A}_1 + \lambda^2 \mathcal{A}_2, \quad (16.197)$$

with the λ -independent part

$$\mathcal{A}_0 \equiv \mathcal{A}_{\text{CS12}} + \mathcal{A}_{\text{GF}} + \int d^3x \left[|\mathbf{D}_1 \Psi_1|^2 + |\nabla \Psi_2|^2 + \sum_{i=1}^2 |\Psi_i|^2 \right], \quad (16.198)$$

a linear coefficient

$$\mathcal{A}_1 \equiv \int d^3x \mathbf{j}_2(\mathbf{x}) \cdot \mathbf{A}_2(\mathbf{x}) \quad (16.199)$$

containing a pseudo-current of the second polymer field

$$\mathbf{j}_2(\mathbf{x}) = i\Psi_2^*(\mathbf{x})\nabla\Psi_2(\mathbf{x}), \quad (16.200)$$

and a quadratic coefficient

$$\mathcal{A}_2 \equiv \frac{1}{4} \int d^3x \mathbf{A}_2^2 |\Psi_2(\mathbf{x})|^2. \quad (16.201)$$

With these definitions we write with the help of (16.198):

$$P_{\vec{z}}(\vec{\mathbf{x}}_1, \vec{\mathbf{x}}_2; 0) = \int \mathcal{D}(\text{fields}) e^{-\mathcal{A}_0} \psi_1^{\alpha_1}(\mathbf{x}_1) \psi_1^{*\alpha_1}(\mathbf{x}'_1) \psi_2^{\alpha_2}(\mathbf{x}_2) \psi_2^{*\alpha_2}(\mathbf{x}'_2). \quad (16.202)$$

In the action (16.198), the fields Ψ_2, Ψ_2^* are obviously free, whereas the fields Ψ_1, Ψ_1^* are apparently not because of the couplings with the Chern-Simons fields in the covariant derivative \mathbf{D}^1 . This coupling is, however, without physical consequences. Indeed, by integrating out A_2^i in (16.202), we find from $\mathcal{A}_{\text{CS12}}$ the flatness condition:

$$\nabla \times \mathbf{A}_1 = 0. \quad (16.203)$$

On a flat space with vanishing boundary conditions at infinity this implies $\mathbf{A}_1 = 0$. As a consequence, the functional integral (16.202) factorizes as follows [compare (15.370)]

$$P_{\vec{z}}(\vec{\mathbf{x}}_1, \vec{\mathbf{x}}_2; 0) = G_0(\mathbf{x}_1 - \mathbf{x}'_1; z_1) G_0(\mathbf{x}_2 - \mathbf{x}'_2; z_2), \quad (16.204)$$

where $G_0(\mathbf{x}_i - \mathbf{x}'_i; z_i)$ are the free correlation functions of the polymer fields:

$$G_0(\mathbf{x}_i - \mathbf{x}'_i; z_i) = \langle \psi_i^{\alpha_i}(\mathbf{x}_i) \psi_i^{*\alpha_i}(\mathbf{x}'_i) \rangle. \quad (16.205)$$

In momentum space, the correlation functions are

$$\langle \tilde{\psi}_i^{\alpha_i}(\mathbf{k}_i) \tilde{\psi}_i^{*\alpha_i}(\mathbf{k}'_i) \rangle = \delta^{(3)}(\mathbf{k}_i - \mathbf{k}'_i) \frac{1}{\mathbf{k}_i^2 + m_i^2}, \quad (16.206)$$

such that

$$G_0(\mathbf{x}_i - \mathbf{x}'_i; z_i) = \int \frac{d^3k}{(2\pi)^3} e^{i\mathbf{k}\cdot\mathbf{x}} \frac{1}{\mathbf{k}_i^2 + m_i^2}, \quad (16.207)$$

and

$$\begin{aligned} G_0(\mathbf{x}_i - \mathbf{x}'_i; L_i) &= \int_{c-i\infty}^{c+i\infty} \frac{M dz_i}{2\pi i} e^{z_i L_i} G_0(\mathbf{x}_i - \mathbf{x}'_i; z_i) \\ &= \frac{1}{2} \left(\frac{M}{4\pi L_i} \right)^{3/2} e^{-M(\mathbf{x}_i - \mathbf{x}'_i)/2L_i}. \end{aligned} \quad (16.208)$$

The partition function (16.196) is then given by the integral

$$Z = 2\pi \int d^3x_1 d^3x_2 \lim_{\substack{\mathbf{x}'_1 \rightarrow \mathbf{x}_1 \\ \mathbf{x}'_2 \rightarrow \mathbf{x}_2}} G_0(\mathbf{x}_1 - \mathbf{x}'_1; L_1) G_0(\mathbf{x}_2 - \mathbf{x}'_2; L_2). \quad (16.209)$$

The integrals at coinciding endpoints can easily be performed, yielding

$$Z = \frac{2\pi M^3 V^2}{(8\pi)^3} (L_1 L_2)^{-3/2}. \quad (16.210)$$

It is important to realize that in Eq. (16.195) the limits of coinciding endpoints $\mathbf{x}'_i \rightarrow \mathbf{x}_i$ and the inverse Laplace transformations do *not* commute unless a proper renormalization scheme is chosen to eliminate the divergences caused by the insertion of the composite operators $|\psi^\alpha(\mathbf{x})|^2$. This can be seen for a single polymer. If we were to commuting the limit of coinciding endpoints with the Laplace transform, we would obtain

$$\int_{c-i\infty}^{c+i\infty} \frac{dz}{2\pi} e^{zL} \lim_{\mathbf{x}' \rightarrow \mathbf{x}} G_0(\mathbf{x} - \mathbf{x}'; z) = \int_{c-i\infty}^{c+i\infty} \frac{dz}{2\pi i} e^{zL} G_0(\mathbf{0}, z), \quad (16.211)$$

where

$$G_0(\mathbf{0}; z) = \langle |\psi(\mathbf{x})|^2 \rangle. \quad (16.212)$$

This expectation value, however, is linearly divergent:

$$\langle |\psi(\mathbf{x})|^2 \rangle = \int \frac{d^3k}{k^2 + m^2} \rightarrow \infty. \quad (16.213)$$

16.8.3 Calculation of Numerator in Second Moment

Let us now turn to the numerator in Eq. (16.181):

$$N \equiv \int d^3x_1 d^3x_2 \int_{-\infty}^{\infty} dm m^2 P_{L_1, L_2}(\mathbf{x}_1, \mathbf{x}_2; m). \quad (16.214)$$

We shall set up a functional integral for N in terms of the auxiliary probability $P_{\vec{z}}(\vec{\mathbf{x}}_1, \vec{\mathbf{x}}_2; 0)$ analogous to Eq. (16.195). First we observe that

$$\begin{aligned} N &= \int d^3x_1 d^3x_2 \int_{-\infty}^{\infty} dm m^2 \lim_{\substack{\mathbf{x}'_1 \rightarrow \mathbf{x}_1 \\ \mathbf{x}'_2 \rightarrow \mathbf{x}_2}} \int_{c-i\infty}^{c+i\infty} \frac{Mdz_1}{2\pi i} \frac{Mdz_2}{2\pi i} \\ &\times e^{z_1 L_1 + z_2 L_2} \int_{-\infty}^{\infty} d\lambda e^{-im\lambda} P_{\vec{z}}(\vec{\mathbf{x}}_1, \vec{\mathbf{x}}_2; \lambda). \end{aligned} \quad (16.215)$$

The integration in m is easily performed after noting that

$$\int_{-\infty}^{\infty} dm m^2 e^{-im\lambda} P_{\vec{z}}(\vec{\mathbf{x}}_1, \vec{\mathbf{x}}_2; \lambda) = - \int_{-\infty}^{\infty} dm \left(\frac{\partial^2}{\partial \lambda^2} e^{-im\lambda} \right) P_{\vec{z}}(\vec{\mathbf{x}}_1, \vec{\mathbf{x}}_2; \lambda). \quad (16.216)$$

After two integrations by parts in λ , and an integration in m , we obtain

$$\begin{aligned} N &= \int d^3x_1 d^3x_2 \lim_{\substack{\mathbf{x}'_1 \rightarrow \mathbf{x}_1 \\ \mathbf{x}'_2 \rightarrow \mathbf{x}_2}} (-1) \int_{c-i\infty}^{c+i\infty} \frac{Mdz_1}{2\pi i} \frac{Mdz_2}{2\pi i} e^{z_1 L_1 + z_2 L_2} \\ &\times \int_{-\infty}^{\infty} d\lambda \delta(\lambda) \left[\frac{\partial^2}{\partial \lambda^2} P_{\vec{z}}(\vec{\mathbf{x}}_1, \vec{\mathbf{x}}_2; \lambda) \right]. \end{aligned} \quad (16.217)$$

Performing the now the trivial integration over λ yields

$$N = \int d^3x_1 d^3x_2 \lim_{\substack{\mathbf{x}'_1 \rightarrow \mathbf{x}_1 \\ \mathbf{x}'_2 \rightarrow \mathbf{x}_2}} (-1) \int_{c-i\infty}^{c+i\infty} \frac{Mdz_1}{2\pi i} \frac{Mdz_2}{2\pi i} e^{z_1 L_1 + z_2 L_2} \left[\frac{\partial^2}{\partial \lambda^2} P_{\bar{z}}(\bar{\mathbf{x}}_1, \bar{\mathbf{x}}_2; 0) \right]. \quad (16.218)$$

To compute the term in brackets, we use again (16.197) and Eqs. (16.198)–(16.223), to find

$$\begin{aligned} N &= \int d^3x_1 d^3x_2 \lim_{\substack{n_1 \rightarrow 0 \\ n_2 \rightarrow 0}} \int_{c-i\infty}^{c+i\infty} \frac{Mdz_1}{2\pi i} \frac{Mdz_2}{2\pi i} e^{z_1 L_1 + z_2 L_2} \\ &\quad \times \int \mathcal{D}(\text{fields}) \exp(-\mathcal{A}_0) |\psi_1^{\alpha_1}(\mathbf{x}_1)|^2 |\psi_2^{\alpha_2}(\mathbf{x}_2)|^2 \\ &\quad \times \left[\left(\int d^3x \mathbf{A}_2 \cdot \Psi_2^* \nabla \Psi_2 \right)^2 + \frac{1}{2} \int d^3x \mathbf{A}_2^2 |\Psi_2|^2 \right]. \end{aligned} \quad (16.219)$$

In this equation we have taken the limits of coinciding endpoint inside the Laplace integral over z_1, z_2 . This will be justified later on the grounds that the potentially dangerous Feynman diagrams containing the insertions of operations like $|\Psi_i|^2$ vanish in the limit $n_1, n_2 \rightarrow 0$.

In order to calculate (16.219), we decompose the action into a free part

$$\mathcal{A}_0^0 \equiv \mathcal{A}_{\text{CS}} + \int d^3x \left[|\mathbf{D}^1 \Psi_1|^2 + |\nabla \Psi_2|^2 + \sum_{i=1}^2 2|\Psi_i|^2 \right], \quad (16.220)$$

and interacting parts

$$\mathcal{A}_1^0 \equiv \int d^3x \mathbf{j}_1(\mathbf{x}) \cdot \mathbf{A}_1(\mathbf{x}), \quad (16.221)$$

with a “current” of the first polymer field

$$\mathbf{j}_1(\mathbf{x}) \equiv i\Psi_1^*(\mathbf{x}) \nabla \Psi_1(\mathbf{x}), \quad (16.222)$$

and

$$\mathcal{A}_0^2 \equiv \frac{1}{4} \int d^3x \mathbf{A}_1^2 |\Psi_1(\mathbf{x})|^2. \quad (16.223)$$

Expanding the exponential

$$e^{\mathcal{A}_0} = e^{\mathcal{A}_0^0 + \mathcal{A}_1^0 + \mathcal{A}_0^2} = e^{\mathcal{A}_0^0} \left[1 - \mathcal{A}_1^0 + \frac{(\mathcal{A}_0^1)^2}{2} - \mathcal{A}_0^2 + \dots \right], \quad (16.224)$$

and keeping only the relevant terms, the functional integral (16.219) can be rewritten as a purely Gaussian expectation value

$$\begin{aligned} N &= \kappa^2 \int d^3x_1 d^3x_2 \lim_{\substack{n_1 \rightarrow 0 \\ n_2 \rightarrow 0}} \int_{c-i\infty}^{c+i\infty} \frac{Mdz_1}{2\pi i} \frac{Mdz_2}{2\pi i} e^{z_1 L_1 + z_2 L_2} \\ &\quad \times \int \mathcal{D}(\text{fields}) \exp(-\mathcal{A}_0^0) |\psi_1^{\alpha_1}(\mathbf{x}_1)|^2 |\psi_2^{\alpha_2}(\mathbf{x}_2)|^2 \\ &\quad \times \left[\left(\int d^3x \mathbf{A}_1 \cdot \Psi_1^* \nabla \Psi_1 \right)^2 + \frac{1}{2} \int d^3x \mathbf{A}_1^2 |\Psi_1|^2 \right] \\ &\quad \times \left[\left(\int d^3x \mathbf{A}_2 \cdot \Psi_2^* \nabla \Psi_2 \right)^2 + \frac{1}{2} \int d^3x \mathbf{A}_2^2 |\Psi_2|^2 \right]. \end{aligned} \quad (16.225)$$

Figure 16.23 Four diagrams contributing in Eq. (16.225). The lines indicate correlation functions of Ψ_i -fields. The crossed circles with label i denote the insertion of $|\Psi_i(\mathbf{x}_i)|^2$.

Note that the initially asymmetric treatment of polymers C_1 and C_2 in the action (16.187) has led to a completely symmetric expression for the second moment.

Only four diagrams shown in Fig. 16.23 contribute in Eq. (16.225). The first diagram is divergent due to the divergence of the loop formed by two vector correlation functions. This infinity may be absorbed in the four- Ψ interaction accounting for the excluded volume effect which we do not consider at the moment. We now calculate the four diagrams separately.

16.8.4 First Diagram in Fig. 16.23

From Eq. (16.225) one has to evaluate the following integral

$$N_1 = \frac{\kappa^2}{4} \lim_{\substack{n_1 \rightarrow 0 \\ n_2 \rightarrow 0}} \int_{c-i\infty}^{c+i\infty} \frac{Mdz_1}{2\pi i} \frac{Mdz_2}{2\pi i} e^{z_1 L_1 + z_2 L_2} \int d^3 x_1 d^3 x_2 \int d^3 x'_1 d^3 x'_2 \quad (16.226)$$

$$\times \left\langle |\psi_1^{\alpha_1}(\mathbf{x}_1)|^2 |\psi_2^{\alpha_2}(\mathbf{x}_2)|^2 (|\Psi_1|^2 \mathbf{A}_1^2)_{\mathbf{x}'_1} (|\Psi_2|^2 \mathbf{A}_2^2)_{\mathbf{x}'_2} \right\rangle.$$

As mentioned before, there is an ultraviolet-divergent contribution which must be regularized. The system has, of course, a microscopic scale, which is the size of the monomers. This, however, is not the appropriate short-distance scale to be used here. The model treats the polymers as random chains. However, the monomers of a polymer in the laboratory are usually not freely movable, so that polymers have a certain stiffness. This gives rise to a certain persistence length ξ_0 over which a polymer is stiff. This length scale is increased to $\xi > \xi_0$ by the excluded-volume effects. This is the length scale which should be used as a proper physical short-distance cutoff. We may impose this cutoff by imagining the model as being defined on a simple cubic lattice of spacing ξ . This would, of course, make analytical calculations quite difficult. Still, as we shall see, it is possible to estimate the dependence of the integral N_1 and the others in the physically relevant limit in which the lengths of the polymers are much larger than the persistence length ξ .

An alternative and simpler regularization is based on cutting off all ultraviolet-divergent continuum integrals at distances smaller than ξ .

After such a regularization, the calculation of N_1 is rather straightforward. Replacing the expectation values by the Wick contractions corresponding to the first diagram in Fig. 16.23, and performing the integrals as shown in Appendix 16A, we obtain

$$N_1 = \frac{V}{4\pi} \frac{M^4}{(8\pi)^6} (L_1 L_2)^{-\frac{1}{2}} \int_0^1 ds [(1-s)s]^{-\frac{3}{2}} \int d^3 x e^{-M\mathbf{x}^2/2s(1-s)} \quad (16.227)$$

$$\times \int_0^1 dt [(1-t)t]^{-\frac{3}{2}} \int d^3 y e^{-M\mathbf{y}^2/2t(1-t)} \int d^3 x'_1 \frac{1}{|\mathbf{x}'_1|^4}.$$

The variables \mathbf{x} and \mathbf{y} have been rescaled with respect to the original ones in order to extract the behavior of N_1 in L_1 and L_2 . As a consequence, the lattices where \mathbf{x} and \mathbf{y} are defined have now spacings $\xi/\sqrt{L_1}$ and $\xi/\sqrt{L_2}$ respectively.

The \mathbf{x}, \mathbf{y} integrals may be explicitly computed in the physical limit $L_1, L_2 \gg \xi$, in which the above spacings become small. Moreover, it is possible to approximate the integral in \mathbf{x}_1'' with an integral over a continuous variable l and a cutoff in the ultraviolet region:

$$\int d^3 x_1'' \frac{1}{|\mathbf{x}_1''|^4} \sim 4\pi^2 \int_{\xi}^{\infty} \frac{dl}{l^2}. \quad (16.228)$$

After these approximations, we finally obtain

$$N_1 = V\pi^{1/2} \frac{M}{(4\pi)^3} (L_1 L_2)^{-1/2} \xi^{-1}. \quad (16.229)$$

16.8.5 Second and Third Diagrams in Fig. 16.23

Here we have to calculate

$$N_2 = \kappa^2 \lim_{\substack{n_1 \rightarrow 0 \\ n_2 \rightarrow 0}} \int_{c-i\infty}^{c+i\infty} \frac{Mdz_1}{2\pi i} \frac{Mdz_2}{2\pi i} e^{z_1 L_1 + z_2 L_2} \int d^3 x_1 d^3 x_2 \int d^3 x_1' d^3 x_1'' d^3 x_2' \\ \times \left\langle |\psi_1^{\alpha_1}(\mathbf{x}_1)|^2 |\psi_2^{\alpha_2}(\mathbf{x}_2)|^2 (\mathbf{A}_1 \cdot \Psi_1^* \nabla \Psi_1)_{\mathbf{x}_1'} (\mathbf{A}_1 \cdot \Psi_1^* \nabla \Psi_1)_{\mathbf{x}_1''} (\mathbf{A}_2^2 |\Psi_2|^2)_{\mathbf{x}_2'} \right\rangle. \quad (16.230)$$

The above amplitude has no ultraviolet divergence, so that no regularization is required. The Wick contractions pictured in the second Feynman diagrams of Fig. 16.23 lead to the integral

$$N_2 = -4\sqrt{2}V L_2^{-1/2} L_1^{-1} \frac{M^3}{\pi^6} \int_0^1 dt \int_0^t dt' C(t, t'), \quad (16.231)$$

where $C(t, t')$ is a function independent of L_1 and L_2 :

$$C(t, t') = [(1-t)t'(t-t')]^{-3/2} \int d^3 x d^3 y d^3 z e^{-M(\mathbf{y}-\mathbf{x})^2/2(1-t)} \\ \times \left(\nabla_{\mathbf{y}}^j e^{-M\mathbf{y}^2/2t'} \right) \left(\nabla_{\mathbf{x}}^i e^{-M\mathbf{x}^2/2(t-t')} \right) \frac{[\delta_{ij} \mathbf{z} \cdot (\mathbf{z} + \mathbf{x}) - (z+x)_i z_j]}{|\mathbf{z}|^3 |\mathbf{z} + \mathbf{x}|^3}. \quad (16.232)$$

As in the previous section, the variables $\mathbf{x}, \mathbf{y}, \mathbf{z}$ have been rescaled with respect to the original ones in order to extract the behavior in L_1 .

If the polymer lengths are much larger than the persistence length one can ignore the fact that the monomers have a finite size and it is possible to compute $C(t, t')$ analytically, leading to

$$N_2 = -\frac{V L_2^{-1/2} L_1^{-1}}{(2\pi)^6} M^{3/2} 4K, \quad (16.233)$$

where K is the constant

$$K \equiv \frac{1}{6} B\left(\frac{3}{2}, \frac{1}{2}\right) + \frac{1}{2} B\left(\frac{5}{2}, \frac{1}{2}\right) - B\left(\frac{7}{2}, \frac{1}{2}\right) + \frac{1}{3} B\left(\frac{9}{2}, \frac{1}{2}\right) = \frac{19\pi}{384} \approx 0.154, \quad (16.234)$$

and $B(a, b) = \Gamma(a)\Gamma(b)/\Gamma(a+b)$ is the Beta function. For large $L_1 \rightarrow \infty$, this diagram gives a negligible contribution with respect to N_1 .

The third diagram in Fig. 16.23 give the same as the second, except that L_1 and L_2 are interchanged.

$$N_3 = N_2|_{L_1 \leftrightarrow L_2}. \quad (16.235)$$

16.8.6 Fourth Diagram in Fig. 16.23

Here we have the integral

$$\begin{aligned}
 N_4 = & -4\kappa^2 \frac{1}{2} \lim_{\substack{n_1 \rightarrow 0 \\ n_2 \rightarrow 0}} \int_{c-i\infty}^{c+i\infty} \frac{Mdz_1}{2\pi i} \frac{Mdz_2}{2\pi i} e^{z_1 L_1 + z_2 L_2} \int d^3 x_1 d^3 x_2 \int d^3 x'_1 d^3 x'_2 d^3 x''_1 d^3 x''_2 \\
 & \times \left\langle |\psi_1^{\alpha_1}(\mathbf{x}_1)|^2 |\psi_2^{\alpha_2}(\mathbf{x}_2)|^2 (\mathbf{A}_1 \cdot \Psi_1^* \nabla \Psi_1)_{\mathbf{x}'_1} (\mathbf{A}_1 \cdot \Psi_1^* \nabla \Psi_1)_{\mathbf{x}''_1} \right. \\
 & \quad \left. \times (\mathbf{A}_2 \cdot \Psi_2^* \nabla \Psi_2)_{\mathbf{x}'_2} (\mathbf{A}_2 \cdot \Psi_2^* \nabla \Psi_2)_{\mathbf{x}''_2} \right\rangle, \tag{16.236}
 \end{aligned}$$

which has no ultraviolet divergence. After some analytic effort we find

$$N_4 = -\frac{1}{16} \frac{M^5 V}{(2\pi)^{11}} (L_1 L_2)^{-1/2} \int_0^1 ds \int_0^s ds' \int_0^1 dt \int_0^t dt' C(s, s', t, t'), \tag{16.237}$$

where

$$\begin{aligned}
 C(s, s'; t, t') = & [(1-s)s'(s-s')]^{-3/2} [(1-t)t'(t-t')]^{-3/2} \\
 & \times \int \frac{d^3 p}{(2\pi)^3} \left[\epsilon_{ik\alpha} \frac{p^\alpha}{\mathbf{p}^2} \epsilon_{jl\beta} \frac{p^\beta}{\mathbf{p}^2} + \epsilon_{il\alpha} \frac{p^\alpha}{\mathbf{p}^2} \epsilon_{jk\beta} \frac{p^\beta}{\mathbf{p}^2} \right] \\
 & \times \left[\int d^3 x' d^3 y' e^{-i\sqrt{L_1} \mathbf{p}(\mathbf{x}' - \mathbf{y}')} e^{-M \mathbf{x}'^2 / 2(1-s)} \left(\nabla_{\mathbf{y}'}^j e^{-M \mathbf{y}'^2 / 2t'} \right) \left(\nabla_{\mathbf{x}'}^i e^{-M(\mathbf{x} - \mathbf{y})^2 / 2(s-s')} \right) \right] \\
 & \times \left[\int d^3 u' d^3 v' e^{-i\sqrt{L_2} \mathbf{p}(\mathbf{u}' - \mathbf{v}')} e^{-M \mathbf{v}'^2 / 2(1-t)} \left(\nabla_{\mathbf{v}'}^l e^{-M \mathbf{v}'^2 / 2t'} \right) \left(\nabla_{\mathbf{u}'}^k e^{-M(\mathbf{u}' - \mathbf{v}')^2 / 2(t-t')} \right) \right], \tag{16.238}
 \end{aligned}$$

and \mathbf{x}', \mathbf{y}' are scaled variables. To take into account the finite persistence length, they should be defined on a lattice with spacing $\xi/\sqrt{L_1}$. Similarly, \mathbf{u}', \mathbf{v}' should be considered on a lattice with spacing $\xi/\sqrt{L_2}$. Without performing the space integrations $d^3 x' d^3 y' d^3 u' d^3 v'$, the behavior of N_4 as a function of the polymer lengths can be easily estimated in the following limits:

1. $L_1 \gg 1; L_1 \gg L_2$

$$N_4 \propto L_1^{-1} \tag{16.239}$$

2. $L_2 \gg 1; L_2 \gg L_1$

$$N_4 \propto L_2^{-1} \tag{16.240}$$

3. $L_1, L_2 \gg 1, L_2/L_1 = \alpha = \text{finite}$

$$N_4 \propto L_1^{-3/2}. \tag{16.241}$$

Moreover, if the lengths of the polymers are considerably larger than the persistence length, the function $C(s, s', t, t')$ can be computed in a closed form:

$$\begin{aligned}
 N_4 \approx & -\frac{128V}{\pi^5} \frac{M}{\pi^{3/2}} (L_1 L_2)^{-1/2} \int_0^1 ds \int_0^1 dt (1-s)(1-t)(st)^{1/2} \\
 & \times [L_1 t(1-s) + L_2(1-t)s]^{-1/2}. \tag{16.242}
 \end{aligned}$$

It is simple to check that this expression has exactly the above behaviors.

16.8.7 Second Topological Moment

Collecting all contributions we obtain the result for the second topological moment:

$$\langle m^2 \rangle = \frac{N_1 + N_2 + N_3 + N_4}{Z}, \quad (16.243)$$

with N_1, N_2, N_3, N_4, Z given by Eqs. (16.210), (16.229), (16.233), (16.235), and (16.231).

In all formulas, we have assumed that the volume V of the system is much larger than the size of the volume occupied by a single polymer, i.e., $V \gg L_1^3$.

To discuss the physical content of the result (16.232), we assume C_2 to be a long effective polymer representing all polymers in a uniform solution. We introduce the polymer concentration l as the average mass density of the polymers per unit volume:

$$l = \frac{M}{V}, \quad (16.244)$$

where M is the total mass of the polymers

$$M = \sum_{i=1}^{N_p} m_a \frac{L_k}{a}. \quad (16.245)$$

Here m_a is the mass of a single monomer of length a , L_k is the length of polymer C_k , and N_p is the total number of polymers. Thus L_k/a is the number of monomers in the polymer C_k . The polymer C_1 is singled out as any of the polymers C_k , say $C_{\bar{k}}$, of length $L_1 = L_{\bar{k}}$. The remaining ones are replaced by a long effective polymer C_2 of length $L_2 = \sigma_{k \neq \bar{k}} L_k$. From the above relations we may also write

$$L_2 \approx \frac{aVl}{m_a}. \quad (16.246)$$

In this way, the length of the effective molecule C_2 is expressed in terms of physical parameters, the concentration of polymers, the monomer length, and the mass and volume of the system. Inserting (16.246) into (16.232), with N_1, N_2, N_3, N_4, Z given by Eqs. (16.210), (16.229), (16.233), (16.235), and (16.231). and keeping only the leading terms for $V \gg 1$, we find for the second topological moment $\langle m^2 \rangle$ the approximation

$$\langle m^2 \rangle \approx \frac{N_1 + N_2}{Z}, \quad (16.247)$$

and this has the approximate form

$$\langle m^2 \rangle = \frac{al}{m_a} \left[\frac{\xi^{-1} L_i}{2\pi^{1/2} M^2} - \frac{2KL_1^{1/2}}{\pi^4 M^{3/2}} \right], \quad (16.248)$$

with K of (16.234).

Thus we have succeeded in setting up a topological field theory to describe two fluctuating polymers C_1 and C_2 , and calculated the second topological moment for the linking number m between C_1 and C_2 . The result is used as an approximation for the second moment for a single polymer with respect to all others in a solution of many polymers.

An interesting remaining problem is to calculate the effect of the excluded volume.

16.9 Chern-Simons Theory of Statistical Interaction

The Chern-Simons theory (16.153) together with the coupling (16.152) generates the desired topological interaction corresponding to the Gaussian integral between

pairs of curves C and C' . We now demonstrate that this topological interaction is the same as the statistical interaction introduced in Eq. (7.279) and encountered again in (16.26), where it governed the physics of a charged particle running around a magnetic flux tube. This observation will make the Gaussian integral and thus the Chern-Simons action relevant for the description of the statistical properties of nonrelativistic particle orbits. In contrast to the electromagnetic generation of fractional statistics for particle orbits in Section 16.2 via the Aharonov-Bohm effect, the field theory involving the statisto-magnetic vector potential has the advantage of removing the asymmetry between the particles, of which one had to carry a charge, the other one a magnetic flux. An arbitrary number of identical particle orbits can now be endowed with a fractional statistics, the same that was produced by topological interaction (7.279).

To prove the equality between the two topological interactions in two space and one time dimension, consider an electron in a plane encircling an infinitely thin magnetic “flux tube” at the origin (the word flux tube stands between quotation marks since the “tube” is only a point in the two-dimensional space). In a Euclidean spacetime, the worldline of the electron C winds itself around the straight “flux tube” C' along the τ -axis. For this geometry, the integral over C' in (16.134) can easily be done using the formula $\int_{-\infty}^{\infty} dt/\sqrt{t^2 + d^2} = 2$. The result is

$$G(C, C') = \frac{1}{2\pi} \int d\tau \dot{\mathbf{x}}(\tau) \nabla \varphi(\mathbf{x}(\tau)) = \frac{1}{2\pi} \int d\tau \dot{\varphi}(\mathbf{x}(\tau)), \quad (16.249)$$

where $\varphi(\mathbf{x}(\tau))$ denotes the azimuthal angle of the electron with respect to the “flux tube” at the time τ

Up to a factor 2π , the expression (16.249) agrees with the statistical interaction in (16.26) and (7.279). In two space and one time dimension, the behavior under particle exchange can be assigned to an amplitude at will by adding to the Euclidean action a Gaussian integral with a suitable prefactor. A phase factor $e^{i\theta}$ is produced by the exchange when choosing the following Euclidean action-at-a-distance:

$$\mathcal{A}_{e,\text{int}} = i2\hbar\theta G(C, C'). \quad (16.250)$$

This topological interaction is generated by the Chern-Simons action

$$\mathcal{A}_{e,\text{CS}} = \frac{1}{4\theta\hbar i} \int d^3x \mathbf{A} \cdot (\nabla \times \mathbf{A}). \quad (16.251)$$

The phase angle θ is related to the former parameter μ_0 of the statistical interactions (16.26) and (7.279) by

$$\theta = \pi\mu_0. \quad (16.252)$$

For $\mu_0 = \pm 1, \pm 3, \pm 5, \dots$, the particle orbits have Fermi statistics; for $\mu_0 = 0, \pm 2, \pm 4, \dots$, they have Bose statistics. Fractional values of μ_0 lead to fractional statistics. In contrast to the magnetic generation of fractional statistics, the Chern-Simons mechanism applies to any number of particle orbits. By one of the methods

discussed after Eq. (16.169) it must, however, be assured that the Gaussian “self-energy” does not render any undesirable nontopological contributions.

To maintain the analogy with the magnetic interactions as far as possible, we write the Chern-Simons action for a gas of electrons in the form

$$\mathcal{A}_{e,\text{CS}} = \frac{1}{4\pi i} \frac{e^2}{c^2 \hbar \mu_0} \int d^3x \mathbf{A} \times (\nabla \times \mathbf{A}), \quad (16.253)$$

and the coupling of the statisto-magnetic vector potential to the particle orbits as

$$\mathcal{A}_{e,\text{curr}} = -i \frac{e}{c} \oint_C d\mathbf{x} \mathbf{A}(\mathbf{x}) - i \frac{e}{c} \oint_{C'} d\mathbf{x} \mathbf{A}(\mathbf{x}). \quad (16.254)$$

This looks precisely like the Euclidean coupling of an ordinary vector potential to electrons. For an arbitrary number of orbits we define the Euclidean two-dimensional current density

$$\mathbf{j}(\mathbf{x}) \equiv ec \sum_{\alpha} \oint_{C_{\alpha}} d\mathbf{x}_{\alpha} \delta^{(3)}(\mathbf{x} - \mathbf{x}_{\alpha}) \quad (16.255)$$

and write the interaction (16.254) as

$$\mathcal{A}_{e,\text{curr}} = -i \frac{1}{c^2} \int d^3x \mathbf{j}(\mathbf{x}) \mathbf{A}(\mathbf{x}). \quad (16.256)$$

The curl of the vector potential

$$\mathbf{B} \equiv \nabla \times \mathbf{A} \quad (16.257)$$

is referred to as a *statisto-magnetic field*. By varying (16.253) plus (16.256) with respect to $\mathbf{A}(\mathbf{x})$, we obtain the field equation

$$\mathbf{B}(\mathbf{x}) = \mu_0 \frac{2\pi \hbar c}{e^2} \mathbf{j}(\mathbf{x}). \quad (16.258)$$

With the help of the elementary flux quantum Φ_0 , this can also be written as

$$\mathbf{B}(\mathbf{x}) = \mu_0 \Phi_0 \frac{1}{e} \mathbf{j}(\mathbf{x}). \quad (16.259)$$

To apply the above formulas, we must transform them from the three-dimensional Euclidean spacetime to the Minkowski space, where the curves C_{α} become particle orbits in two space dimensions whose coordinates $\mathbf{x}_{\perp} = (x, y)$ are functions of the time t . Specifically, we substitute the three coordinates (x_1, x_2, x_3) as follows:

$$\begin{aligned} (x_1, x_2) &\rightarrow \mathbf{x}_{\perp} \equiv (x, y), \\ x_3 &\rightarrow ix_0 \equiv ict. \end{aligned}$$

The Euclidean field components $A_{1,2,3}$ go over into the Minkowskian *statisto-electric potential* ϕ and two spatial components $A_{x,y}$. The three fields $B_{1,2,3}$ turn into the Minkowskian *statisto-electric fields* E_y, E_x and a *statisto-magnetic field* B_z :

$$\begin{aligned} A_3 &= i\phi = iA_0, & A_1 &= A_x, & A_2 &= A_y, \\ B_3 &= iB_z, & B_1 &= -iE_y, & B_2 &= iE_x. \end{aligned} \quad (16.260)$$

The Euclidean currents become, up to a factor i , the two-dimensional charge and current densities:

$$\begin{aligned} j_3 &= ij_0 = ic\rho(\mathbf{x}_\perp), & \rho(\mathbf{x}) &\equiv e \sum_\alpha \delta^{(2)}(\mathbf{x}_\perp - \mathbf{x}_{\perp\alpha}), \\ j_1 &= ij_x(\mathbf{x}_\perp) = e \sum_\alpha \dot{x}_\alpha \delta^{(2)}(\mathbf{x}_\perp - \mathbf{x}_{\perp\alpha}), \\ j_2 &= ij_y(\mathbf{x}_\perp) = e \sum_\alpha \dot{y}_\alpha \delta^{(2)}(\mathbf{x}_\perp - \mathbf{x}_{\perp\alpha}), \end{aligned} \quad (16.261)$$

where ρ is the particle density per unit area. The motion of a particle in an external field ϕ, A_x, A_y is then governed by the interaction

$$\mathcal{A}_{\text{int}} = \int dt d^2x \left[\rho\phi - \frac{1}{c}(j_x A_x + j_y A_y) \right]. \quad (16.262)$$

Conversely, particles with fractional statistics in a 2+1-dimensional spacetime generate Minkowskian *statisto-electromagnetic fields* following the equations

$$B_z = \mu_0 \Phi_0 \rho, \quad E_x = \mu_0 \Phi_0 \frac{1}{c} j_y, \quad E_y = \mu_0 \Phi_0 \frac{1}{c} j_x. \quad (16.263)$$

The electromagnetic normalization in Eq. (16.262) has the advantage that a charged particle cannot distinguish a *statisto-magnetic field* from a true magnetic field. This property forms the basis for a simple interpretation of the fractional quantum Hall effect as will be seen in Section 18.9.

16.10 Second-Quantized Anyon Fields

After the developments in Chapter 7, we should expect that the phase factor $e^{i\mu_0\pi}$, appearing in the path integral upon exchanging the endpoints of two anyonic orbits, can also be found in a second-quantized operator formulation. To verify this, we consider a free Bose field with the action (7.286) and couple it with a *statisto-electromagnetic field* subject to a Chern-Simons action. The resulting free anyon action reads

$$\mathcal{A}_{\text{anyon}} = \mathcal{A}_{\text{CS}} + \mathcal{A}_{\text{boson}}, \quad (16.264)$$

where

$$\begin{aligned} \mathcal{A}_{\text{boson}} &= \int d^2x \int_{t_a}^{t_b} dt \left\{ \psi^*(\mathbf{x}, t) \left[i\hbar \left(\partial_t + i\frac{e}{\hbar} \phi(\mathbf{x}, t) \right) + \mu \right] \psi(\mathbf{x}, t) \right. \\ &\quad \left. - \frac{\hbar^2}{2M} \left| \left[\nabla - i\frac{e}{\hbar c} \mathbf{A}(\mathbf{x}, t) \right] \psi(\mathbf{x}, t) \right|^2 \right\}. \end{aligned} \quad (16.265)$$

The latter corresponds to the action (7.286) in the continuum limit with the derivatives replaced by covariant derivatives according to the usual minimal substitution rule (2.644):

$$p_0 \rightarrow p_0 - \frac{e}{c}\phi, \quad \mathbf{p} \rightarrow \mathbf{p} - \frac{e}{c}\mathbf{A}. \quad (16.266)$$

The first field equation in (16.263) now reads

$$B_z(\mathbf{x}, t) = \mu_0 \Phi_0 \psi^\dagger(\mathbf{x}, t) \psi(\mathbf{x}, t), \quad (16.267)$$

so that the vector potential satisfies the differential equation

$$\partial_x A_y(\mathbf{x}, t) - \partial_y A_x(\mathbf{x}, t) = \mu_0 \Phi_0 \psi^\dagger(\mathbf{x}, t) \psi(\mathbf{x}, t). \quad (16.268)$$

It determines (A_x, A_y) up to the gauge freedom $(\partial_x \Lambda, \partial_y \Lambda)$, where $\Lambda(\mathbf{x}, t)$ is an arbitrary single-valued function satisfying Schwarz' integrability condition

$$(\partial_x \partial_y - \partial_y \partial_x) \Lambda(\mathbf{x}, t) = 0. \quad (16.269)$$

In the present case, it is useful to allow for a violation of this condition by searching for a multivalued function $\alpha(\mathbf{x}, t)$ whose gradient is equal to a given vector potential:

$$(A_x, A_y) = (\partial_x \alpha, \partial_y \alpha). \quad (16.270)$$

This function must obey the differential equation (recall the discussion in Appendix 10A)

$$(\partial_x \partial_y - \partial_y \partial_x) \alpha(\mathbf{x}, t) = \mu_0 \frac{2\pi \hbar c}{e} \psi^\dagger(\mathbf{x}, t) \psi(\mathbf{x}, t). \quad (16.271)$$

The Green function of this differential equation, which is the elementary building block for the construction of all multivalued functions in two dimensions, is the function used before in Eq. (16.249) [see also (10A.30)]:

$$\varphi(\mathbf{x} - \mathbf{x}') \equiv \arctan[(y - y')/(x - x')]. \quad (16.272)$$

It gives the angle between the vectors \mathbf{x} and \mathbf{x}' and violates the Schwarz integrability condition at the points where the vectors coincide [recall (10A.33)]:

$$(\partial_x \partial_y - \partial_y \partial_x) \varphi(\mathbf{x} - \mathbf{x}') = 2\pi \delta^{(2)}(\mathbf{x} - \mathbf{x}'). \quad (16.273)$$

To satisfy this equation, the cut of the arctan in the complex plane must be avoided, which is always possible by deforming it appropriately. The function $\varphi(\mathbf{x} - \mathbf{x}')$ has the important property

$$\varphi(\mathbf{x} - \mathbf{x}') - \varphi(\mathbf{x}' - \mathbf{x}) = \pi. \quad (16.274)$$

In the two terms on the left-hand side, the point \mathbf{x}' is moved around the point \mathbf{x} in the anticlockwise sense.

With the help of the multivalued Green function (16.272) we find immediately the solution of Eq. (16.271):

$$\alpha(\mathbf{x}, t) = \mu_0 \frac{\hbar c}{e} \int d^2x \varphi(\mathbf{x} - \mathbf{x}') \psi^\dagger(\mathbf{x}, t) \psi(\mathbf{x}, t). \quad (16.275)$$

The relation (16.270) permits the elimination of the statisto-magnetic field from the action. Actually, this statement is true in general. One can always multiply the fields $\psi(\mathbf{x}, t)$ by a phase factor

$$\exp \left[-i \frac{e}{\hbar c} \int^{\mathbf{x}} d\mathbf{x}' \mathbf{A}(\mathbf{x}', t) \right],$$

where the contour integral is taken to \mathbf{x} from any fixed point along some fixed path. In front of the transformed field

$$\Psi(\mathbf{x}, t) = e^{-i(e/\hbar c) \int^{\mathbf{x}} d\mathbf{x}' \mathbf{A}(\mathbf{x}', t)} \psi(\mathbf{x}, t), \quad (16.276)$$

the covariant derivatives

$$D_i \psi(\mathbf{x}, t) = (\partial_i - i \frac{e}{\hbar c} A_i) \psi(\mathbf{x}, t) \quad (16.277)$$

become ordinary derivatives ∂_i . Unfortunately, the new field $\Psi(\mathbf{x}, t)$ depends on the vector potential in a complicated nonlocal way so that this transformation is in general not worthwhile. In the present case, however, the equation of motion for the vector potential is so simple that the transformation *can* be done explicitly. In fact, the nonlocality has precisely the desired property of changing the statistics of the fields from Bose statistics to any statistics.

We show this by considering the field operators $\hat{\psi}(\mathbf{x}, t)$ which are canonically quantized according to Eq. (7.294). In the continuum limit they satisfy the commutation rules

$$\begin{aligned} [\hat{\psi}(\mathbf{x}, t), \hat{\psi}^\dagger(\mathbf{x}', t)] &= \delta^{(2)}(\mathbf{x} - \mathbf{x}'), \\ [\hat{\psi}^\dagger(\mathbf{x}, t), \hat{\psi}^\dagger(\mathbf{x}', t)] &= 0, \\ [\hat{\psi}(\mathbf{x}, t), \hat{\psi}(\mathbf{x}', t)] &= 0. \end{aligned} \quad (16.278)$$

The transformed field operators satisfy the corresponding commutation rules modified by a phase factor $e^{i\mu_0\pi}$:

$$\begin{aligned} \hat{\psi}(\mathbf{x}, t) \hat{\psi}^\dagger(\mathbf{x}', t) - e^{i\pi\mu_0} \hat{\psi}^\dagger(\mathbf{x}', t) \hat{\psi}(\mathbf{x}, t) &= \delta^{(2)}(\mathbf{x} - \mathbf{x}'), \\ \hat{\psi}^\dagger(\mathbf{x}, t) \hat{\psi}^\dagger(\mathbf{x}', t) - e^{i\pi\mu_0} \hat{\psi}^\dagger(\mathbf{x}', t) \hat{\psi}^\dagger(\mathbf{x}, t) &= 0, \\ \hat{\psi}(\mathbf{x}, t) \hat{\psi}(\mathbf{x}', t) - e^{i\pi\mu_0} \hat{\psi}(\mathbf{x}', t) \hat{\psi}(\mathbf{x}, t) &= 0. \end{aligned} \quad (16.279)$$

As in (16.274), the vector \mathbf{x}' on the left-hand side has to be carried around \mathbf{x} in the anticlockwise sense. Using the relation (16.270), the integral in the prefactor of

(16.276) can immediately be performed and the transformed fields are simply given by

$$\tilde{\psi}(\mathbf{x}, t) = e^{-i\frac{e}{\hbar c}\alpha(\mathbf{x}, t)}\psi(\mathbf{x}, t), \quad \tilde{\psi}^\dagger(\mathbf{x}, t) = \psi(\mathbf{x}, t)e^{i\frac{e}{\hbar c}\alpha(\mathbf{x}, t)}. \quad (16.280)$$

The same relations hold for the second-quantized field operators. This makes it quite simple to prove the commutation rules (16.279). We do this here only for the second rule which controls the behavior of the many-body wave functions under the exchange of any two-particle coordinates:

$$\hat{\psi}^\dagger(\mathbf{x}, t)\hat{\psi}^\dagger(\mathbf{x}', t) - e^{i\pi\mu_0}\hat{\psi}^\dagger(\mathbf{x}', t)\hat{\psi}^\dagger(\mathbf{x}, t) = 0.$$

This amounts to the relation

$$\hat{\psi}^\dagger(\mathbf{x}, t)e^{i\frac{e}{\hbar c}\hat{\alpha}(\mathbf{x}, t)}\hat{\psi}^\dagger(\mathbf{x}', t)e^{i\frac{e}{\hbar c}\hat{\alpha}(\mathbf{x}', t)} = e^{i\pi\mu_0}\hat{\psi}^\dagger(\mathbf{x}', t)e^{i\frac{e}{\hbar c}\hat{\alpha}(\mathbf{x}', t)}\hat{\psi}^\dagger(\mathbf{x}, t)e^{i\frac{e}{\hbar c}\hat{\alpha}(\mathbf{x}, t)}. \quad (16.281)$$

The phase factors in the middle can be taken to the right-hand side by using the transformation formula

$$e^{i\int d^2x' f(\mathbf{x}', t)\hat{\psi}^\dagger(\mathbf{x}, t)\hat{\psi}(\mathbf{x}, t)}\hat{\psi}^\dagger(\mathbf{x}, t)e^{-i\int d^2x' f(\mathbf{x}', t)\hat{\psi}^\dagger(\mathbf{x}, t)\hat{\psi}(\mathbf{x}, t)} = e^{if(\mathbf{x}, t)}\hat{\psi}^\dagger(\mathbf{x}, t), \quad (16.282)$$

which follows from the Lie expansion [recall (1.297)]

$$e^{i\hat{A}}\hat{B}e^{-i\hat{A}} = 1 + i[\hat{A}, \hat{B}] + \frac{i^2}{2!}[\hat{A}, [\hat{A}, \hat{B}]] + \dots \quad (16.283)$$

Setting $f(\mathbf{x})$ equal to $\mu_0\varphi(\mathbf{x} - \mathbf{x}')$, Eq. (16.281) goes over into

$$\begin{aligned} \hat{\psi}^\dagger(\mathbf{x}, t)\hat{\psi}^\dagger(\mathbf{x}', t)e^{i\mu_0\varphi(\mathbf{x}-\mathbf{x}')}e^{i\frac{e}{\hbar c}[\hat{\alpha}(\mathbf{x}, t)+\hat{\alpha}(\mathbf{x}', t)]} \\ = e^{i\pi\mu_0}\hat{\psi}^\dagger(\mathbf{x}', t)\hat{\psi}^\dagger(\mathbf{x}, t)e^{i\mu_0\varphi(\mathbf{x}'-\mathbf{x})}e^{i\frac{e}{\hbar c}[\hat{\alpha}(\mathbf{x}', t)+\hat{\alpha}(\mathbf{x}, t)]}. \end{aligned} \quad (16.284)$$

The correctness of this equation follows directly from the property (16.274) of the $\varphi(\mathbf{x})$ field and from the commutativity of the Bose fields $\psi^\dagger(\mathbf{x}, t)$ with each other. This proves the second of the anyon commutation rules (16.279). The others are obtained similarly.

Note that we could just as well have constructed the anyon fields from Fermi fields by shifting the exchange phase by an angle π .

16.11 Fractional Quantum Hall Effect

If particles obeying fractional statistics move in an ordinary magnetic field, they are also subject to a *statisto-magnetic field*. As observed earlier, this acts upon each particle in the same way as an additional true magnetic field. This observation provides a key for the understanding of the *fractional quantum Hall effect*. The arguments will now be sketched.

To measure the effect experimentally, a thin slab of conducting material (the original experiment used the compound $\text{Al}_x\text{Ga}_{1-x}\text{As}$) is placed at low temperatures

(≈ 0.5 K) in the xy -plane traversed by a strong magnetic field B_z (between 10 and 200 kG) along the z -axis. An electric field E_x is applied in the x -direction and an electric *Hall current* j_y per length unit is measured in the y -direction. Such a current is expected in a dissipative electron gas with a number density (per unit area) ρ , where the fields satisfy the relation

$$E_x = -\frac{1}{\rho ec} j_y B_z \quad (16.285)$$

(see Appendix 16E). The transverse resistance defined by

$$R_{xy} \equiv \frac{B_z}{\rho ec} \quad (16.286)$$

rises linearly in B_z . Its dimension is sec/cm. In contrast with this naive expectation, the experimental data for R_{xy} rise stepwise with a number of plateaus whose resistance take the values $h/e^2\nu$, where ν is a rational number with odd denominators:

$$\nu = \frac{1}{5}, \frac{2}{7}, \frac{1}{3}, \frac{2}{5}, \frac{2}{3}, \dots \quad (16.287)$$

We have omitted the observed number $\nu = \frac{5}{2}$ since its theoretical explanation requires additional physical considerations (see the references at the end of the chapter).

Similar plateaus had been observed at integer values of ν . Those are explained as follows.

In an ideal Fermi liquid at zero temperature, the electron orbits have energies $\mathbf{p}^2/2M$. Their momenta fill a Fermi sphere of radius p_F . The size of p_F is determined from the particle number per unit area ρ via the phase space integral

$$\rho L_x L_y = 2 \times \int \frac{dp_x dp_y L_x L_y}{(2\pi\hbar)^2}, \quad (16.288)$$

where L_x and L_y are the lengths of the rectangular layered material in the x - and y -directions. The factor 2 accounts for the two spin orientations. The rotationally invariant integration up to p_F yields

$$p_F = \sqrt{2\pi\rho\hbar}. \quad (16.289)$$

By switching on a magnetic field B_z , the rotational invariance is destroyed and the electrons circle with a velocity $v = \omega r$ on Landau orbits around the z -direction with the cyclotron frequency $\omega = eB/Mc$. In quantum mechanics, the system corresponds to an ensemble of harmonic oscillators which in the gauge $\mathbf{A} = (0, Bx, 0)$ [see Eq. (9.93)] move back and forth in the x -direction and have a spectrum $(n + 1/2)\hbar\omega$ [see Eq. (9.100)]. The phase space integral in the x -direction $\int dp_x L_x / (2\pi\hbar)$ becomes therefore a sum over n . The center of oscillations is $x_0 = p_y/M\omega$ [see

Eq. (9.95)], so that the remaining phase space integral $\int dp_y L_y / (2\pi\hbar)$ can be integrated to $M\omega L_x / (2\pi\hbar)$. Thus (16.288) gives, for each spin orientation,

$$\rho = M\omega \frac{1}{2\pi\hbar} \sum_{n=0}^{n_F}. \quad (16.290)$$

The number of filled levels is $\nu = n_F + 1$. In the vacuum, the levels of one orientation are degenerate with those of the opposite orientation at a neighboring n (up to radiative corrections of the order $\alpha \approx 1/137$). This is due to the anomalous magnetic moment of the spin-1/2 electron being equal to one Bohr magneton $\mu_B = e\hbar/2Mc \approx 0.927 \times 10^{-20}$ erg/gauss (i.e., twice as large as classically expected, the factor 2 being caused by the relativistic Thomas precession). Due to the factor 2, the energy levels for the two orientations are split by $\omega\hbar$, which is precisely equal to the energy difference between levels of neighboring n . In a solid material, however, the anomalous magnetic moment is strongly renormalized and the degeneracy is removed. There, every level has a definite spin orientation.

According to Eq. (16.290), the highest level is occupied completely if each level has taken up a particle number corresponding to its maximal filling density

$$\rho_{\max} = \frac{M\omega}{2\pi\hbar}. \quad (16.291)$$

At smaller magnetic fields, this density is small and the electrons are spread over many levels whose number ν is given by

$$\rho = \frac{M\omega}{2\pi\hbar} \nu. \quad (16.292)$$

Expressing ω in terms of B_z leads to

$$\frac{B_z}{\rho} = \frac{hc}{e} \frac{1}{\nu}. \quad (16.293)$$

Using the flux quantum $\Phi_0 = hc/e$, this equation states that the magnetic flux per electron

$$\Phi \equiv \frac{B_z}{\rho} \quad (16.294)$$

has the value

$$\frac{\Phi}{\Phi_0} = \frac{1}{\nu}. \quad (16.295)$$

If the magnetic field is increased, the Landau levels can accommodate more electrons which then reside in a decreasing number ν of levels. By inserting into Eq. (16.286) the values of B_z at which the highest level becomes depleted, one obtains precisely the experimentally observed quantized Hall resistances

$$R_{xy} = \frac{h}{e^2} \frac{1}{\nu} \quad (16.296)$$

Figure 16.24 Values of parameter ν , at which plateaus in fractional quantum Hall resistance $h/e^2\nu$ are expected theoretically. The right-hand side shows the values $\nu^{\text{eff}}/(2m\nu^{\text{eff}} + 1)$, the left-hand side $\nu^{\text{eff}}/(2m\nu^{\text{eff}} - 1)$. The full circles indicate the values found experimentally.

with integer values of ν . The assumption of a statisto-magnetic interaction makes it possible to explain the fractional quantum Hall effect by reducing it to the ordinary quantum Hall effect.

In the fractional quantum Hall effect, the magnetic field is so strong that even the lowest Landau level is only partially filled. This is why one did not expect any plateaus at all. According to a simple idea due to Jain, however, it is possible to relate the fractional plateaus to the integer plateaus. For this one assumes that the electrons in the ground state of the fractional quantum Hall effect carry an even statisto-magnetic flux $-2m\Phi_0$ due to the presence of a Chern-Simons action. For the wave function, this amounts to a statistical phase factor $e^{i2\pi m}$ under the exchange of two particle coordinates; it leaves the Fermi statistics of the electrons unchanged. Now one takes advantage of the observation made in the last section that the electrons cannot distinguish a statisto-magnetic field from an external magnetic field. They move in Landau orbits enforced by the combined field

$$B_z^{\text{eff}} = B_z - B_z^{\text{stat}}, \quad B_z^{\text{stat}} = 2m\Phi_0\rho. \tag{16.297}$$

The cyclotron frequency of the electrons in their Landau orbits is

$$\omega^{\text{eff}} = eB_z^{\text{eff}}/Mc. \tag{16.298}$$

Since the effective field is now much smaller than the external field, the Landau levels possess a greatly reduced capacity. Thus the electrons must be distributed

over several levels in spite of the large magnetic field. The number decreases as the field grows further. The steps appear at those places where the effective magnetic field has its integer quantum Hall plateaus, i.e., at the effective magnetic fields

$$B_z^{\text{eff}} = \pm \rho \Phi_0 / \nu^{\text{eff}}, \quad \nu^{\text{eff}} = 1, 2, 3, \dots \quad (16.299)$$

The values of ν_{eff} are related to the ν -values of the external magnetic field as follows:

$$\pm \frac{1}{\nu^{\text{eff}}} = \frac{1}{\nu} - 2m. \quad (16.300)$$

From this one has

$$\nu = \frac{\nu^{\text{eff}}}{2m\nu^{\text{eff}} \pm 1}. \quad (16.301)$$

The resulting values of ν on the integer-valued plane spanned by the numbers m and ν^{eff} are shown in Fig. 16.24. Only odd denominators are allowed. The values of ν found by this simple hypothesis agree well with those of the lower experimental levels (16.287).

16.12 Anyonic Superconductivity

At the end of Section 16.3 we have mentioned that an ensemble of particles with fractional statistics in 2+1 spacetime dimensions exhibits Meissner screening. This has given rise to speculations that the presently poorly understood phenomenon of *high-temperature superconductivity* may be explained by anyons physics. The new kind of superconductivity is observed in materials which contain pronounced layer structures, and it is conceivable that the currents move in these two-dimensional subspaces without dissipation. With some effort it can indeed be shown that in 2+1 dimensions a Chern-Simons action may be generated in principle¹⁰ by integrating out Fermi fields. Accepting this, we can easily derive that an addition of this action to the usual electromagnetic field action gives the magnetic field a finite range, i.e., a finite penetration depth. The usual electromagnetic action reads

$$\mathcal{A} = \frac{1}{8\pi} \int dt d^3x [\mathbf{E}^2 - (\nabla \times \mathbf{A})^2], \quad (16.302)$$

where \mathbf{E} is the electric field

$$\mathbf{E} = -\frac{1}{c} \frac{\partial \mathbf{A}}{\partial t} - \nabla A_0. \quad (16.303)$$

In the Euclidean formulation with $x_4 = ict$, the action becomes

$$\mathcal{A}_e = \frac{1}{8\pi c} \int d^4x [\mathbf{E}^2 + (\nabla \times \mathbf{A})^2]. \quad (16.304)$$

¹⁰See Notes and References at the end of the chapter.

To add the Chern-Simons action, we restrict the spacetime dimensionality to 3. The restriction is imposed by considering a system in 4 spacetime dimensions and assuming it to be translationally invariant along the fourth coordinate direction x_4 . Then there are no electric fields, and the Euclidean action becomes

$$\mathcal{A}_e = \frac{L}{8\pi c} \int d^3x (\nabla \times \mathbf{A})^2, \quad (16.305)$$

where L denotes the length of the system in the x_4 -direction. To this, we now add the Chern-Simons action (16.253) and the current coupling (16.256). By extremizing the total action, we obtain the field equation:

$$\frac{L}{4\pi c} \nabla \times (\nabla \times \mathbf{A}) + i \frac{e^2}{2\pi c^2 \hbar \mu_0} \nabla \times \mathbf{A} = i \frac{1}{c^2} \mathbf{j}. \quad (16.306)$$

For the magnetic field $\mathbf{B} = \nabla \times \mathbf{A}$, the equation reads

$$\frac{L}{4\pi c} (\nabla \times \mathbf{B} + i\lambda^{-1} \mathbf{B}) = i \frac{1}{c^2} \mathbf{j}, \quad (16.307)$$

where the parameter λ denotes the following length ($\alpha = e^2/\hbar c =$ fine-structure constant $\approx 1/137$):

$$\lambda \equiv \frac{c\hbar\mu_0}{2e^2} L = \frac{\mu_0}{2\alpha} L. \quad (16.308)$$

By multiplying (16.307) vectorially with ∇ and using the equation once more, we obtain

$$\frac{L}{4\pi c} (-\nabla^2 + \lambda^{-2}) \mathbf{B} = i \frac{1}{c^2} \nabla \times \mathbf{j} + \frac{1}{c^2} \lambda^{-1} \mathbf{j}. \quad (16.309)$$

In the current-free case, the magnetic field is seen to have only a finite penetration depth λ into the material. In an ordinary superconductor, this phenomenon is known as the *Meissner effect*. There it can be understood as a consequence of the induction of supercurrents in an ideal (i.e., incompressible and frictionless) liquid of charged particles, which lowers the invading magnetic field according to Lenz' rule. In the absence of friction, there is a complete extinction.

Recall that a superconductor with time-dependent currents and fields is governed by the characteristic London equation (see Appendix 16D)

$$\nabla \times \mathbf{j} \propto \mathbf{B}. \quad (16.310)$$

For a two-dimensional superconductor, this amounts to

$$(\nabla \times \mathbf{j}_\perp)_z \propto B_z. \quad (16.311)$$

The above anyonic system shows a similar induction phenomenon. In the absence of currents, Eq. (16.309) determines the magnetic field B_z from the particle density by

$$B_z = \mu_0 \Phi_0 \rho. \quad (16.312)$$

If there are currents in the xy -plane $\mathbf{j}_\perp = (j_x, j_y)$, the magnetic field is increased by ΔB_z in accordance with the equation

$$\frac{L}{4\pi c}(-\nabla^2 + \lambda^{-2})\Delta B_z = \frac{1}{c^2}(\nabla \times \mathbf{j}_\perp)_z. \quad (16.313)$$

This is the desired relation between the magnetic field and the curl of the current which indicates the superconducting character of the system expressed before in the London equation (16.311). The contact with the London equation is established by a restriction to smooth field configurations in which the first term in (16.313) can be ignored.

Thus we conclude that the currents and magnetic fields in a two-dimensional system of anyons show Meissner screening. This is not sufficient to make the system superconductive since it does not automatically imply the absence of dissipation. In a usual superconductor, the existence of an energy gap makes the dissipative part of the current-current correlation function vanish for wave vectors smaller than some value k_c . This value determines the *critical current strength* above which superconductivity returns to normal. In the anyonic system, the absence of dissipation was proved in an approximation. Recent studies of higher corrections, however, have shown the presence of dissipation after all, destroying the hope for an anyonic superconductor.

16.13 Non-Abelian Chern-Simons Theory

The topological field interaction (16.153) can be generalized to nonabelian gauge groups. For the local symmetry group $SU(N)$ it reads

$$\mathcal{A}_{e,CS} = \frac{k}{4\pi i} \int d^3x \epsilon_{ijk} \text{tr}_N \left(A_i \nabla_j A_k + \frac{2}{3} A_i A_j A_k \right), \quad (16.314)$$

where A_i are Hermitian traceless $N \times N$ -matrices and tr_N denotes the associated trace. In the nonabelian theory, the gauge transformations are

$$A_i \leftrightarrow U A_i U^{-1} + i(\partial_i U) U^{-1}. \quad (16.315)$$

It can be shown that they transform $\mathcal{A}_{e,CS}$ as follows [10]:

$$\mathcal{A}_{e,CS} \rightarrow \mathcal{A}_{e,CS} + 2\pi i n k \hbar, \quad n = \text{integer}. \quad (16.316)$$

Thus, the action is not completely gauge-invariant. For integer values of k , however, the additional $2\pi i n k \hbar$ does not have any effect upon the phase factor $e^{-\mathcal{A}_{e,CS}/\hbar}$ in the path integral associated with the orbital fluctuations. Thus there is gauge invariance for integer values of k (in contrast to the abelian case where k is arbitrary).

In the nonabelian theory, gauge fixing is a nontrivial issue. It is no longer possible to simply add a gauge fixing functional of the type (16.163). The reason is that the volume in the field space of gauge transformations depends on the gauge field. For

a consistent gauge fixing, this volume has to be divided out of the gauge-fixing functional as was first shown by Fadeev and Popov [11]. For an adequate discussion of this interesting topic which lies beyond the scope of this quantum-mechanical text the reader is referred to books on quantum field theory.

As in the abelian case, the functional derivative of the Chern-Simons action with respect to the vector potential gives the field strength

$$B_i \equiv \epsilon_{ijk} F_{jk}, \quad (16.317)$$

where F_{ij} is the nonabelian version of the curl:

$$F_{ij} \equiv \partial_i A_j - \partial_j A_i - i[A_i, A_j]. \quad (16.318)$$

In 1989, Witten found an important result: The expectation value of a gauge-invariant integral defined for any loop L ,

$$W_L[\mathbf{A}] \equiv \text{tr}_N \hat{W}[\mathbf{A}] \equiv \text{tr}_N \hat{P} e^{i \oint_L d\mathbf{x} \mathbf{A}}, \quad (16.319)$$

the so-called *Wilson loop integral*, possesses a close relationship with the Jones polynomials of knot theory. The loop L can consist of several components linked in an arbitrary way, in which case the integral in $W_L[\mathbf{A}]$ runs successively over all components. The operator \hat{P} in front of the exponential function denotes the *path-ordering operator*. It is defined in analogy with the time-ordering operator \hat{T} in (1.241): If the exponential function in (16.319) is expanded into a Taylor series, it specifies the order in which the $N \times N$ -matrices $A_i(\mathbf{x})$, which do not commute for different \mathbf{x} and i , appear in the products. If the path is labeled by a “time parameter”, the earlier matrices stand to the right of the later ones. The fluctuations of the vector potential are controlled by the Chern-Simons action (16.314). Expectation values of the loop integrals are defined by the functional integral

$$\langle W_L[\mathbf{A}] \rangle \equiv \frac{\int \mathcal{D}A_i e^{-\mathcal{A}_{e,\text{CS}}/\hbar} W_L[\mathbf{A}]}{\int \mathcal{D}A_i e^{-\mathcal{A}_{e,\text{CS}}/\hbar}}. \quad (16.320)$$

To calculate the self-interaction of a loop, we proceed as described in the abelian case after Eq. (16.169) by spreading the line out into an infinitely thin ribbon of parallel lines. The borders of the ribbon are positioned in such a way that their linking number L_k vanishes. If 0 denotes a circle, i.e., a trivial knot, one can show that

$$\langle W_0[\mathbf{A}] \rangle = \frac{q^{N/2} - q^{-N/2}}{q^{1/2} - q^{-1/2}}, \quad (16.321)$$

with

$$q \equiv e^{-2\pi i/(N+k)}. \quad (16.322)$$

For an arbitrary link L one finds the skein relation (see Appendix 16C)

$$q^{N/2} \langle W_{L_+}[\mathbf{A}] \rangle - q^{-N/2} \langle W_{L_-}[\mathbf{A}] \rangle = (q^{1/2} - q^{-1/2}) \langle W_{L_0}[\mathbf{A}] \rangle. \quad (16.323)$$

If $N = 2$, this agrees up to the sign of the right-hand side with the relation (16.114) for the Jones polynomials $J_L(t)$. For general values of $N \neq 2$, we obviously obtain with $t = q^{-N/2}$ and $\alpha = q^{1/2} - q^{-1/2} = -(t^{1/N} - t^{-1/N})$ the skein relations (16.122) of the HOMFLY polynomials. The important relation is

$$\frac{\langle W_L[\mathbf{A}] \rangle}{\langle W_0[\mathbf{A}] \rangle} = H_L(t, -(t^{1/N} - t^{-1/N})), \quad t = e^{\pi i/k}. \quad (16.324)$$

Since the second variable in $H_L(t, \alpha)$ appears only in even or odd powers, $H_L(t, -(t^{1/2} - t^{-1/2}))$ is a Jones polynomial up to a sign $(-1)^{s+1}$, where s is the number of loops in L .

A favored choice of framing is one in which the self-linking number L_k of each component is equal to the twist number or writhe w introduced in Eq. (16.110). Then the ribbon lies flat on the projection plane of the knot. This framing can easily be drawn on the blackboard by splitting the line L into two parallel running lines; it is therefore called the *blackboard framing*. Incidentally, each choice of framing can be drawn as a blackboard framing if one adds to the loop L an appropriate number of windings via a Reidemeister move of type I. These are trivial for lines and nontrivial only for ribbons (see Fig. 16.6). In the blackboard framing, each such winding changes the values L_k and w simultaneously by one unit. Thus $L_k = w$ can be brought to any desired value. Take, for example, the trefoil knot in Fig. 16.2. In the blackboard framing it has the self-linking number $L_k = w = -3$. This can be brought to zero by adding three windings via a Reidemeister move of type I.¹¹

In the framing $L_k = w$, the right-hand side of (16.324) carries an extra phase factor c^w , where

$$c = e^{-i2\pi(N^2-1)/2Nk}. \quad (16.325)$$

For comparison: In the abelian Chern-Simons theory, the phase factor is $c = e^{-2\pi i/k}$, and the expectation $\langle W_L[\mathbf{A}] \rangle$ has the value $c^{\sum_{i \neq j} L_{kij}}$ for a link of several loops labeled by i with vanishing individual self-linking numbers L_{ki} . In the framing $L_{ki} = w_i$, the value is $c^{\sum_{i \neq j} L_{kij} + \sum_i w_i}$.

The investigation of the properties of loops with nonabelian topological interactions is an interesting task of present-day research.

Appendix 16A Calculation of Feynman Diagrams in Polymer Entanglement

For the calculation of the amplitudes N_1, \dots, N_4 in Eqs. (16.226), (16.230), (16.235), and (16.236), we need the following simple tensor formulas involving two completely antisymmetric tensors ε^{ijl} :

$$\varepsilon_{ijk}\varepsilon^{imn} = \delta_j^m\delta_k^n - \delta_j^n\delta_k^m, \quad \varepsilon_{ijk}\varepsilon^{ijl} = 2\delta_k^l. \quad (16A.1)$$

The Feynman diagrams shown in Fig. 16.23 corresponds to integrals over products of the polymer correlation functions G_0 defined in Eq. (16.213), which have to be integrated over space and

¹¹Mathematicians usually prefer another framing in which the ribbons lie flat on the so-called *Seifert surfaces*.

Laplace transformed. For the latter we make use of the convolution property of the integral over two Laplace transforms $\tilde{f}(z)$ and $\tilde{g}(z)$ of the functions f, g :

$$\int_{c-i\infty}^{c+i\infty} \frac{Mdz}{2\pi i} e^{zL} \tilde{f}(z) \tilde{g}(z) = \int_0^L ds f(s) g(L-S). \quad (16A.2)$$

All spatial integrals are Gaussian of the form

$$\int d^3x e^{-a\mathbf{x}^2 + 2b\mathbf{x}\cdot\mathbf{y}} = (2\pi)^{3/2} a^{-3/2} e^{b^2\mathbf{y}^2/a}, \quad a > 0. \quad (16A.3)$$

Contracting the fields in Eq. (16.226), and keeping only the contributions which do not vanish in the limit of zero replica indices, we find with the help of Eqs. (16A.1) and (16A.2):

$$\begin{aligned} N_1 &= \int d^3x_1, d^3x_2 \int_0^{L_1} ds \int_0^{L_2} dt \int d^3x'_1 d^3x'_2 G_0(\mathbf{x}_1 - \mathbf{x}'_1; s) G_0(\mathbf{x}'_1 - \mathbf{x}_1; L_1 - s) \\ &\times G_0(\mathbf{x}_2 - \mathbf{x}'_2; t) G_0(\mathbf{x}'_2 - \mathbf{x}_2; L_2 - t) \frac{l}{|\mathbf{x}'_1 - \mathbf{x}'_2|^4}. \end{aligned} \quad (16A.4)$$

Performing the changes of variables

$$s' = \frac{s}{L_1}, \quad t' = \frac{t}{L_2}, \quad \mathbf{x} = \frac{\mathbf{x}_1 - \mathbf{x}'_1}{\sqrt{L_1}}, \quad \mathbf{y} = \frac{\mathbf{x}_2 - \mathbf{x}'_2}{\sqrt{L_2}}, \quad (16A.5)$$

and setting $\mathbf{x}''_1 \equiv \mathbf{x}'_1 - \mathbf{x}'_2$, we easily derive (16.227).

For small $\xi/\sqrt{L_1}$ and $\xi/\sqrt{L_2}$, we use the approximation (16.228). The space integrals can be done using the formula (16A.3). After some work we obtain the result (16.240).

For the amplitude N_2 in Eq. (16.230) we obtain likewise the integral

$$\begin{aligned} N_2 &= \int d^3x_1 d^3x_2 \int d^3x'_1 d^3x''_1 d^3x'_2 \\ &\times \left[\int_0^{L_1} ds \int_0^S ds' G_0(\mathbf{x}'_1 - \mathbf{x}_1; L_1 - s) \nabla_{x''_1}^j G_0(\mathbf{x}_1 - \mathbf{x}''_1; s') \nabla_{x'_1}^i G_0(\mathbf{x}''_1 - \mathbf{x}'_1; s - s') \right] \\ &\times D_{ik}(\mathbf{x}'_1 - \mathbf{x}_2) D_{jk}(\mathbf{x}''_1 - \mathbf{x}'_2) \left[\int_0^{L_2} dt G_0(\mathbf{x}_2 - \mathbf{x}'_2; L_2 - t) G_0(\mathbf{x}'_2 - \mathbf{x}_2; t) \right], \end{aligned} \quad (16A.6)$$

where $D_{ij}(\mathbf{x}, \mathbf{x}')$ are the correlation functions (16.174) and (16.175) of the vector potentials. Setting $\mathbf{x}_2 \equiv \sqrt{L_2}\mathbf{u} + \mathbf{x}'_2$ and supposing that $\xi/\sqrt{L_2}$ is small, the integral over \mathbf{u} can be easily evaluated with the help of the Gaussian integral (16A.3). After the substitutions $\mathbf{x}''_1 = \sqrt{L_1}\mathbf{y} + \mathbf{x}_1$, $\mathbf{x}'_1 = \sqrt{L_1}(\mathbf{y} - \mathbf{x}) + \mathbf{x}_1$, $\mathbf{x}'_2 = \sqrt{L_1}(\mathbf{y} - \mathbf{x} - \mathbf{z}) + \mathbf{x}_1$ and a rescaling of the variables s, s' by a factor L_1^{-1} , we derive Eq. (16.231) with (16.232).

For small $\xi/\sqrt{L_1}, \xi/\sqrt{L_2}$, the spatial integrals are easily evaluated leading to:

$$N_2 = \frac{-\sqrt{2}V L_2^{-1/2} L_1^{-1} M^{-1/2}}{(4n)^6} \int_0^1 dt \int_0^t dt' t' (1-t) \sqrt{\frac{t-t'}{1-t+t'}}. \quad (16A.7)$$

After the change of variable $t' \rightarrow t'' = t - t'$, the double integral is reduced to a sum of integrals the type

$$c(n, m) = \int_0^1 dt t^m \int_0^t dt' t'^n \sqrt{\frac{t'}{1-t'}}, \quad m, n = \text{integers}.$$

These can be simplified by replacing t^m by $dt^{m+1}/dt(m+1)$, and doing the integrals by parts. In this way, we end up with a linear combination of integrals of the form:

$$\int_0^1 dt \frac{t^{\kappa+\frac{1}{2}}}{\sqrt{1-t}} = B\left(\kappa + \frac{3}{2}, \frac{1}{2}\right). \quad (16A.8)$$

The calculations of N_3 and N_4 are very similar, and are therefore omitted.

Appendix 16B Kauffman and BLM/Ho Polynomials

The Kauffman polynomials are given by $F(a, x) = a^{-w}\Lambda(a, x)$, where w is the writhe and $\Lambda(a, x)$ satisfies the skein relation

$$\Lambda_{L_+}(a, x) + \Lambda_{L_-}(a, x) = x[\Lambda_{L_0}(a, x) + \Lambda_{L_\infty}(a, x)]. \tag{16B.1}$$

The subscripts refer to the same loop configurations as in Figs. 16.10 and 16.12. The trivial loop has

$$\Lambda(a, x) = \frac{a + a^{-1}}{z} - 1. \tag{16B.2}$$

While the Kauffman polynomial is a knot invariant, the Λ -polynomial is only a ribbon invariant.¹² If a winding L_{T_+} or L_{T_-} is removed from a loop with the help of a Reidemeister move of type I in Fig. 16.6 (which for infinitely thin lines would be trivial while changing the writhe of a ribbon by one unit) then $\Lambda(a, x)$ receives a factor a or a^{-1} , respectively (see Fig. 16.25).

Figure 16.25 Trivial windings L_{T_+} and L_{T_-} . Their removal by means of Reidemeister move of type I decreases or increases writhe w by one unit.

The Kauffman polynomials arise from Wilson loop integrals of a nonabelian Chern-Simons theory, if the action (16.314) is $SO(N)$ - rather than $SU(N)$ -symmetric. A list of these polynomials can be found in papers by Lickorish and Millet and by Doll and Hoste quoted at the end of the chapter.

The BLM/Ho polynomials are special cases of the Kauffman polynomials. The relation between them is $Q(x) \equiv F(1, x)$.

Appendix 16C Skein Relation between Wilson Loop Integrals

Here we sketch the derivation of the skein relation (16.323) for the expectation values of Wilson’s loop integrals (16.319). Let us decompose A_i in terms of the $N^2 - 1$ generators T_a of the group $SO(N)$:

$$A_i = \sum_a A_i^a T_a. \tag{16C.1}$$

They satisfy the commutation rules

$$[T_a, T_b] = if_{abc}T_c. \tag{16C.2}$$

¹²More precisely, $F(a, x)$ is invariant under the three Reidemeister moves which, in the projected picture of the knot in Fig. 16.6, define the ambient isotopy, whereas Λ changes under the first Reidemeister move, associated only with regular isotopy. whereas

For simplicity, we assume k to be very large so that we can restrict the treatment to the lowest order in $1/k$. To avoid inessential factors of the constants e, c, \hbar , we set these equal to 1. Under a small variation of the fields one has

$$\frac{\delta \hat{W}_L[\mathbf{A}]}{\delta A_i^a(\mathbf{x})} = i \hat{P} \int_L dx'_i \delta^{(3)}(\mathbf{x} - \mathbf{x}') T_a(\mathbf{x}') \hat{W}_L[\mathbf{A}], \quad (16C.3)$$

where the path-ordering operator \hat{P} arranges the expression to its right in such a way that T_a is situated in \hat{W}_L at the correct path-ordered place. To emphasize this, we have recorded the position of T_a by means of an \mathbf{x} -argument. More precisely, if we discretize the loop integral and write

$$\hat{W}_L[\mathbf{A}] = e^{iA_i(\bar{\mathbf{x}}^1)\Delta x_i^1} e^{iA_i(\bar{\mathbf{x}}^2)\Delta x_i^2} \dots e^{iA_i(\bar{\mathbf{x}}^n)\Delta x_i^n} \dots, \quad (16C.4)$$

where $\bar{\mathbf{x}}^n$ are the midpoints of the intervals Δx_i^n , a differentiation with respect to one of the $A_i(\bar{\mathbf{x}}^n)$ -fields replaces the associated factor $e^{iA_i(\bar{\mathbf{x}}^n)\Delta x_i^n}$ by $i T_a e^{iA_i(\bar{\mathbf{x}}^n)\Delta x_i^n}$. With the δ -function on a line L defined in Eq. (10A.8), we write (16C.3) as

$$\frac{\delta \hat{W}_L[\mathbf{A}]}{\delta A_i^a(\mathbf{x})} = i \hat{P} \delta_i(\mathbf{x}, L) T_a(\mathbf{x}) \hat{W}_L[\mathbf{A}]. \quad (16C.5)$$

For simplicity, we assume \mathbf{x} to be only once traversed by the loop L .

If the shape of the loop is deformed infinitesimally by $dS_i = \epsilon_{ijk} dx_i d'x_j$, then \hat{W}_L changes by

$$\delta \hat{W}_L = i dx_i d'x_j \hat{P} F_{ij}^a(\mathbf{x}) T_a(\mathbf{x}) \hat{W}_L, \quad (16C.6)$$

where F_{ij}^a are the $N^2 - 1$ components of the nonabelian field strengths

$$F_{ij} = \partial_i A_j - \partial_j A_i - i[A_i, A_j] \quad (16C.7)$$

and \mathbf{x} the midpoints of the parallelograms spanned by $d\mathbf{x}$ and $d'\mathbf{x}$. The derivation of Eq. (16C.6) is based on the observation that a change of the path by a small parallelogram adds to the line integral \hat{W}_L a factor \hat{W}_{\square} , which is a Wilson loop integral around the small parallelogram. The latter is evaluated as follows:

$$\begin{aligned} \hat{W}_{\square} &= e^{iA_i(\mathbf{x}-d'\mathbf{x}/2)dx_i} e^{iA_j(\mathbf{x}+d\mathbf{x}/2)d'x_j} e^{-iA_i(\mathbf{x}+d'\mathbf{x}/2)dx_i} e^{-iA_j(\mathbf{x}-d\mathbf{x}/2)d'x_j} \\ &= e^{i[A_i(\mathbf{x})dx_i - \partial_j A_i(\mathbf{x})dx_i d'x_j + \dots]} e^{i[A_j(\mathbf{x})d'x_j + \partial_i A_j(\mathbf{x})dx_i d'x_j + \dots]} \\ &\times e^{-i[A_i(\mathbf{x})dx_i + \partial_j A_i(\mathbf{x})dx_i d'x_j + \dots]} e^{-i[A_j(\mathbf{x})d'x_j - \partial_i A_j(\mathbf{x})dx_i d'x_j + \dots]} \\ &= e^{iF_{ij}(\mathbf{x})dx_i d'x_j}. \end{aligned} \quad (16C.8)$$

The last line is found with the help of the Baker-Hausdorff formula $e^A e^B = e^{A+B+[A,B]/2+\dots}$ (recall Appendix 2A).

Let us denote the Chern-Simons functional integral over $\hat{W}_L[\mathbf{A}]$ by \overline{W}_L . Their $N \times N$ -traces are $W_L[A]$ and \overline{W}_L . The latter differs from the expectation $\langle W_L[\mathbf{A}] \rangle$ in (16.320) by not containing the normalizing denominator, i.e.,

$$\overline{W}_L \equiv \int \mathcal{D}\mathbf{A} e^{-\mathcal{A}_{e,\text{CS}}} W_L[\mathbf{A}]. \quad (16C.9)$$

This changes under the loop deformation by

$$\begin{aligned} \delta \overline{W}_L &= \int \mathcal{D}\mathbf{A} \delta W_L[\mathbf{A}] e^{-\mathcal{A}_{e,\text{CS}}} \\ &= i dx_i d'x_j \int \mathcal{D}\mathbf{A} F_{ij}^a(\mathbf{x}) T_a(\mathbf{x}) W_L[\mathbf{A}] e^{-\mathcal{A}_{e,\text{CS}}}, \end{aligned} \quad (16C.10)$$

with the tacit agreement that a generator $T_a(\mathbf{x})$ written in front of the trace has to be evaluated within the trace at the correct path-ordered position. Now we observe that F_{ij}^a can also be obtained by applying a functional derivative to the Chern-Simons action (16.314):

$$i \frac{4\pi}{k} \epsilon_{ijk} \frac{\delta \mathcal{A}_{e,CS}}{\delta A_k^a(\mathbf{x})} = F_{ij}^a(\mathbf{x}). \tag{16C.11}$$

This allows us to rewrite (16C.10) as

$$-\frac{4\pi}{k} \int \mathcal{D}\mathbf{A} \int dS_i \frac{\delta \mathcal{A}_{e,CS}}{\delta A_i^a(\mathbf{x})} T_a(\mathbf{x}) W_L[\mathbf{A}] e^{-\mathcal{A}_{e,CS}}$$

and further as

$$\frac{4\pi}{k} \int \mathcal{D}\mathbf{A} dS_i T_a(\mathbf{x}) W_L \frac{\delta}{\delta A_i^a(\mathbf{x})} e^{-\mathcal{A}_{e,CS}}.$$

A partial functional integration produces

$$-\frac{4\pi}{k} \int \mathcal{D}\mathbf{A} \int dS_i T_a(\mathbf{x}) \frac{\delta W_L[\mathbf{A}]}{\delta A_i^a(\mathbf{x})} e^{-\mathcal{A}_{e,CS}},$$

which brings the variation to the form

$$\delta \overline{W}_L = -\frac{4\pi i}{k} \int \mathcal{D}\mathbf{A} dS_i \delta_i(\mathbf{x}, L) T_a(\mathbf{x}) T_a(\mathbf{x}) W_L[\mathbf{A}] e^{-\mathcal{A}_{e,CS}}. \tag{16C.12}$$

The expectation of Wilson’s loop integral \overline{W}_L changes under a deformation only if the loop crosses another line element. This property makes \overline{W}_L a ribbon invariant, i.e., an invariant of regular isotopy.

For a finite deformation, the right-hand side has to be integrated over the area S across which the line has swept. Using the integral formula

$$\int_S dS_i \delta_i(\mathbf{x}, L) = \left\{ \begin{array}{c} 1 \\ 0 \end{array} \right\} \text{ if the line } L \left\{ \begin{array}{l} \text{pierces } S \\ \text{misses } S \end{array} \right\}, \tag{16C.13}$$

we obtain for each crossing

$$\overline{W}_{L_+} - \overline{W}_{L_-} \equiv \Delta \overline{W}_L = -\frac{4\pi i}{k} \int \mathcal{D}\mathbf{A} T_a(\mathbf{x}) T_a(\mathbf{x}) W_L[\mathbf{A}] e^{-\mathcal{A}_{e,CS}}. \tag{16C.14}$$

The two generators $T_a(\mathbf{x})$ lie path-ordered on the different line pieces of the crossing. To establish contact with the knot polynomials, the left-hand sides have been labeled by the loop subscripts L_+ and L_- appearing in the skein relations of Eq. 16.114.

The product of the generators on the right-hand side is the Casimir operator of the $N \times N$ -representation of $SO(N)$:

$$(T_a)_{\alpha\beta} (T_a)_{\gamma\delta} = \frac{1}{2} \delta_{\alpha\delta} \delta_{\beta\gamma} - \frac{1}{2N} \delta_{\alpha\beta} \delta_{\gamma\delta}. \tag{16C.15}$$

When inserted into Eq. (16C.14), we obtain the graphical relation:

The second graph on the right-hand side can be decomposed into

Taking these two terms to the left-hand side of (16C.14), we obtain the skein relation

$$\left(1 - \frac{\pi i}{Nk}\right) \overline{W}_{L_+} - \left(1 + \frac{\pi i}{Nk}\right) \overline{W}_{L_-} = -\frac{2\pi i}{k} \overline{W}_{L_0}. \tag{16C.16}$$

We now apply this relation to the windings displayed in Fig. 16.25. They decompose into a line and a circle. Due to the trace operation in \overline{W}_{L_0} , the circle contributes a factor N . Thus we obtain the relation

$$\left(1 - \frac{\pi i}{Nk}\right) \overline{W}_{L_{T^+}} - \left(1 + \frac{\pi i}{Nk}\right) \overline{W}_{L_{T^-}} = -\frac{2\pi i}{k} N \overline{W}_{L_{T^0}}. \tag{16C.17}$$

Now we remove on the left-hand side the windings according to the graphical rules of Fig. 16.25. Under this operation, the Wilson loop integral is not invariant. Like BLM/Ho polynomials, it acquires a factor a or a^{-1} :

$$\overline{W}_{L_{T^+}} = a \overline{W}_{L_{T^0}}, \quad \overline{W}_{L_{T^-}} = a^{-1} \overline{W}_{L_{T^0}}. \tag{16C.18}$$

To be compatible with (16C.17), the parameter a must satisfy

$$a = 1 - \frac{\pi i}{Nk}(N^2 - 1), \quad a^{-1} = 1 + \frac{\pi i}{Nk}(N^2 - 1). \tag{16C.19}$$

Due to (16C.18), the Wilson loop integral is only a ribbon invariant exhibiting regular isotopy. A proper knot invariant which distinguishes ambient isotopy classes arises when multiplying \overline{W}_L by a^{-w} . The polynomials $H_L \equiv e^{-w} \overline{W}_L$ satisfy the skein relation

$$\left[\left(1 - \frac{\pi i}{Nk}\right) a\right] H_{L_+} - \left[\left(1 + \frac{\pi i}{Nk}\right) a^{-1}\right] H_{L_-} = -\frac{2\pi i}{k} H_{L_0}. \tag{16C.20}$$

The prefactors on the left-hand side can be written for large k as $1 - 2\pi i N/k \approx q^{N/2}$ and $1 + 2\pi i N/k \approx q^{-N/2}$ with $q = 1 - 2\pi i \pi/k$. The prefactor on the right-hand side is equal to $q^{1/2} - q^{-1/2}$. To leading order in $1/k$, we have thus derived the skein relation (16.323) for the HOMFLY polynomials H_L .

Appendix 16D London Equations

Consider an ideal fluid of charged particles. By definition, it is non-viscous and incompressible, satisfying $\nabla \cdot \mathbf{v} = 0$. If the charge of the particles is e (which we take to be negative for electrons), the electric current density is

$$\mathbf{j} = \rho e \mathbf{v}, \tag{16D.1}$$

where ρ is the particle density. The current is obviously conserved.

The equation of motion of the particles in an electric and magnetic field is governed by the Lorentz force and reads

$$M \dot{\mathbf{v}} = e \left(\mathbf{E} + \frac{1}{c} \mathbf{v} \times \mathbf{B} \right). \tag{16D.2}$$

Using the kinematic identity

$$\frac{d\mathbf{v}}{dt} = \frac{\partial\mathbf{v}}{\partial t} + (\mathbf{v} \cdot \nabla)\mathbf{v} = \frac{\partial\mathbf{v}}{\partial t} + \nabla \left(\frac{1}{2} \mathbf{v}^2 \right) - \mathbf{v} \times (\nabla \times \mathbf{v}), \quad (16D.3)$$

this leads to the partial differential equation for the velocity field $\mathbf{v}(\mathbf{x}, t)$

$$M \frac{\partial\mathbf{v}}{\partial t} + \nabla \left(\frac{M}{2} \mathbf{v}^2 \right) = e\mathbf{E} + M\mathbf{v} \cdot \left(\nabla \times \mathbf{v} + \frac{e}{Mc} \mathbf{B} \right). \quad (16D.4)$$

Consider the time dependence of the vector field on the right-hand side

$$\mathbf{X} = \nabla \times \mathbf{v} + \frac{e}{Mc} \mathbf{B}. \quad (16D.5)$$

Using Maxwell's equation

$$\frac{\partial}{\partial t} \mathbf{B} = -c \nabla \times \mathbf{E}, \quad (16D.6)$$

we derive

$$\frac{\partial}{\partial t} \mathbf{X} = \nabla \times (\nabla \times \mathbf{X}). \quad (16D.7)$$

Suppose now that there is initially no \mathbf{B} -field in the ideal fluid at rest which therefore has $\mathbf{X} \equiv 0$ everywhere. If a magnetic field is turned on, Eq. (16D.7) guarantees that \mathbf{X} remains zero at all times. This implies that

$$\nabla \times \mathbf{j} = -\frac{\rho e^2}{Mc} \mathbf{B}, \quad (16D.8)$$

which is the first London equation. By inserting the first London equation into Eq. (16D.4), we find the second London equation

$$\frac{\partial}{\partial t} \mathbf{v} + \nabla \left(\frac{M}{2} \mathbf{v}^2 \right) = e\mathbf{E}. \quad (16D.9)$$

If the vector potential is taken in the transverse gauge $\nabla \cdot \mathbf{A} = 0$ (which in this context is also called *London gauge*), then the first London equation can be solved and yields

$$\mathbf{j} = -\frac{\rho e^2}{Mc} \mathbf{A}. \quad (16D.10)$$

By inserting this equation into the Maxwell equation with no electric field \mathbf{E} , we obtain

$$\nabla \times \mathbf{B} = \frac{4\pi}{c} \mathbf{j} = -\frac{\rho 4\pi e^2}{Mc^2} \mathbf{A}. \quad (16D.11)$$

When rewritten in the form

$$\nabla \times (\nabla \times \mathbf{A}) + \lambda^{-2} \mathbf{A} = 0, \quad (16D.12)$$

with

$$\lambda^{-2} = \frac{\rho 4\pi e^2}{Mc^2}, \quad (16D.13)$$

the equation exhibits directly the finite penetration depth λ of a magnetic field into the fluid, the celebrated Meissner effect. It is the ideal manifestation of the Lenz rule, according to which an incoming magnetic field induces currents reducing the magnetic field — in the present case to extinction.

Appendix 16E Hall Effect in Electron Gas

A gas of electrons with a density ρ carries an electric current

$$\mathbf{j} = \rho e \mathbf{v}. \quad (16E.1)$$

In a magnetic field, the particle velocities change due to the Lorentz force by

$$M \dot{\mathbf{v}} = e \left(\mathbf{E} + \frac{1}{c} \mathbf{v} \times \mathbf{B} \right). \quad (16E.2)$$

If σ_0 denotes the conductivity of the system without a magnetic field, the electric current is obviously given by

$$\begin{aligned} \mathbf{j} &= \sigma_0 \left(\mathbf{E} + \frac{1}{c} \mathbf{v} \times \mathbf{B} \right) \\ &= \sigma_0 \left(\mathbf{E} + \frac{1}{\rho e c} \mathbf{j} \times \mathbf{B} \right). \end{aligned} \quad (16E.3)$$

The second term shows the classical Hall resistance (16.286).

Path integrals in multiply connected spaces and their history are discussed in the textbook

L.S. Schulman, *Techniques and Applications of Path Integration*, Wiley, New York, 1981.

Details on Lippmann-Schwinger equation is found in most standard textbooks, say

S.S. Schweber, *Relativistic Quantum Field Theory*, Harper and Row, New York, 1961, Section 11b.

In chemistry, the properties of self-entangled polymer rings, called *catenanes*, were first investigated by

H.L. Frisch and E. Wasserman, J. Am. Chem. Soc. **83**, 3789 (1961).

Their existence was proved mass-spectroscopically by

R. Wolovsky, J. Am. Chem. Soc. **92**, 2132 (1961);

D.A. Ben-Efraim, C. Batich, and E. Wasserman, J. Am. Chem. Soc. **92**, 2133 (1970).

In optics, the Kirchoff diffraction formula can be rewritten as a path integral formula with linking terms:

J.H. Hannay, Proc. Roy. Soc. Lond. A **450**, 51 (1995),

In biophysics,

J.C. Wang, Accounts Chem. Res. D **10**, 2455 (1974)

showed that DNA molecules can get entangled and must be disentangled during replication.

The path integral approach to the entanglement problem in polymer systems was pioneered by

S.F. Edwards, Proc. Phys. Soc. **91**, 513 (1967);

S.F. Edwards, J. Phys. A **1**, 15 (1968).

The author is grateful for a copy of them.

A collection of many relevant articles is found in

T. Kuhno (ed.), *New Developments in the Theory of Knots*, World Scientific, Singapore, 1990.

A short introduction to the classification problem of knots is given in the popular articles

W.F.R. Jones, *Scientific American*, November 1990, p. 52,

I. Stewart, *Spektrum der Wissenschaft*, August 1990, p. 12.

The Chern-Simons actions have in recent years received increasing attention due to their relevance for explaining the fractional quantum Hall effect and a possible presence in high-temperature superconductivity. Actions of this type were first observed in four-dimensional quantum field theories in the form of so-called anomalies by

J. Wess and B. Zumino, *Phys. Lett. B* **36**, 95 (1971).

The action (16.253) in three spacetime dimensions was first analyzed by

S. Deser, R. Jackiw, and S. Templeton, *Ann. Phys.* **140**, 372 (1982),

who pointed out the connection with the Chern classes of differential geometry described by

S. Chern, *Complex Manifolds without Potential Theory*, Springer, Berlin, 1979.

In particular they found the mass of the electromagnetic field which was conjectured to be the origin of the Meissner effect in high-temperature superconductors. See

A.L. Fetter, C. Hanna, and R.B. Laughlin, *Phys. Rev. B* **39**, 9679 (1989);

Y.-H. Chen, F. Wilczek, E. Witten, and B.I. Halperin, *Int. J. Mod. Phys. B* **3**, 1001 (1989);

A. Schakel, *Phys. Rev. D* **44**, 1198 (1992).

However, the recent finding of dissipation in anyonic systems by

D.V. Khveshchenko and I.I. Kogan, *Int. J. Mod. Phys. B* **5**, 2355 (1991) speaks against an anyon mechanism of this phenomenon.

A Chern-Simons type of action appeared when integrating out fermions in

H. Kleinert, *Fortschr. Phys.* **26**, 565 (1978) (<http://www.physik.fu-berlin.de/~kleinert/55>).

The relation with Chern classes was recognized by

M.V. Berry, *Proc. Roy. Soc. A* **392**, 45 (1984);

B. Simon, *Phys. Rev. Lett.* **51**, 2167 (1983).

The Chern-Simons action in the text was derived for a degenerate electron liquid in two dimensions by

T. Banks and J.D. Lykken, Nucl. Phys. B **336**, 500 (1990);
S. Randjbar-Daemi, A. Salam, and J. Strathdee, Nucl. Phys. B **340**, 403 (1990),
P.K. Panigrahi, R. Ray, and B. Sakita, Phys. Rev. B **42**, 4036 (1990).

There is related work by

M. Stone, Phys. Rev. D **33**, 1191 (1986);
I.J.R. Aitchison, Acta Physica Polonica B **18**, 207 (1987).

See also the reprints of many papers on this subject in

A. Shapere and F. Wilczek, *Geometric Phases in Physics*, World Scientific, Singapore, 1989.

F. Wilczek, *Fractional Statistics and Anyon Superconductivity*, World Scientific, Singapore, 1990,
which itself provides a clear introduction to the subject and contains many important reprints. A
good review is also contained in the lectures

J.J. Leinaas, *Topological Charges in Gauge Theories*, Nordita Preprint, 79/43, ISSN 0106-2646.

Textbooks on this subject are

A. Lerda, *Anyons-Quantum Mechanics of Particles with Fractional Statistics*, Lecture Notes in
Physics, m14, Springer, Berlin 1992;

A. Khare, *Fractional Statistics and Quantum Theory*, World Scientific, Singapore, 1997.

The Lerda book contains many useful examples and explains the origin of difficulties in treating
interacting anyons. The Khare book provides a well-motivated treatment and includes a brief
introduction to the Braid group. Both include discussions of the Quantum Hall Effect and Anyon
Superconductivity.

Tunneling

Tunneling processes govern the decay of metastable atomic and nuclear states, as well as the transition of overheated or undercooled thermodynamic phases to a stable equilibrium phase. Path integrals are an important tool for describing these processes theoretically. For high tunneling barriers, the decay proceeds slowly and its properties can usually be explained by a semiclassical expansion of a simple model path integral. By combining this expansion with the variational methods of Chapter 5, it is possible to extend the range of applications far into the regime of low barriers.

In this chapter we present a novel theory of tunneling through high and low barriers and discuss several typical examples in detail. A useful fundamental application arises in the context of perturbation theory since the large-order behavior of perturbation expansions is governed by semiclassical tunneling processes. Here the new theory is used to calculate perturbation coefficients to any order with a high degree of accuracy.

17.1 Double-Well Potential

A simple model system for tunneling processes is the symmetric double-well potential of Eq. (5.78). It may be rewritten in the form

$$V(x) = \frac{\omega^2}{8a^2}(x-a)^2(x+a)^2, \quad (17.1)$$

which exhibits the two degenerate symmetric minima at $x = \pm a$ (see Fig. 17.1). The coupling strength is

$$g = \omega^2/2a^2. \quad (17.2)$$

Near the minima, the potential looks approximately like a harmonic oscillator potential $V_{\pm}(x) = \omega^2(x \mp a)^2/2$:

$$V(x) = \frac{\omega^2}{2}(x \mp a)^2 \left(1 \pm \frac{x \mp a}{a} + \dots \right) \equiv V_{\pm}(x) + \Delta V_{\pm}(x) + \dots \quad (17.3)$$

Figure 17.1 Plot of symmetric double-well potential $V(x) = (x - a)^2(x + a)^2\omega^2/8a^2$ for $\omega = 1$ and $a = 1$.

The height of the potential barrier at the center is

$$V_{\max} = \frac{(\omega a)^2}{8}. \quad (17.4)$$

In the limit $a \rightarrow \infty$ at a fixed frequency ω , the barrier height becomes infinite and the system decomposes into a sum of two independent harmonic-oscillator potentials widely separated from each other. Correspondingly, the wave functions of the system should tend to two separate sets of oscillator wave functions

$$\psi_n(\Delta x_{\pm}) \rightarrow \left(\frac{\omega}{\pi\hbar}\right)^{1/4} \frac{1}{2^{n/2}\sqrt{n!}} e^{-\omega(\Delta x_{\pm})^2/2\hbar} H_n(\Delta x_{\pm}\sqrt{\omega/\hbar}), \quad (17.5)$$

where the quantities

$$\Delta x_{\pm} \equiv x \pm a \quad (17.6)$$

measure the distances of the point x from the respective minima.

A similar separation occurs in the time evolution amplitude which decomposes into the sum of the amplitudes of the individual oscillators

$$\begin{aligned} (x_b t_b | x_a t_a) &\xrightarrow{a \rightarrow \infty} (x_b t_b | x_a t_a)_- + (x_b t_b | x_a t_a)_+ \\ &\equiv \int \mathcal{D}x(t) \exp \left\{ \frac{i}{\hbar} \int_{t_a}^{t_b} dt \left[\dot{x}^2 - \omega^2(x + a)^2 \right] \right\} + (a \rightarrow -a). \end{aligned} \quad (17.7)$$

For convenience, we have assumed a unit particle mass $M = 1$ in the Lagrangian of the system:

$$L = \frac{\dot{x}^2}{2} - V(x). \quad (17.8)$$

If a is no longer infinite, a particle in either of the two oscillator wells has a nonvanishing amplitude for tunneling through the barrier to the other well, and the wave functions of the right- and left-hand oscillators are mixed with each other. Since the action is symmetric under the mirror reflection $x \rightarrow -x$, the solutions of the Schrödinger equation

$$\hat{H}\psi(x, t) = H(-i\partial_x, x)\psi(x, t) = i\hbar\partial_t\psi(x, t), \quad (17.9)$$

with the Hamiltonian

$$H(p, x) = \frac{p^2}{2} + V(x), \quad (17.10)$$

can be separated into symmetric and antisymmetric wave functions. As usual, the symmetric states have a lower energy than the antisymmetric ones since a smaller number of nodes implies less kinetic energy for the particles.

If the distance parameter a is very large, then, to leading order in $a \rightarrow \infty$, the lowest two wave functions coincide approximately with the symmetric and antisymmetric combinations of the harmonic-oscillator wave functions

$$\psi_{s,a} \approx \frac{1}{\sqrt{2}}[\psi_0(x-a) \pm \psi_0(x+a)]. \quad (17.11)$$

Due to tunneling, the lowest two energies show some deviation from the harmonic ground state value

$$E_{s,a}^{(0)} = \frac{1}{2}\hbar\omega + \Delta E_{s,a}^{(0)}. \quad (17.12)$$

At a large distance parameter a , this deviation is very small. In quantum mechanics, the level shifts $\Delta E_{s,a}$ can be calculated in lowest-order perturbation theory by inserting the approximate wave functions (17.11) into the formula

$$\Delta E_{s,a} = \int dx \psi_{s,a} \hat{H} \psi_{s,a}. \quad (17.13)$$

Since the wave functions $\psi_0(x \pm a)$ of the individual potential wells fall off exponentially like $e^{-x^2/2}$ at large x , the level shifts $\Delta E_{s,a}$ are exponentially small in the square distance a^2 .

In this chapter we derive the level shifts ΔE_s , ΔE_a and the related tunneling amplitudes from the path integral of the system. For large a , this will be relatively simple since we can have recourse to the semiclassical approximation developed in Chapter 4 which becomes exact in the limit $a \rightarrow \infty$. As long as we are interested only in the lowest two states, the problem can immediately be simplified. We take the spectral representation of the amplitude

$$\begin{aligned} (x_b t_b | x_a t_a) &= \int \mathcal{D}x(t) e^{(i/\hbar) \int_{t_a}^{t_b} dt [\dot{x}^2/2 - V(x)]} \\ &= \sum_n \psi_n(x_b) \psi_n(x_a) e^{-iE_n(t_b - t_a)/\hbar} \end{aligned} \quad (17.14)$$

to imaginary times $t_{a,b} \rightarrow \tau_{a,b} = \mp iL/2$, where it becomes

$$\begin{aligned} \langle x_b | L/2 | x_a - L/2 \rangle &= \int \mathcal{D}x(\tau) e^{-(1/\hbar) \int_{-L/2}^{L/2} d\tau [x'^2/2 + V(x)]} \\ &= \sum_n \psi_n(x_b) \psi_n(x_a) e^{-E_n L/\hbar}, \end{aligned} \quad (17.15)$$

with the notation $x'(\tau) \equiv dx(\tau)/d\tau$. In the limit of large L , the spectral sum (17.15) is obviously most sensitive to the lowest energies, the contributions of the higher energies E_n being suppressed exponentially. Thus, to calculate the small level shifts of the two lowest states, $\Delta E_{s,a}$, we have only to find the leading and subleading exponential behaviors. Since the wave functions are largest close to the bottoms of the double well at $x \sim \pm a$, we may consider the amplitudes with the initial and final positions x_a and x_b lying precisely at the bottoms, once on the same side of the potential barrier,

$$\langle a | L/2 | a - L/2 \rangle = \langle -a | L/2 | -a - L/2 \rangle, \quad (17.16)$$

and once on the opposite sides

$$\langle a | L/2 | -a - L/2 \rangle = \langle -a | L/2 | a - L/2 \rangle. \quad (17.17)$$

For these amplitudes we now calculate the semiclassical approximation in the limit $L \rightarrow \infty$. The results will lead to level shift formula in Section 17.7.

17.2 Classical Solutions — Kinks and Antikinks

According to Chapter 4, the leading exponential behavior of the semiclassical approximation is obtained from the classical solutions to the path integral. The fluctuation factor requires the calculation of the quadratic fluctuation correction. The result has the form

$$\sum_{\text{class. solutions}} \exp\{-\mathcal{A}_{\text{cl}}/\hbar\} \times F, \quad (17.18)$$

where \mathcal{A}_{cl} denotes the action of each classical solution and F the fluctuation factor.

The amplitude (17.16), which contains the bottom of the same well on either side, is dominated by a trivial classical solution which remains all the time at the same bottom:

$$x(\tau) \equiv \pm a. \quad (17.19)$$

Classical solutions exist also for the other amplitudes (17.17) which connect the different bottoms at $-a$ and a . These solutions cross the barrier and read, in the limit $L \rightarrow \infty$,

$$x(\tau) = x_{\text{cl}}^{\pm}(\tau) \equiv \pm a \tanh[\omega(\tau - \tau_0)/2], \quad (17.20)$$

Figure 17.2 Classical kink solution (solid curve) in double-well potential (short-dashed curve with units marked on the lower half of the vertical axis). The solution connects the two degenerate maxima in the reversed potential. The long-dashed curve shows a solution which starts out at a maximum and slides down into the adjacent abyss.

with an arbitrary parameter τ_0 specifying the point on the imaginary time axis where the crossing takes place. The crossing takes place within a time of the order of $2/\omega$. For large positive and negative τ , the solution approaches $\pm a$ exponentially (see Fig. 17.2). Alluding to their shape, the solutions $x_{\text{cl}}^{\pm}(\tau)$ are called *kink* and *antikink* solutions, respectively.¹

To derive these solutions, consider the equation of motion in real time,

$$\ddot{x}(t) = -V'(x(t)), \quad (17.21)$$

where $V'(x) \equiv dV(x)/dx$. In the Euclidean version with $\tau = -it$, this reads

$$x''(\tau) = V'(x(\tau)). \quad (17.22)$$

Since the differential equation is of second order, there is merely a sign change in front of the potential with respect to the real-time differential equation (17.21). The Euclidean equation of motion corresponds therefore to a usual equation of motion of a point particle in real time, whose potential is turned upside down with respect to Fig. 17.1. This is illustrated in Fig. 17.3. The reversed potential allows obviously for a classical solution which starts out at $x = -a$ for $\tau \rightarrow -\infty$ and arrives at $x = a$ for $\tau \rightarrow +\infty$. The particle needs an infinite time to leave the initial potential mountain and to climb up to the top of the final one. The movement through the central valley proceeds within the finite time $\approx 2/\omega$. If the particle does not start

¹In field-theoretic literature, such solutions are also referred to as instanton or anti-instanton solutions, since the valley is crossed within a short time interval. See the references quoted at the end of the chapter.

Figure 17.3 Reversed double-well potential governing motion of position x as function of imaginary time τ .

its movement exactly at the top but slightly displaced towards the valley, say at $x = -a + \epsilon$, it will reach $x = a - \epsilon$ after a finite time, then return to $x = -a + \epsilon$, and oscillate back and forth forever. In the limit $\epsilon \rightarrow 0$, the period of oscillation goes to infinity and only a single crossing of the valley remains.

To calculate this movement, the differential equation (17.22) is integrated once after multiplying it by $x' = dx/d\tau$ and rewriting it as

$$\frac{1}{2} \frac{d}{d\tau} x'^2 = \frac{d}{d\tau} V(x(\tau)). \quad (17.23)$$

The integration gives

$$\frac{x'^2}{2} + [-V(x(\tau))] = \text{const}. \quad (17.24)$$

If τ is reinterpreted as the physical time, this is the law of *energy conservation* for the motion in the reversed potential $-V(x)$. Thus we identify the integration constant in (17.24) as the total energy E in the reversed potential:

$$\text{const} \equiv E. \quad (17.25)$$

Integrating (17.24) further gives

$$\tau - \tau_0 = \pm \frac{1}{\sqrt{2}} \int_{x(\tau_0)}^{x(\tau)} \frac{dx}{\sqrt{E + V(x)}}. \quad (17.26)$$

A look at the potential in Fig. 17.3 shows that an orbit starting out with the particle at rest for $\tau \rightarrow -\infty$ must have $E = 0$. Inserting the explicit potential (17.1) into (17.26), we obtain for $|x| < a$

$$\begin{aligned} \tau - \tau_0 &= \pm \frac{2a}{\omega} \int_0^x \frac{dx'}{(a - x')(x' + a)} = \pm \frac{1}{\omega} \log \frac{a + x}{a - x} \\ &= \pm \frac{2}{\omega} \operatorname{arctanh} \frac{x}{a}. \end{aligned} \quad (17.27)$$

Thus we find the kink and antikink solutions crossing the barrier:

$$x_{\text{cl}}(\tau) = \pm a \tanh[(\tau - \tau_0)\omega/2]. \quad (17.28)$$

The Euclidean action of such a classical object can be calculated as follows [using (17.24) and (17.25)]:

$$\begin{aligned} \mathcal{A}_{\text{cl}} &= \int_{-\infty}^{\infty} d\tau \left[\frac{x'_{\text{cl}}{}^2}{2} + V(x_{\text{cl}}(\tau)) \right] = \int_{-\infty}^{\infty} d\tau (x'_{\text{cl}}{}^2 - E) \\ &= -EL + \int_{-a}^a dx \sqrt{2[E + V(x)]}. \end{aligned} \quad (17.29)$$

The kink has $E = 0$, so that

$$\sqrt{2[E + V(x)]} = \frac{\omega}{2a}(a^2 - x^2), \quad (17.30)$$

and the classical action becomes

$$\mathcal{A}_{\text{cl}} = \frac{\omega}{2a} \int_{-a}^a dx (a^2 - x^2) = \frac{2}{3}a^2\omega = \frac{\omega^3}{3g}. \quad (17.31)$$

Note that for $E = 0$, the classical action is also given by the integral

$$\mathcal{A}_{\text{cl}} = \int_{-\infty}^{\infty} d\tau x'_{\text{cl}}{}^2. \quad (17.32)$$

There are also solutions starting out at the top of either mountain and sliding down into the adjacent exterior abyss, for instance (see again Fig. 17.3)

$$\begin{aligned} \tau - \tau_0 &= \mp \frac{2a}{\omega} \int_x^{\infty} \frac{dx'}{(x' - a)(x' + a)} = \pm \frac{1}{\omega} \log \frac{x + a}{x - a} \\ &= \pm \frac{2}{\omega} \operatorname{arccoth} \frac{x}{a}. \end{aligned} \quad (17.33)$$

However, these solutions cannot connect the bottoms of the double well with each other and will not be considered further.

Being in the possession of the classical solutions (17.19) and (17.28) with a finite action, we are now ready to write down the classical contributions to the amplitudes (17.16) and (17.17). According to the semiclassical formula (17.18), they are

$$(a \ L/2 | a \ -L/2) = 1 \times F_{\omega}(L) \quad (17.34)$$

and

$$(a \ L/2 | -a \ -L/2) = e^{-\mathcal{A}_{\text{cl}}/\hbar} \times F_{\text{cl}}(L). \quad (17.35)$$

The factor 1 in (17.34) emphasizes the vanishing action of the trivial classical solution (17.19). The exponential $e^{-\mathcal{A}_{\text{cl}}/\hbar}$ contains the action of the kink solutions (17.28).

The degeneracy of the solutions in τ_0 is accounted for by the fluctuation factor $F_{\text{cl}}(L)$, as will be shown below.

Actually, the classical kink and antikink solutions (17.28) do not occur exactly in (17.35) since they reach the well bottoms at $x = \pm a$ only at infinite Euclidean times $\tau \rightarrow \pm\infty$. For the amplitude to be calculated we need solutions for which x is equal to $\pm a$ at large but finite values $\tau = \pm L/2$. Fortunately, the error can be ignored since for large L the kink and antikink solutions approach $\pm a$ exponentially fast. As a consequence the action of a proper solution which would reach $\pm a$ at a finite L differs from the action \mathcal{A}_{cl} only by terms which tend to zero like $e^{-\omega L}$. Since we shall ultimately be interested only in the large- L limit we can neglect such exponentially small deviations.

In the following section we determine the fluctuation factors F_{cl} .

17.3 Quadratic Fluctuations

The semiclassical limit includes the effects of the quadratic fluctuations. These are obtained after approximating the potential around each minimum by a harmonic potential and keeping only the lowest term in the expansion (17.3). The fluctuation factor of a pure harmonic oscillator of frequency ω and unit mass has been calculated in Section 2.3 with the result

$$F_{\omega}(L) = \sqrt{\frac{\omega}{2\pi\hbar \sinh \omega L}} \sim \sqrt{\frac{\omega}{\pi\hbar}} e^{-\omega L/2} + \mathcal{O}(e^{-3\omega L/2}). \quad (17.36)$$

The leading exponential at large L displays the ground state energy $\omega/2$, while the corrections contain all information on the excited states whose energy is $(n + 1/2)\omega$ with $n = 1, 2, 3, \dots$.

Note that according to the spectral representation of the amplitude (17.15), the factor $\sqrt{\omega/\pi\hbar}$ in (17.36) must be equal to the square of the ground state wave function $\Psi_0(\Delta x_{\pm})$ at the potential minimum. This agrees with (17.5).

Consider now the fluctuation factor of a single kink contribution. It is given by the path integral over the fluctuations $y(\tau) \equiv \delta x(\tau)$

$$F_{\text{cl}}(L) = \int \mathcal{D}y(\tau) e^{-(1/\hbar) \int_{-L/2}^{L/2} d\tau (1/2)[y'^2 + V''(x_{\text{cl}}(\tau))y^2]}, \quad (17.37)$$

where $x_{\text{cl}}(\tau)$ is the kink solution, and $y(\tau)$ vanishes at the endpoints:

$$y(L/2) = y(-L/2) = 0. \quad (17.38)$$

Suppose for the moment that $L = \infty$. Then the kink solution is given by (17.28) and we obtain the fluctuation potential

$$\begin{aligned} V''(x_{\text{cl}}(\tau)) &= \frac{3\omega^2}{2a^2} x_{\text{cl}}^2(\tau) - \frac{1}{2}\omega^2 = \omega^2 \left(\frac{3}{2} \tanh^2[\omega(\tau - \tau_0)/2] - \frac{1}{2} \right) \\ &= \omega^2 \left(1 - \frac{3}{2} \frac{1}{\cosh^2[\omega(\tau - \tau_0)/2]} \right). \end{aligned} \quad (17.39)$$

Figure 17.4 Potential (17.41) for quadratic fluctuations around kink solution (17.28) in Schrödinger equation. The dashed lines indicate the bound states at energies 0 and $3\omega^2/4$.

Thus, the quadratic fluctuations are governed by the Euclidean action

$$\mathcal{A}_{\text{fl}}^0 = \int_{-L/2}^{L/2} d\tau \frac{1}{2} \left[y'^2 + \omega^2 \left(1 - \frac{3}{2} \frac{1}{\cosh^2[\omega(\tau - \tau_0)/2]} \right) y^2 \right]. \quad (17.40)$$

The rules for doing a functional integral with a quadratic exponent were explained in Chapter 2. The paths $y(\tau)$ are expanded in terms of eigenfunctions of the differential equation

$$\left[-\frac{d^2}{d\tau^2} + \omega^2 \left(1 - \frac{3}{2} \frac{1}{\cosh^2[\omega(\tau - \tau_0)/2]} \right) \right] y_n(\tau) = \lambda_n y_n(\tau), \quad (17.41)$$

with λ_n being the eigenvalues. This is a Schrödinger equation for a particle moving along the τ -axis in an attractive potential well of the Rosen-Morse type [compare

ref(14.135)(14.135) and see Fig. 17.4]:

lab(14.124)

est(14.158)

$$V(\tau) = \omega^2 \left(1 - \frac{3}{2} \frac{1}{\cosh^2[\omega(\tau - \tau_0)/2]} \right). \quad (17.42)$$

The eigenfunctions $y_n(\tau)$ satisfy the usual orthonormality condition

$$\int_{-\infty}^{\infty} d\tau y_n(\tau) y_{n'}(\tau) = \delta_{nn'}. \quad (17.43)$$

Given a complete set of these solutions $y_n(\tau)$ with $n = 0, 1, 2, \dots$, we now perform the *normal-mode expansion*

$$y^{\xi_0, \xi_1, \dots}(\tau) = \sum_{n=0}^{\infty} \xi_n y_n(\tau). \quad (17.44)$$

After inserting this into (17.40), we perform a partial integration in the kinetic term and the τ -integrals with the help of (17.43), and the Euclidean action of the quadratic fluctuations takes the simple form

$$\mathcal{A} = \frac{1}{2} \sum_{n=0}^{\infty} \lambda_n \xi_n^2. \quad (17.45)$$

With this, the fluctuation factor (17.37) reduces to a product of Gaussian integrals over the normal modes

$$F_{\text{cl}}(L) = \mathcal{N} \prod_{n=0}^{\infty} \left[\int_{-\infty}^{\infty} \frac{d\xi_n}{\sqrt{2\pi\hbar}} \right] e^{-\sum_{n=0}^{\infty} \xi_n^2 \lambda_n / 2\hbar} = \mathcal{N} \frac{1}{\sqrt{\prod_n \lambda_n}}. \quad (17.46)$$

The normalization constant \mathcal{N} , to be calculated below, accounts for the Jacobian which relates the time-sliced measure to the normal mode measure.

First we shall calculate the eigenvalues λ_n . For this we use the amplitude of the Rosen-Morse potential obtained via the Duru-Kleinert transformation (14.138) in ref(14.138) Eq. (14.139). If the potential is written in the form

$$V(\tau) = \omega^2 - \frac{V_0}{\cosh^2[m(\tau - \tau_0)]}, \quad (17.47)$$

there are bound states for $n = 0, 1, 2, \dots, n_{\text{max}} < s$, where s is defined by [2]

$$s \equiv \frac{1}{2} \left[-1 + \sqrt{1 + 4 \frac{V_0}{m^2}} \right]. \quad (17.48)$$

Their wave functions are, according to (14.141), and (14.143),

$$y_n(\tau) = \sqrt{\frac{m}{n!}} \sqrt{\Gamma(s-n)\Gamma(1+2s-n)} \frac{2^{n-s}}{\Gamma(1+s-n)} \cosh^{n-s}[m(\tau - \tau_0)] \times F(-n, 1+2s-n; s-n+1; \frac{1}{2}(1 - \tanh[m(\tau - \tau_0)])), \quad (17.49)$$

where $F(a, b; c; z)$ are the hypergeometric functions (1.453). In terms of s , the parameter V_0 becomes

$$V_0 = m^2 s(s+1). \quad (17.50)$$

The bound-state energies are

$$\lambda_n^2 = \omega^2 - m^2(s-n)^2. \quad (17.51)$$

In the Schrödinger equation (17.41), we have $m = \omega/2$, $V_0 = 3\omega^2/2$, so that $s = 2$ and there are exactly two bound-state solutions. These are

$$y_0(\tau) = -\sqrt{\frac{3\omega}{8}} \frac{1}{\cosh^2[\omega(\tau - \tau_0)/2]} \quad (17.52)$$

and

$$\begin{aligned} y_1(\tau) &= \sqrt{\frac{3\omega}{4}} \frac{1}{\cosh[\omega(\tau - \tau_0)/2]} F(-1, 4; 2; \frac{1}{2}(1 - \tanh[\omega(\tau - \tau_0)/2])) \\ &= \sqrt{\frac{3\omega}{4}} \frac{\sinh[\omega(\tau - \tau_0)/2]}{\cosh^2[\omega(\tau - \tau_0)/2]}. \end{aligned} \quad (17.53)$$

The negative sign in (17.52) is a matter of convention, to give $y_1(\tau)$ the same sign as $x_{cl}(\tau - \tau_0)$ in Eq. (17.89) below. The normalization factors can be checked using the formula

$$\int_0^\infty \frac{\sinh^\mu x}{\cosh^\nu x} = \frac{1}{2} B\left(\frac{\mu+1}{2}, \frac{\nu-\mu}{2}\right), \quad (17.54)$$

with $B(x, y) \equiv \Gamma(x)\Gamma(y)/\Gamma(x+y)$ being the Beta function. The corresponding eigenvalues are

$$\lambda_0 = 0, \quad \lambda_1 = 3\omega^2/4. \quad (17.55)$$

The existence of a zero-eigenvalue mode is a general property of fluctuations around localized classical solutions in a system which is translationally invariant along the τ -axis. It prevents an immediate application of the quadratic approximation, since a zero-eigenvalue mode is not controlled by a Gaussian integral as the others are in Eq. (17.46). This difficulty and its solution will be discussed in Subsection 17.3.1.

In addition to the two bound states, there are continuum wave functions with $\lambda_n \geq \omega^2$. For an energy

$$\lambda_k = \omega^2 + k^2, \quad (17.56)$$

they are given by a linear combination of

$$y_k(\tau) \propto A e^{ik\tau} F(s+1, -s; 1 - ik/m; \frac{1}{2}(1 - \tanh[m(\tau - \tau_0)])) \quad (17.57)$$

and its complex-conjugate (see the end of Subsection 14.4.4). Using the identity for the hypergeometric function²

$$\begin{aligned} F(a, b, c; z) &= \frac{\Gamma(c)\Gamma(c-a-b)}{\Gamma(c-a)\Gamma(c-b)} F(a, b; a+b-c+1; 1-z) \\ &+ (1-z)^{c-a-b} \frac{\Gamma(c)\Gamma(-c+a+b)}{\Gamma(a)\Gamma(b)} F(c-a, c-b; c-a-b+1; 1-z), \end{aligned} \quad (17.58)$$

and $F(a, b; c; 0) = 1$, we find the asymptotic behavior

$$F \xrightarrow{\tau \rightarrow \infty} 1, \quad (17.59)$$

$$F \xrightarrow{\tau \rightarrow -\infty} \frac{\Gamma(-ik/m)\Gamma(1-ik/m)}{\Gamma(-s-ik/m)\Gamma(s+1-ik/m)} + e^{-2ik\tau} \frac{\Gamma(ik/m)\Gamma(1-ik/m)}{\Gamma(-s)\Gamma(1+s)}. \quad (17.60)$$

²M. Abramowitz and I. Stegun, *op. cit.*, formula 15.3.6.

These limits determine the asymptotic behavior of the wave functions (17.57). With an appropriate choice of the normalization factor in (17.57) we fulfill the standard scattering boundary conditions

$$\psi(\tau) \rightarrow \begin{cases} e^{ik\tau} + R_k e^{-ik\tau}, & \tau \rightarrow -\infty, \\ T_k e^{ik\tau}, & \tau \rightarrow \infty. \end{cases} \quad (17.61)$$

These define the transmission and reflection amplitudes. From (17.59) and (17.60) we calculate directly

$$T_k = \frac{\Gamma(-s - ik/m)\Gamma(s + 1 - ik/m)}{\Gamma(-ik/m)\Gamma(1 - ik/m)}, \quad (17.62)$$

$$R_k = \frac{\Gamma(-s - ik/m)\Gamma(s + 1 - ik/m)}{\Gamma(-s)\Gamma(1 + s)} \frac{\Gamma(ik/m)}{\Gamma(-ik/m)} = T_k \frac{\Gamma(ik/m)\Gamma(1 - ik/m)}{\Gamma(-s)\Gamma(1 + s)}. \quad (17.63)$$

Using the relation $\Gamma(z) = \pi / \sin(\pi z)\Gamma(1 - z)$, this can be written as

$$T_k = \frac{\Gamma(s + 1 - ik/m)}{\Gamma(s + 1 + ik/m)} \frac{\Gamma(1 + ik/m)}{\Gamma(1 - ik/m)} \frac{\sin(ik/m)}{\sin(s + ik/m)}, \quad (17.64)$$

$$R_k = T_k \frac{\sin(\pi s)}{\sin(ik/m)}. \quad (17.65)$$

The scattering matrix

$$S_k = \begin{pmatrix} T_k & R_k \\ R_k & T_k \end{pmatrix} \quad (17.66)$$

is unitary since

$$R_k T_k^* + R_k^* T_k = 0, \quad |T_k|^2 + |R_k|^2 = 1. \quad (17.67)$$

It is diagonal on the state vectors

$$\psi^e = \frac{1}{\sqrt{2}} \begin{pmatrix} 1 \\ 1 \end{pmatrix}, \quad \psi^o = \frac{1}{\sqrt{2}} \begin{pmatrix} 1 \\ -1 \end{pmatrix}, \quad (17.68)$$

which, as we shall prove below, correspond to odd and even partial waves. The respective eigenvalues $\lambda_k^{e,o} = e^{2i\delta_k^{e,o}}$ define the phase shifts $\delta_k^{e,o}$, in terms of which

$$T_k = \frac{1}{2}(e^{2i\delta_k^e} + e^{2i\delta_k^o}), \quad (17.69)$$

$$R_k = \frac{1}{2}(e^{2i\delta_k^e} - e^{2i\delta_k^o}). \quad (17.70)$$

Let us verify the association of the eigenvectors (17.68) with the even and odd partial waves. For this we add to the wave function (17.61) the mirror-reflected solution

$$\psi^r(\tau) \rightarrow \begin{cases} T_k e^{-ik\tau}, & \tau \rightarrow -\infty, \\ e^{-ik\tau} + R_k e^{ik\tau}, & \tau \rightarrow \infty, \end{cases} \quad (17.71)$$

and obtain

$$\psi^e(\tau) = \psi(\tau) + \psi^f(\tau) \rightarrow \begin{cases} e^{ik\tau} + (R_k + T_k)e^{-ik\tau}, & \tau \rightarrow -\infty, \\ e^{-ik\tau} + (R_k + T_k)e^{ik\tau}, & \tau \rightarrow \infty. \end{cases} \quad (17.72)$$

Inserting (17.69), this can be rewritten as

$$\psi^e(\tau) \rightarrow \begin{cases} e^{i\delta_k^e} [e^{i(k\tau - \delta_k^e)} + e^{-i(k\tau - \delta_k^e)}] = 2e^{i\delta_k^e} \cos(k|\tau| + \delta_k^e), & \tau \rightarrow -\infty, \\ e^{i\delta_k^e} [e^{-i(k\tau + \delta_k^e)} + e^{i(k\tau + \delta_k^e)}] = 2e^{i\delta_k^e} \cos(k|\tau| + \delta_k^e), & \tau \rightarrow \infty. \end{cases} \quad (17.73)$$

The odd combination, on the other hand, gives

$$\psi^o(\tau) = \psi(\tau) - \psi^f(\tau) \rightarrow \begin{cases} e^{ik\tau} + (R_k - T_k)e^{-ik\tau}, & \tau \rightarrow -\infty, \\ -e^{-ik\tau} - (R_k - T_k)e^{ik\tau}, & \tau \rightarrow \infty, \end{cases} \quad (17.74)$$

and becomes with (17.69):

$$\psi^o(\tau) \rightarrow \begin{cases} e^{i\delta_k^o} [e^{i(k\tau - \delta_k^o)} - e^{-i(k\tau - \delta_k^o)}] = 2ie^{i\delta_k^o} \sin(k|\tau| + \delta_k^o), & \tau \rightarrow -\infty, \\ -e^{i\delta_k^o} [e^{-i(k\tau + \delta_k^o)} - e^{i(k\tau + \delta_k^o)}] = -2ie^{i\delta_k^o} \sin(k|\tau| + \delta_k^o), & \tau \rightarrow \infty. \end{cases} \quad (17.75)$$

From Eqs. (17.69), (17.70) we see that

$$|T_k|^2 = \cos^2(\delta_k^e - \delta_k^o), \quad |R_k|^2 = \sin^2(\delta_k^e - \delta_k^o), \quad (17.76)$$

and further

$$e^{2i(\delta_k^e + \delta_k^o)} = (T_k + R_k)(T_k - R_k) = T_k^2 + \frac{R_k R_k^* T_k}{T_k^*} = T_k^2 + (1 - T_k T_k^*) \frac{T_k}{T_k^*} = \frac{T_k}{T_k^*}. \quad (17.77)$$

From this we find the explicit equation for the sum of even and odd phase shifts

$$\delta_k^e + \delta_k^o = \frac{1}{2} \arg \frac{T_k}{T_k^*} = \arg T_k. \quad (17.78)$$

Similarly we derive the equation for the difference of the phase shifts:

$$-i \sin[2(\delta_k^e - \delta_k^o)] = T_k R_k^* - T_k^* R_k = 2T_k R_k^* = -2 \frac{R_k^*}{T_k^*} |T_k|^2. \quad (17.79)$$

Dividing this by the first equation in (17.76), we obtain

$$-i \tan(\delta_k^e - \delta_k^o) = -\frac{R_k^*}{T_k^*} = -\frac{\sinh(ik/m)}{\sin(\pi s)}, \quad (17.80)$$

and thus

$$\delta_k^e - \delta_k^o = \arctan \frac{\sin(\pi s)}{\sinh(k/m)} \sin(\pi s). \quad (17.81)$$

For $s = \text{integer}$, the even and odd phase shifts become equal,

$$\delta_k^e = \delta_k^o \equiv \delta_k, \quad (17.82)$$

so that the reflection amplitude vanishes, and the transmission amplitude reduces to a pure phase factor $T_k = e^{2i\delta_k}$, with the phase shift determined from (17.78) to

$$2\delta_k = -i \log T_k. \quad (17.83)$$

Now the wave functions have the simple asymptotic behavior

$$y_k(\tau) \rightarrow e^{i(k\tau \pm \delta_k)}, \quad \tau \rightarrow \pm\infty, \quad (17.84)$$

and (17.64) reduces for both even and odd phase shifts to

$$e^{2i\delta_k} = (-1)^s \frac{\Gamma(s+1-ik/m)}{\Gamma(1-ik/m)} \frac{\Gamma(1+ik/m)}{\Gamma(s+1+ik/m)}. \quad (17.85)$$

For the Schrödinger equation (17.41) with $s = 2$, this becomes simply

$$e^{2i\delta_k} = \frac{2-ik/m}{2+ik/m} \frac{1-ik/m}{1+ik/m}, \quad (17.86)$$

and hence

$$\delta_k = \arctan[k/m] + \arctan[k/2m]. \quad (17.87)$$

If we now try to evaluate the product of eigenvalues in (17.46), two difficulties arise:

- 1) The zero eigenvalue causes the result to be infinite.
- 2) The continuum states make the evaluation of the product of eigenvalues $\prod_n \sqrt{\lambda_n}$ nontrivial.

These two difficulties will be removed in the following two subsections.

17.3.1 Zero-Eigenvalue Mode

The physical origin of the infinity caused by the zero-eigenvalue solution in the fluctuation integral over ξ_0 in (17.46) lies in the time-translational invariance of the system. This fact supplies the key to removing the infinity. A kink at an imaginary time τ_0 contributes as much to the path integral as a kink at any other time τ'_0 . The difference between two adjacent solutions at an infinitesimal temporal distance can be viewed as a small kink fluctuation which does not change the Euclidean action. There is a zero eigenvalue associated with this difference. If there is only a single zero-eigenvalue solution as in the Schrödinger equation (17.41) its wave function must be proportional to the derivative of the kink solution:

$$\begin{aligned} y_0 &= \alpha \left[\frac{x_{\text{cl}}(\tau - \tau_0) - x_{\text{cl}}(\tau - \tau_1)}{\tau_0 - \tau_1} \right]_{\tau_0 \rightarrow \tau_1} = \alpha x'_{\text{cl}}(\tau - \tau_0) \\ &= -\alpha \frac{a\omega/2}{\cosh^2[\omega(\tau - \tau_0)/2]}. \end{aligned} \quad (17.88)$$

This coincides indeed with the zero-eigenvalue solution (17.52). The normalization factor α is fixed by the integral

$$\alpha = \left[\int_{-\infty}^{\infty} d\tau x'_{\text{cl}}{}^2 \right]^{-1/2}. \quad (17.89)$$

With the help of (17.32) the right-hand side can also be expressed in terms of the kink action:

$$\alpha = \frac{1}{\sqrt{\mathcal{A}_{\text{cl}}}}. \quad (17.90)$$

Inserting (17.2) and (17.31), this becomes

$$\alpha = \sqrt{3/2a^2\omega} = \sqrt{3g/\omega^3} \quad (17.91)$$

[the positive square root corresponding to the negative sign in (17.52)]. The zero-eigenvalue mode is associated with a shift of the position of the kink solution from τ_0 to any other place τ'_0 . For an infinite length L of the τ -axis, this is the source of the infinity of the integral over ξ_0 in the product (17.46). At a finite L , on the other hand, only a τ -interval of length L is available for displacements. Therefore, the infinite $1/\sqrt{\lambda_0}$ should become proportional to L for large L :

$$\frac{1}{\sqrt{\lambda_0}} = \text{const} \cdot L. \quad (17.92)$$

What is the proportionality constant? We find it by transforming the integration measure (17.46),

$$\mathcal{N} \int_{-\infty}^{\infty} \frac{d\xi_0}{\sqrt{2\pi\hbar}} \prod_{n=1}^{\infty} \left[\int_{-\infty}^{\infty} \frac{d\xi_n}{\sqrt{2\pi\hbar}} \right], \quad (17.93)$$

to a form in which the translational degree of freedom appears explicitly

$$\mathcal{N} \frac{1}{\sqrt{2\pi\hbar}} \int_{-\infty}^{\infty} d\tau_0 \prod_{n \neq 0} \int_{-\infty}^{\infty} \left[\frac{d\xi_n}{\sqrt{2\pi\hbar}} \right] \left| \frac{\partial \xi_0}{\partial \tau_0}(\xi_1, \xi_2, \dots) \right|. \quad (17.94)$$

The Jacobian appearing in the integrand satisfies the identity

$$\int d\tau_0 \delta(\xi_0) \left| \frac{\partial \xi_0}{\partial \tau_0} \right| = 1. \quad (17.95)$$

Let us calculate this Jacobian using the method developed by Faddeev and Popov [3]. Given an arbitrary fluctuation $y^{\xi_0, \xi_1, \xi_2, \dots}$, the parameter ξ_0 may be recovered by forming the scalar product with the zero-eigenvalue wave function $y_0(\tau)$:

$$\xi_0 = \int_{-\infty}^{\infty} d\tau y^{\xi_0, \xi_1, \xi_2, \dots}(\tau) y_0(\tau). \quad (17.96)$$

Moreover, it is easy to see that the fluctuation $y^{\xi_0, \xi_1, \xi_2, \dots}$ can be replaced by the full path

$$x^{\xi_0, \xi_1, \xi_2, \dots}(\tau) = x_{\text{cl}}(\tau) + y^{\xi_0, \xi_1, \xi_2, \dots}(\tau), \quad (17.97)$$

so that we can also write

$$\xi_0 = \int_{-\infty}^{\infty} d\tau x^{\xi_0, \xi_1, \xi_2, \dots}(\tau) y_0(\tau). \quad (17.98)$$

This follows from the fact that the additional kink solution $x_{\text{cl}}(\tau)$ does not have any overlap with its derivative. Indeed,

$$\begin{aligned} \int_{-\infty}^{\infty} d\tau x_{\text{cl}}(\tau - \tau_0) y_0(\tau - \tau_0) &\propto \int_{-\infty}^{\infty} d\tau x_{\text{cl}}(\tau - \tau_0) x'_{\text{cl}}(\tau - \tau_0) \\ &\propto \left. \frac{1}{2} x_{\text{cl}}^2 \right|_{-\infty}^{\infty} = 0. \end{aligned} \quad (17.99)$$

With (17.98), the delta function $\delta(\xi_0)$ appearing in (17.95) can be rewritten in the form

$$\delta(\xi_0) = \delta \left(\int_{-\infty}^{\infty} d\tau x^{\xi_0, \xi_1, \xi_2, \dots}(\tau) y_0(\tau) \right). \quad (17.100)$$

To establish the relation between the normal coordinate ξ_0 and the kink position τ_0 , we now replace $x^{\xi_0, \xi_1, \xi_2, \dots}$ by an alternative parametrization of the paths in which the role of the variable ξ_0 is traded against the position of the kink solution, i.e., we rewrite the fluctuating path

$$x^{\xi_0, \xi_1, \xi_2, \dots}(\tau) = x_{\text{cl}}(\tau) + \sum_{n=0}^{\infty} \xi_n y_n(\tau) \quad (17.101)$$

in the form

$$x^{\tau_0, \xi_1, \xi_2, \dots}(\tau) \equiv x_{\text{cl}}(\tau - \tau_0) + \sum_{n=1}^{\infty} \xi_n y_n(\tau - \tau_0). \quad (17.102)$$

By definition the point $\tau_0 = 0$ coincides with $\xi_0 = 0$. Thus, if we insert (17.102) into (17.100) and use this δ -function in the identity (17.95), we find the condition for the Jacobian $\partial \xi_0 / \partial \tau_0$:

$$\int_{-\infty}^{\infty} d\tau_0 \delta \left(\int_{-\infty}^{\infty} d\tau x^{\tau_0, \xi_1, \xi_2, \dots}(\tau) y_0(\tau) \right) \left| \frac{\partial \xi_0}{\partial \tau_0} \right| = 1. \quad (17.103)$$

Since the δ -function has a vanishing argument at $\tau_0 = 0$, we expand the argument in powers of τ_0 , keeping only the lowest order. Writing $y_0(\tau) = \alpha x'_{\text{cl}}(\tau)$, we obtain

$$\int_{-\infty}^{\infty} d\tau x^{\tau_0, \xi_1, \xi_2, \dots}(\tau) y_0(\tau) = -\alpha \tau_0 \left[\int_{-\infty}^{\infty} d\tau x_{\text{cl}}'^2 + \sum_{n=1}^{\infty} \xi_n \int_{-\infty}^{\infty} d\tau x'_{\text{cl}} y'_n \right] + \mathcal{O}(\tau_0^2). \quad (17.104)$$

Using (17.32) and abbreviating the scalar products in the brackets as

$$r_n \equiv \int_{-\infty}^{\infty} d\tau x'_{\text{cl}} y'_n, \quad (17.105)$$

we may express the right-hand side of (17.104) more succinctly as

$$-\alpha\tau_0 \left[\mathcal{A}_{\text{cl}} + \sum_{n=1}^{\infty} \xi_n r_n \right] + \mathcal{O}(\tau_0^2). \quad (17.106)$$

Inserting this into (17.103), and using (17.90), we arrive at the Jacobian

$$\left| \frac{\partial \xi_0}{\partial \tau_0} \right| = \mathcal{A}_{\text{cl}}^{1/2} \left(1 + \mathcal{A}_{\text{cl}}^{-1} \sum_{n=1}^{\infty} \xi_n r_n \right). \quad (17.107)$$

As a consequence, the zero-eigenvalue modes contribute to the fluctuation factor (17.46) as follows:

$$\begin{aligned} F_{\text{cl}}(L) &= \mathcal{N} \prod_{n=1}^{\infty} \left[\int_{-\infty}^{\infty} \frac{d\xi_n}{\sqrt{2\pi\hbar}} e^{-(1/2\hbar) \sum_{n=1}^{\infty} \xi_n^2 \lambda_n} \int_{-\infty}^{\infty} \frac{d\xi_0}{\sqrt{2\pi\hbar}} e^{-(1/2\hbar) \xi_0^2 \lambda_0} \right. \\ &= \mathcal{N} \prod_{n=1}^{\infty} \left[\int_{-\infty}^{\infty} \frac{d\xi_n}{\sqrt{2\pi\hbar}} e^{-(1/2\hbar) \sum_{n=1}^{\infty} \xi_n^2 \lambda_n} \right] \int_{-\infty}^{\infty} \frac{d\tau_0}{\sqrt{2\pi\hbar}} \mathcal{A}_{\text{cl}}^{1/2} \left(1 + \mathcal{A}_{\text{cl}}^{-1} \sum_{n=1}^{\infty} \xi_n r_n \right) \\ &= \mathcal{N} \frac{1}{\sqrt{\prod_{n=1}^{\infty} \lambda_n}} \sqrt{\frac{\mathcal{A}_{\text{cl}}}{2\pi\hbar}} \int_{-\infty}^{\infty} d\tau_0. \end{aligned} \quad (17.108)$$

The linear terms in the large parentheses disappear at the level of quadratic fluctuations since they are odd in ξ . Thus we may use for *quadratic fluctuations* the simple *mnemonic rule*

$$-\frac{\partial \xi_0}{\partial \tau_0} = \frac{\partial x(\tau)/\partial \tau_0}{\partial x(\tau)/\partial \xi_0} = \frac{\dot{x}_{\text{cl}}(\tau) + \dots}{\alpha \dot{x}_{\text{cl}}(\tau)} = \frac{1}{\alpha} + \dots = \sqrt{\mathcal{A}_{\text{cl}}} + \dots, \quad (17.109)$$

where \dots stands for the irrelevant linear terms in ξ_n inside the integral (17.108).

For higher-order fluctuations, the linear terms in the large parentheses cannot be ignored. They contribute an effective Euclidean action

$$\mathcal{A}_{\text{e}}^{\text{eff}} = -\hbar \log \left[1 + \mathcal{A}_{\text{cl}}^{-1} \sum_{n=1}^{\infty} \xi_n r_n \right] = -\hbar \log \left[1 + \mathcal{A}_{\text{cl}}^{-1} \int d\tau x'_{\text{cl}}(\tau) y'(\tau) \right], \quad (17.110)$$

which will be needed for calculations in Section 17.8.

The integral over τ_0 is now an appropriate place to impose the finiteness of the time interval $\tau \in (-L/2, L/2)$, namely

$$\int_{-L/2}^{L/2} d\tau_0 = L. \quad (17.111)$$

A comparison of (17.108) with (17.46) shows that the correct evaluation of the formally diverging zero-eigenvalue contribution $1/\sqrt{\lambda_0}$ is equivalent to the following replacement:

$$\frac{1}{\sqrt{\lambda_0}} \equiv \int \frac{d\xi_0}{\sqrt{2\pi\hbar}} e^{-(1/2\hbar) \lambda_0 \xi_0^2} \longrightarrow \sqrt{\frac{\mathcal{A}_{\text{cl}}}{2\pi\hbar}} \int_{-L/2}^{L/2} d\tau_0 = \sqrt{\frac{\mathcal{A}_{\text{cl}}}{2\pi\hbar}} L. \quad (17.112)$$

17.3.2 Continuum Part of Fluctuation Factor

We now turn to the second problem, the calculation of the product of the continuum eigenvalues in (17.46). To avoid carrying around the overall normalization factor \mathcal{N} it is convenient to factor out the quadratic fluctuations (17.36) in the absence of a kink solution. Let λ_n^0 be the associated eigenvalues. Their fluctuation potential $V''(x_{\text{cl}}(\tau)) = \omega^2 x^2$ is harmonic [compare (17.39)] with a fluctuation factor known from (2.171). Comparing this with the expression (17.46) without a kink, we obtain for the normalization factor the equation

$$\mathcal{N} \frac{1}{\sqrt{\prod_n \lambda_n^0}} = F_\omega(L) = \sqrt{\frac{\omega}{2\pi\hbar \sinh \omega L}} \sim \sqrt{\frac{\omega}{\pi\hbar}} e^{-\omega L/2}. \quad (17.113)$$

Pulling this factor out of the product on the right-hand side of (17.46), we are left with a ratio of eigenvalue products:

$$F_{\text{cl}}(L) = \mathcal{N} \frac{1}{\sqrt{\prod_n \lambda_n}} = \mathcal{N} \frac{1}{\sqrt{\prod_n \lambda_n^0}} \sqrt{\frac{\prod_n \lambda_n^0}{\prod_n \lambda_n}} = F_\omega(L) \sqrt{\frac{\prod_n \lambda_n^0}{\prod_n \lambda_n}}. \quad (17.114)$$

As long as L is finite, the continuum wave functions are all discrete. Let $\partial n/\partial k$ denote their density of states per momentum interval. Then the ratio of the continuum eigenvalues can be written for large L as

$$\sqrt{\frac{\prod_n \lambda_n^0}{\prod_n \lambda_n}} \Big|_{\text{cont}} = \exp \left[-\frac{1}{2} \int_0^\infty dk \left(\frac{\partial n}{\partial k} - \frac{\partial n}{\partial k} \Big|_0 \right) \log \lambda_n \right]. \quad (17.115)$$

The density of states, in turn, may be extracted from the phase shifts (17.85). For this we observe that for a very large L where boundary conditions are a matter of choice, we may impose the periodic boundary condition

$$y(\tau + L) = y(\tau). \quad (17.116)$$

Together with the asymptotic forms (17.84), this implies

$$e^{i(kL/2 + \delta_k)} = e^{-i(kL/2 + \delta_k)}, \quad (17.117)$$

which quantizes the wave vectors k to discrete values satisfying

$$kL + 2\delta_k = 2\pi n. \quad (17.118)$$

The derivative with respect to k yields the density of states

$$\frac{\partial n}{\partial k} = \frac{L}{2\pi} + \frac{1}{\pi} \frac{d\delta_k}{dk}. \quad (17.119)$$

Since the phase shifts vanish in the absence of a kink solution, this implies

$$\frac{\partial n}{\partial k} \Big|_0 = \frac{L}{2\pi}, \quad (17.120)$$

and the general formula (17.115) becomes simply

$$\sqrt{\frac{\prod_n \lambda_n^0}{\prod_n \lambda_n}} \Big|_{\text{cont}} = \exp \left[-\frac{1}{2\pi} \int_0^\infty dk \frac{d\delta_k}{dk} \log(\omega^2 + k^2) \right]. \quad (17.121)$$

To calculate the integral for our specific fluctuation problem (17.41), we use the expression (17.85) to find the derivative of the phase shift for any integer value of s :

$$\frac{d\delta_k}{dk} = -\frac{1}{m} \left[\frac{2}{4 + (k/m)^2} + \dots + \frac{s}{s^2 + (k/m)^2} \right]. \quad (17.122)$$

For $s = 2$, the exponent in (17.121) becomes

$$\frac{1}{2\pi} \int_{-\infty}^\infty dx \left(\frac{1}{1+x^2} + \frac{2}{4+x^2} \right) \log \left[\omega^2 (1 + x^2 m^2 / \omega^2) \right]. \quad (17.123)$$

The ω^2 -term in the logarithm can be separated from this using Levinson's theorem [1]. It states that the integral $\int_0^\infty dk (\partial n / \partial k - \partial n / \partial k|_0)$ is equal to the number of bound states:

$$\int_0^\infty dk \left(\frac{\partial n}{\partial k} - \frac{\partial n}{\partial k} \Big|_0 \right) = \frac{1}{\pi} \int_0^\infty dk \frac{d\delta_k}{dk} = s. \quad (17.124)$$

This relation is obviously fulfilled by (17.122). It is a consequence of the fact that a potential with s bound states has s states less in the continuum than a free system. Using this property, the integral (17.123) can be rewritten as

$$\log \omega^2 + \int_{-\infty}^\infty \frac{dx}{2\pi} \left(\frac{1}{1+x^2} + \frac{2}{4+x^2} \right) \log(1 + x^2 m^2 / \omega^2). \quad (17.125)$$

The rescaled integral is calculated using the formula

$$\int_{-\infty}^\infty \frac{dx}{2\pi} \frac{\log(1 + p^2 x^2)}{r^2 + s^2 x^2} = \frac{1}{rs} \log \left(1 + p \frac{r}{s} \right). \quad (17.126)$$

The result is

$$\log \omega^2 + \log \left(1 + \frac{m}{\omega} 1 \right) + \log \left(1 + \frac{m}{\omega} 2 \right). \quad (17.127)$$

When inserted into the exponent of (17.121), it yields

$$\sqrt{\frac{\prod_n \lambda_n^0}{\prod_n \lambda_n}} \Big|_{\text{cont}} = \omega^2 \left(1 + \frac{m}{\omega} \right) \left(1 + \frac{m}{\omega} 2 \right). \quad (17.128)$$

In our case with $m = \omega/2$, this reduces to $3\omega^2$. Including the bound-state eigenvalue λ_1 of Eq. (17.55) in the denominator, this amounts to

$$\sqrt{\frac{\prod_n \lambda_n^0}{\prod'_n \lambda_n}} = \frac{1}{\sqrt{3\omega^2/4}} 3\omega^2 = \sqrt{12}\omega \equiv K'. \quad (17.129)$$

Multiplying this with the zero-eigenvalue contribution as evaluated in Eq. (17.108), we arrive at the final result for the fluctuation factor in the presence of a kink or an antikink solution:

$$F_{\text{cl}}(L) = F_{\omega}(L)KL, \quad (17.130)$$

with

$$K = \frac{1}{\sqrt{\lambda_0 L}} K' = \sqrt{\frac{\mathcal{A}_{\text{cl}}}{2\pi\hbar}} \sqrt{12}\omega. \quad (17.131)$$

17.4 General Formula for Eigenvalue Ratios

The above-calculated ratio of eigenvalue products

$$\sqrt{\frac{\prod_n \lambda_n^0}{\prod_n \lambda_n}} \Big|_{\text{cont}} \quad (17.132)$$

of the Rosen-Morse Schrödinger equation appears in many applications with different potential strength parameters s . It is therefore useful to derive a formula for this ratio which is valid for any s . The eigenvalue equation reads

$$\left[-\frac{d^2}{d\tau^2} + \omega^2 - \frac{m^2 s(s+1)}{\cosh^2 m(\tau - \tau_0)} \right] y_n(\tau) = \lambda_n y_n(\tau). \quad (17.133)$$

First we consider the case of an arbitrary integer value of s . Following the previous discussion, the ratio of eigenvalue products is found to be

$$\begin{aligned} \sqrt{\frac{\prod_n \lambda_n^0}{\prod_n \lambda_n}} \Big|_{\text{cont}} &= \exp \left[-\frac{1}{2\pi} \int_0^\infty dk \frac{d\delta_k}{dk} \log(\omega^2 + k^2) \right] \\ &= \exp \left\{ -\frac{1}{2\pi} \int_0^\infty d(k/m) \sum_{n=1}^s \frac{n}{n^2 + (k/m)^2} \log[\omega^2 + (k/m)^2 m^2] \right\}. \end{aligned} \quad (17.134)$$

The ω^2 -term in the logarithm is eliminated by the generalization of (17.124) to any integer s :

$$\frac{1}{\pi} \int_{-\infty}^\infty d(k/m) \sum_{n=1}^s \frac{n}{n^2 + (k/m)^2} = s. \quad (17.135)$$

Hence

$$\sqrt{\frac{\prod_n \lambda_n^0}{\prod_n \lambda_n}} \Big|_{\text{cont}} = \omega^s \exp \left[\frac{1}{2\pi} \int_{-\infty}^\infty dx \sum_{n=1}^s \frac{n}{n^2 + x^2} \log(1 + x^2 m^2 / \omega^2) \right]. \quad (17.136)$$

The integrals can be done using formula (17.126), and we obtain

$$\sqrt{\frac{\prod_n \lambda_n^0}{\prod_n \lambda_n}} \Big|_{\text{cont}} = \omega^s \prod_{n=1}^s \left(1 + \frac{m}{\omega} n \right). \quad (17.137)$$

For $s = 2$, and $m = \omega/2$, this reduces to the previous result (17.128).

Only a little more work is required to find the ratio of all discrete and continuous eigenvalue products for a noninteger value of s . Introduce a new parameter z , let s be a parameter smaller than 1 so that there are no bound states, and consider the fluctuation equation

$$\left[-\frac{d^2}{d\tau^2} + m^2 \left(z - \frac{s(s+1)}{\cosh^2 m(\tau - \tau_0)} \right) \right] y_n(\tau) = \lambda_n y_n(\tau). \quad (17.138)$$

The general Schrödinger operator under consideration (17.133) corresponds to $z = \omega^2/m^2$. Since there are no bound states by assumption, the first line in formula (17.134) now gives the ratio of *all* eigenvalues:

$$\sqrt{\frac{\prod_n \lambda_n^0}{\prod_n \lambda_n}} = \exp \left[-\frac{1}{2\pi} \int_{-\infty}^{\infty} dk \frac{d\delta_k}{dk} \log(m^2 z + k^2) \right]. \quad (17.139)$$

Here δ_k is equal to the average of even and odd phase shifts $(\delta_k^e + \delta_k^o)/2$. For the same reason, we can replace $\log(m^2 z + k^2)$ by $\log(z + k^2/m^2)$ without error [using the generalization of (17.124)]. After substituting $k^2 \rightarrow \omega^2 \epsilon$, we find

$$\sqrt{\frac{\prod_n \lambda_n^0}{\prod_n \lambda_n}} = \exp \left[-\frac{1}{2\pi} \int_C d\epsilon \frac{d\delta\omega\sqrt{\epsilon}}{d\epsilon} \log(z + \epsilon) \right], \quad (17.140)$$

where the contour of integration C encircles the right-hand cut clockwise in the ϵ -plane. A partial integration brings this to

$$\exp \left(\frac{1}{2\pi} \int_C d\epsilon \delta_{m\sqrt{\epsilon}} \frac{1}{z + \epsilon} \right). \quad (17.141)$$

For $z < 0$, the contour of integration can be deformed to encircle the only pole at $\epsilon = -z$ counterclockwise, yielding

$$\sqrt{\frac{\prod_n \lambda_n^0}{\prod_n \lambda_n}} = \exp[i\delta_{m\sqrt{-z}}]. \quad (17.142)$$

Inserting for δ_k the average of even and odd phase shifts from (17.78), we obtain

$$\sqrt{\frac{\prod_n \lambda_n^0}{\prod_n \lambda_n}} = \left[\frac{\Gamma(\sqrt{z} - s)\Gamma(\sqrt{z} + s + 1)}{\Gamma(\sqrt{z})\Gamma(\sqrt{z} + 1)} \right]^{1/2}. \quad (17.143)$$

In the fluctuation equation (17.41), the parameters m^2 and $\omega^2 = zm^2$ are such as to create a zero eigenvalue at $n = 0$ according to formula (17.51). Then $z = s^2$. In the neighborhood of this z -value, the eigenvalue

$$\lambda_0 = m^2[z - s^2] \quad (17.144)$$

is a would-be zero eigenvalue. Dividing it out of the product (17.143), we obtain an equation which remains valid in the limit $z \rightarrow s^2$:

$$\sqrt{\frac{\prod_n \lambda_n^0}{\prod_n' \lambda_n}} = m \left[(\sqrt{z} + s) \frac{\Gamma(\sqrt{z} - s + 1)\Gamma(\sqrt{z} + s + 1)}{\Gamma(\sqrt{z})\Gamma(\sqrt{z} + 1)} \right]^{1/2}. \quad (17.145)$$

This can be continued analytically to arbitrary z and s , as long as z remains sufficiently close to $s = 2$. For $s = 2$ and $z = 4$ (corresponding to $m = \omega/2$) we recover the earlier result (17.129):

$$\sqrt{\frac{\prod_n \lambda_n^0}{\prod_n' \lambda_n}} = \sqrt{12}\omega. \quad (17.146)$$

17.5 Fluctuation Determinant from Classical Solution

The above evaluations of the fluctuation determinant require the complete knowledge of the bound and continuum spectrum of the fluctuation equation. Fortunately, there exists a way to find the determinant which needs much less information, requiring only the knowledge of the large- τ behavior of the classical solution and the value of its action. The basis for this derivation is the Gelfand-Yaglom formula derived in Section 2.4. According to it, the fluctuation determinant of a differential operator

$$\hat{\mathcal{O}} = -\frac{d^2}{d\tau^2} + \omega^2 - \frac{m^2 s(s+1)}{\cosh^2[m(\tau - \tau_0)]} \quad (17.147)$$

is given by the value of the zero-eigenvalue solution $D(\tau)$ at the final τ value $\tau = L/2$

$$\det \hat{\mathcal{O}} = \mathcal{N}D(L/2), \quad (17.148)$$

provided that it was chosen to satisfy the initial conditions at $\tau = -L/2$:

$$D(-L/2) = 0, \quad \dot{D}(-L/2) = 1. \quad (17.149)$$

The normalization factor \mathcal{N} is irrelevant when considering ratios of fluctuation determinants, as we do in the problem at hand.³ To satisfy the boundary conditions (17.149), we need two linearly independent solutions of zero eigenvalue. One is known from the invariance under time translations. It is proportional to the time derivative of the classical solution [see (17.88)]:

$$y_0(\tau) = \alpha x'_{\text{cl}}(\tau). \quad (17.150)$$

³If the determinant is calculated for the time-sliced operator $\hat{\mathcal{O}}$ with $d/d\tau$ replaced by the difference operator ∇_τ , the normalization is $\mathcal{N} = 1/\epsilon$ where ϵ is the thickness of the time slices. See Chapter 2.

In the above fluctuation problem (17.41) with $s = 2$ and $m = \omega/2$, the classical solution is $x_{\text{cl}}(\tau) = \text{arctanh}[\omega(\tau - \tau_0)/2]$. It has the asymptotic behavior

$$y_0(\tau) \rightarrow \frac{\omega}{2} e^{-\omega|\tau|} \quad \text{for } \tau \rightarrow \pm\infty, \quad (17.151)$$

with a symmetric exponential falloff in both directions of the τ -axis. In the sequel it will be convenient to work with zero-eigenvalue solutions without the prefactor $\omega/2$, which behave asymptotically like a pure exponential. These will be denoted by $\xi(\tau)$ and $\eta(\tau)$, the solution $\xi(\tau)$ being proportional to y_0 , i.e.,

$$\xi(\tau) \rightarrow e^{-\omega|\tau|} \quad \text{for } \tau \rightarrow \pm\infty. \quad (17.152)$$

The second independent solution can be found from d'Alembert's formula (2.236). Its explicit form is not required; only its asymptotic behavior is relevant. Assuming the Lagrangian to be invariant under time reversal, which is usually the case, this asymptotic behavior is found via the following argument: Since $\phi_0^{(2)}(\tau)$ is linearly independent of $\phi_0^{(1)}(\tau)$, we can be sure that it has asymptotically the opposite exponential behavior (i.e., it grows with τ) and the opposite symmetry under time reversal (i.e., it is antisymmetric). Thus η must behave as follows:

$$\eta(\tau) \rightarrow \pm e^{\omega|\tau|} \quad \text{for } \tau \rightarrow \pm\infty. \quad (17.153)$$

We now form the linear combination which satisfies the boundary conditions (17.149) for large negative $\tau = -L/2$:

$$D(\tau) = \frac{1}{W} [\xi(-L/2)\eta(\tau) - \eta(-L/2)\xi(\tau)], \quad (17.154)$$

where

$$W \equiv W[\xi(\tau)\eta(\tau)] = \xi(\tau)\dot{\eta}(\tau) - \eta(\tau)\dot{\xi}(\tau) \quad (17.155)$$

is the *Wronskian* of the two solutions. It is independent of τ and can be evaluated from the asymptotic behavior as

$$W = 2\omega. \quad (17.156)$$

Inserting (17.152) and (17.153) into (17.154), we find the solution

$$D(\tau) = \frac{1}{W} [e^{-\omega L/2}\eta(\tau) + e^{\omega L/2}\xi(\tau)]. \quad (17.157)$$

Even without knowing the solutions $\phi_0^{(1)}(\tau)$, $\phi_0^{(2)}(\tau)$ at a finite τ , the fluctuation determinant at large $\tau = L/2$ can be written down:

$$D(L/2) = \frac{2}{W} = \frac{1}{\omega}. \quad (17.158)$$

For fluctuations around the constant classical solution, the zero-eigenvalue solution with the boundary conditions (17.149) is

$$D^{(0)}(\tau) = \frac{1}{\omega} \sinh[\omega(\tau + L/2)]. \quad (17.159)$$

It behaves for large $\tau = L$ like

$$D^{(0)}(L/2) \rightarrow \frac{1}{2\omega} e^{\omega L} \quad \text{for large } L. \quad (17.160)$$

The ratio is therefore

$$\frac{D^{(0)}(L/2)}{D(L/2)} \rightarrow \frac{1}{2} e^{\omega L} \quad \text{for large } L. \quad (17.161)$$

This exponentially large number is a signal for the presence of a would-be zero eigenvalue in $D(L/2)$. Since the τ -interval $(-L/2, L/2)$ is finite, there exists no exactly vanishing eigenvalue. In the finite interval, the derivative (17.150) of the kink solution does not quite satisfy the Dirichlet boundary condition. If the vanishing at the endpoints was properly enforced, the particle distribution would have to be compressed somewhat, and this would shift the energy slightly upwards. The shift is exponentially small for large L , so that the would-be zero eigenvalue has an exponentially small eigenvalue $\lambda_0 \propto e^{-\omega L}$. A finite result for $L \rightarrow \infty$ is obtained by removing this mode from the ratio (17.161) and considering the limit

$$\frac{\prod_n \lambda_n^0}{\prod_n' \lambda_n} = \lim_{L \rightarrow \infty} \frac{D^{(0)}(L/2)}{D(L/2)} \lambda_0. \quad (17.162)$$

The leading $e^{-\omega L}$ -behavior of the would-be zero eigenvalue can be found perturbatively using as before only the asymptotic behavior of the two independent solutions. To lowest order in perturbation theory, an eigenfunction satisfying the Dirichlet boundary condition at finite L is obtained from an eigenfunction ϕ_0 which vanishes at $\tau = -L/2$ by the formula

$$\phi_0^L(\tau) = \phi_0(\tau) + \frac{\lambda_0}{W} \int_{-L/2}^{\tau} d\tau' [\xi(\tau)\eta(\tau') - \eta(\tau)\xi(\tau')] \phi_0(\tau'). \quad (17.163)$$

The limits of integration ensure that $\phi_0^L(\tau)$ vanishes at $\tau = -L/2$. The eigenvalue λ_0 is determined by enforcing the vanishing also at $\tau = L/2$. Taking for $\phi_0(\tau)$ the zero-eigenvalue solution $D(\tau)$

$$\lambda_0 = -D(L/2)W \left[\xi(L/2) \int_{-L/2}^{L/2} d\tau \eta(\tau)D(\tau) - \eta(L/2) \int_{-L/2}^{L/2} d\tau \xi(\tau)D(\tau) \right]^{-1}. \quad (17.164)$$

Inserting (17.154) and using the orthogonality of $\xi(\tau)$ and $\eta(\tau)$ (following from the fact that the first is symmetric and the second antisymmetric), this becomes

$$\lambda_0 = -D(L/2)W^2 \left[\xi(-L/2)\xi(L/2) \int_{-L/2}^{L/2} d\tau \eta^2(\tau) + \eta(-L/2)\eta(L/2) \int_{-L/2}^{L/2} d\tau \xi^2(\tau) \right]^{-1}. \quad (17.165)$$

Invoking once more the symmetry of $\xi(\tau)$ and $\eta(\tau)$ and the asymptotic behavior (17.152) and (17.153), we obtain

$$\lambda_0 = -D(L/2)W^2 \left[e^{-\omega L} \int_{-L/2}^{L/2} d\tau \eta^2(\tau) - e^{\omega L} \int_{-L/2}^{L/2} d\tau \xi^2(\tau) \right]^{-1}. \quad (17.166)$$

The first integral diverges like $e^{\omega L}$; the second is finite. The prefactor makes the second integral much larger than the first, so that we find for large L the would-be zero eigenvalue

$$\lambda_0 = D(L/2)e^{-\omega L} \frac{W^2}{\int_{-\infty}^{\infty} d\tau \xi^2(\tau)}. \quad (17.167)$$

This eigenvalue is exponentially small and positive, as expected. Inserting it into (17.162) and using (17.156) and (17.160), we find the eigenvalue ratio

$$\frac{\prod_n \lambda_n^0}{\prod'_n \lambda_n} = \lim_{L \rightarrow \infty} 2\omega \frac{1}{\int_{-\infty}^{\infty} d\tau \xi^2(\tau)}. \quad (17.168)$$

The determinant $D(L/2)$ has disappeared and the only nontrivial quantity to be evaluated is the normalization integral over the translational eigenfunction $\xi(\tau)$.

The normalization integral requires the knowledge of the full τ -behavior of the zero-eigenvalue solution $\phi_0^{(1)}(\tau)$; the asymptotic behavior used up to this point is insufficient. Fortunately, the classical solution $x_{\text{cl}}(\tau)$ also supplies this information. The normalized solution is $y_0 = \alpha x'_{\text{cl}}(\tau)$ behaving asymptotically like $2a\omega e^{-\omega\tau}$. Imposing the normalization convention (17.152) for $\phi_0^{(1)}(\tau)$, we identify

$$\xi(\tau) = \frac{1}{2a\omega\alpha} \alpha x'_{\text{cl}}(\tau). \quad (17.169)$$

Using the relation (17.32), the normalization integral is simply

$$\int_{-\infty}^{\infty} d\tau \xi(\tau)^2 = \frac{\mathcal{A}_{\text{cl}}}{4a^2\omega^2}. \quad (17.170)$$

With it the eigenvalue ratio (17.168) becomes

$$\frac{\prod_n \lambda_n^0}{\prod'_n \lambda_n} = 2\omega \frac{4a^2\omega}{\mathcal{A}_{\text{cl}}}. \quad (17.171)$$

By inserting the value of the classical action $\mathcal{A}_{\text{cl}} = 2a^2\omega/3$ from (17.31), we obtain

$$\frac{\prod_n \lambda_n^0}{\prod'_n \lambda_n} = 12\omega^2, \quad (17.172)$$

just as in (17.146) and (17.129).

It is remarkable that the calculation of the ratio of the fluctuation determinants with this method requires only the knowledge of the classical solution $x_{\text{cl}}(\tau)$.

17.6 Wave Functions of Double-Well

The semiclassical result for the amplitudes

$$(a \ L/2|a \ -L/2), \quad (a \ L/2|-a \ -L/2), \quad (17.173)$$

with the endpoints situated at the bottoms of the potential wells can easily be extended to variable endpoints $x_b \neq a, x_a \neq \pm a$, as long as these are situated near the bottoms. The extended amplitudes lead to approximate particle wave functions for the lowest two states. The extension is trivial for the formula (17.34) without a kink solution. We simply multiply the fluctuation factor by the exponential $\exp(-\mathcal{A}_{\text{cl}}/\hbar)$ containing the classical action of the path from x_a to x_b . If x_a and x_b are both near one of the bottoms of the well, the entire classical orbit remains near this bottom. If the distance of the orbit from the bottom is less than $1/a\sqrt{\omega}$, the potential can be approximated by the harmonic potential $\omega^2 x^2$. Thus near the bottom at $x = a$, we have the simple approximation to the action

$$\mathcal{A}_{\text{cl}} \approx \frac{\omega}{2\hbar \sinh \omega L} \left\{ [(x_a - a)^2 + (x_b - a)^2] \cosh \omega L - 2(x_b - a)(x_a - a) \right\}. \quad (17.174)$$

For a very long Euclidean time L , this tends to

$$\mathcal{A}_{\text{cl}} \approx \frac{\omega}{2\hbar} [(x_b - a)^2 + (x_a - a)^2]. \quad (17.175)$$

The amplitude (17.34) can therefore be generalized to

$$(x_b \ L/2|x_a \ L/2) \approx \sqrt{\frac{\omega}{\pi\hbar}} e^{-(\omega/2\hbar)[(x_b-a)^2+(x_a-a)^2]} e^{-\omega L/2\hbar}.$$

This can also be written in terms of the bound-state wave functions (17.5) for $n = 0$ as

$$(x_b \ L/2|x_a \ L/2) \approx \psi_0(x_b - a)\psi_0(x_a - a)e^{-\omega L/2\hbar}. \quad (17.176)$$

For the amplitude (17.35) with the path running from one potential valley to the other, the construction is more subtle. The approximate solution is obtained by combining a harmonic classical path running from $(x_a, -L/2)$ to $(a, -L/4)$, a kink solution running from $(a, -L/4)$ to $(a, L/4)$, and a third harmonic classical path running from $(a, L/4)$ to $(x_b, L/2)$. This yields the amplitude

$$\sqrt{\frac{\omega}{\pi\hbar}} e^{-(\omega/2\hbar)(x_b-a)^2} K L e^{-\mathcal{A}_{\text{cl}}/\hbar} e^{-(\omega/2\hbar)(x_a-a)^2}. \quad (17.177)$$

Note that by patching the three pieces together, it is impossible to obtain a true classical solution. For this we would have to solve the equations of motion containing a kink with the modified boundary conditions $x(-L/2) = x_a, x(L/2) = x_b$. From the exponential convergence of $x(\tau) \rightarrow \pm a$ (like $e^{-\omega L}$) it is, however, obvious that the

true classical action differs from the action of the patched path only by exponentially small terms.

As before, the prefactor in (17.177) can be attributed to the ground state wave functions $\psi_0(x)$, and we find the amplitude for x_b close to $-a$ and x_a close to a :

$$(x_b \approx L/2 | x_a \approx -L/2) \approx \psi_0(x_b + a)\psi_0(x_a - a)KLe^{-\mathcal{A}_{cl}/\hbar}e^{-\omega L/2\hbar}. \quad (17.178)$$

17.7 Gas of Kinks and Antikinks and Level Splitting Formula

The above semiclassical treatment is correct to leading order in $e^{-\omega L}$. This accuracy is not sufficient to calculate the degree of level splitting between the two lowest states of the double well caused by tunneling. Further semiclassical contributions to the path integral must be included. These can be found without further effort. For very large L , it is quite easy to accommodate many kinks and antikinks along the τ -axis without a significant deviation of the path from the equation of motion. Due to the fast approach to the potential bottoms $x = \pm a$ near each kink or antikink solution, an approximate solution can be constructed by smoothly combining a number of individual solutions as long as they are widely separated from each other. The deviations from a true classical solution are all exponentially small if the separation distance $\Delta\tau$ on the τ -axis is much larger than the size of an individual kink (i.e., $\Delta\tau \gg 1/\omega$). The combined solution may be thought of as a very dilute gas of kinks and antikinks on the τ -axis. This situation is referred to as the *dilute-gas limit*. Consider such an “almost-classical solution” consisting of N kink-antikink solutions $x_{cl}(\tau) = \pm a \tanh[\omega(\tau - \tau_i)/2]$ in alternating order positioned at, say, $\tau_1 \gg \tau_2 \gg \tau_3 \gg \dots \gg \tau_N$ and smoothly connected at some intermediate points $\bar{\tau}_1, \dots, \bar{\tau}_{N-1}$. In the dilute-gas approximation, the combined action is given by the sum of the individual actions. For the amplitude (17.34) in which the paths connect the same potential valleys, the number of kinks must be equal to the number of antikinks. The action combined is then an even multiple of the single kink action:

$$\mathcal{A}_{2n} \approx 2n\mathcal{A}_{cl}. \quad (17.179)$$

For the amplitude (17.35), where the total number is odd, the combined action is

$$\mathcal{A}_{2n+1} \approx (2n + 1)\mathcal{A}_{cl}. \quad (17.180)$$

As the kinks and antikinks are localized objects of size $2/\omega$, it does not matter how they are distributed on the large- τ interval $[-L/2, L/2]$, as long as their distances are large compared with their size. In the dilute-gas limit, we can neglect the sizes. In the path integral, the translational degree of freedom of widely spaced N kinks and antikinks leads, via the zero-eigenvalue modes, to the multiple integral

$$\int_{-L/2}^{L/2} d\tau_N \int_{-L/2}^{\tau_N} d\tau_{N-1} \dots \int_{-L/2}^{\tau_1} d\tau_1 = \frac{L^N}{N!}. \quad (17.181)$$

The Jacobian associated with these N integrals is [see (17.112)]

$$\sqrt{\frac{\mathcal{A}_{\text{cl}}}{2\pi\hbar}}^N. \quad (17.182)$$

The fluctuations around the combined solution yield a product of the individual fluctuation factors. For a given set of connection points we have

$$\frac{1}{\sqrt{\prod'_n \lambda_n}|_{\bar{L}_N}} \frac{1}{\sqrt{\prod'_n \lambda_n}|_{\bar{L}_{N-1}}} \times \dots \times \frac{1}{\sqrt{\prod'_n \lambda_n}|_{\bar{L}_1}}, \quad (17.183)$$

where $\bar{L}_i \equiv \bar{\tau}_i - \bar{\tau}_{i-1}$ are the patches on the τ -axis in which the individual solutions are exact. Their total sum is

$$L = \sum_{i=1}^N \bar{L}_i. \quad (17.184)$$

We now include the effect of the fluctuations at the intermediate times $\bar{\tau}_i$ where the individual solutions are connected. Remembering the amplitudes (17.176), we see that the fluctuation factor for arbitrary endpoints x_i, x_{i-1} near the bottom of the potential valley must be multiplied at each end with a wave function ratio $\psi_0(x \pm a)/\psi_0(0)$. Thus we have to replace

$$\frac{1}{\sqrt{\prod'_n \lambda_n}} \rightarrow \frac{\psi_0(x_i \pm a)}{\psi_0(0)} \frac{1}{\sqrt{\prod'_n \lambda_n}} \frac{\psi_0^\dagger(x_{i-1} \pm a)}{\psi_0^\dagger(0)}. \quad (17.185)$$

The adjacent x_i -values of all fluctuation factors are set equal and integrated out, giving

$$\begin{aligned} \frac{1}{\sqrt{\prod'_n \lambda_n}} \Big|_L &= \int dx_N \dots dx_1 \frac{1}{\sqrt{\prod'_n \lambda_n}} \Big|_{L_N} \frac{\psi_0(x_{N-1} - a)\psi_0^\dagger(x_{N-1} - a)}{|\psi_0(0)|^2} \frac{1}{\sqrt{\prod'_n \lambda_n}} \Big|_{L_{N-1}} \\ &\times \dots \times \frac{\psi_0(x_1 - a)\psi_0^\dagger(x_1 - a)}{|\psi_0(0)|^2} \frac{1}{\sqrt{\prod'_n \lambda_n}} \Big|_{L_1}. \end{aligned} \quad (17.186)$$

Due to the unit normalization of the ground state wave functions, the integrals are trivial. Only the $|\psi_0(0)|^2$ -denominators survive. They yield a factor

$$\frac{1}{|\psi_0(0)|^{2(N-1)}} = \sqrt{\frac{\omega}{\pi\hbar}}^{-(N-1)}. \quad (17.187)$$

It is convenient to multiply and divide the result by the square root of the product of eigenvalues of the harmonic kink-free fluctuations, whose total fluctuation factor is known to be

$$\frac{1}{\sqrt{\prod'_n \lambda_n^0}|_L} = \sqrt{\frac{\omega}{\pi\hbar}} e^{-\omega L/2\hbar}. \quad (17.188)$$

Then we obtain the total corrected fluctuation factor

$$\sqrt{\frac{\omega}{\pi\hbar}}^{-(N-2)} e^{-\omega L/2\hbar} \sqrt{\prod_n \lambda_n^0} \Big|_L \frac{1}{\sqrt{\prod'_n \lambda_n} \Big|_{L_1}} \frac{1}{\sqrt{\prod'_n \lambda_n} \Big|_{L_2}} \times \dots \times \frac{1}{\sqrt{\prod'_n \lambda_n} \Big|_{L_N}}. \quad (17.189)$$

We now observe that the harmonic fluctuation factor (17.188) for the entire interval $\sqrt{\prod_n \lambda_n^0} \Big|_L = \sqrt{\omega/\pi\hbar} \exp(-\omega L/2\hbar)$ can be factorized into a product of such factors for each interval $\bar{\tau}_i, \bar{\tau}_{i-1}$ as follows:

$$\sqrt{\prod_n \lambda_n^0} \Big|_L = \sqrt{\frac{\omega}{\pi\hbar}}^{-(N-1)} \sqrt{\prod_n \lambda_n^0} \Big|_{L_1} \dots \sqrt{\prod_n \lambda_n^0} \Big|_{L_N}. \quad (17.190)$$

The total corrected fluctuation factor can therefore be rewritten as

$$\sqrt{\frac{\omega}{\pi\hbar}} e^{-\omega L/2\hbar} \sqrt{\frac{\prod_n \lambda_n^0}{\prod'_n \lambda_n} \Big|_{L_1}} \times \dots \times \sqrt{\frac{\prod_n \lambda_n^0}{\prod'_n \lambda_n} \Big|_{L_N}}. \quad (17.191)$$

Each eigenvalue ratio gives the L_i -independent result

$$K' = \sqrt{\frac{\prod_n \lambda_n^0}{\prod'_n \lambda_n} \Big|_{L_i}}, \quad (17.192)$$

with K' of Eq. (17.131). Expressing K' in terms of K via

$$K' = \sqrt{\frac{\mathcal{A}_{\text{cl}}}{2\pi\hbar}}^{-1} K, \quad (17.193)$$

the factors $\sqrt{\mathcal{A}_{\text{cl}}/2\pi\hbar}^{-1}$ remove the Jacobian factors (17.182) arising from the positional integrals (17.181). Altogether, the total fluctuation factor of N kink-antikink solutions with all possible distributions on the τ -axis is

$$\sqrt{\frac{\omega}{\pi\hbar}} e^{-\omega L/2\hbar} \frac{L^N}{N!} K^N e^{-N\mathcal{A}_{\text{cl}}/\hbar}. \quad (17.194)$$

Summing over all even and odd kink-antikink configurations, we thus obtain

$$(a \ L/2 | \pm a \ -L/2) = \sqrt{\frac{\omega}{\pi\hbar}} e^{-\omega L/2\hbar} \sum_{\substack{\text{even} \\ \text{odd}}} \frac{1}{N!} (K L e^{-\mathcal{A}_{\text{cl}}/\hbar})^N. \quad (17.195)$$

This can be summed up to

$$(a \ L/2 | \pm a \ -L/2) = \sqrt{\frac{\omega}{\pi\hbar}} e^{-\omega L/2\hbar} \times \frac{1}{2} \left[\exp(K L e^{-\mathcal{A}_{\text{cl}}/\hbar}) \pm \exp(-K L e^{-\mathcal{A}_{\text{cl}}/\hbar}) \right]. \quad (17.196)$$

As in the previous section, we generalize this result to positions x_b, x_a near the potential minima (with a maximal distance of the order of $\sqrt{\hbar/\omega}$). Using the classical action (17.175) and expressing it in terms of ground state wave functions, we can now add the contribution of the amplitudes for all possible configurations, arriving at

$$\begin{aligned} (x_b \ L/2 | x_a \ -L/2) &= e^{-\omega L/2\hbar} \\ &\times \left\{ \psi_0(x_b - a) \psi_0(x_a - a) \frac{1}{2} \left[\exp(K e^{-\mathcal{A}_{cl}/\hbar} L) + \exp(-K e^{-\mathcal{A}_{cl}/\hbar} L) \right] \right. \\ &\quad + \psi_0(x_b - a) \psi_0(x_a - a) \frac{1}{2} \left[\exp(K e^{-\mathcal{A}_{cl}/\hbar} L) - \exp(-K e^{-\mathcal{A}_{cl}/\hbar} L) \right] \\ &\quad \left. + (x_b \rightarrow -x_b) + (x_a \rightarrow -x_a) + (x_b \rightarrow -x_b, x_a \rightarrow -x_a) \right\}. \end{aligned} \quad (17.197)$$

The right-hand side is recombined to

$$\begin{aligned} &\frac{1}{\sqrt{2}} [\psi_0(x_b - a) + \psi_0(x_b + a)] \times \frac{1}{\sqrt{2}} [\psi_0(x_a - a) + \psi_0(x_a + a)] \\ &\quad \times \exp \left[- \left(\frac{\omega}{2} - K e^{-\mathcal{A}_{cl}/\hbar} \right) L \right] \\ &+ \frac{1}{\sqrt{2}} [\psi_0(x_b - a) - \psi_0(x_b + a)] \times \frac{1}{\sqrt{2}} [\psi_0(x_a - a) - \psi_0(x_a + a)] \\ &\quad \times \exp \left[- \left(\frac{\omega}{2} + K e^{-\mathcal{A}_{cl}/\hbar} \right) L \right]. \end{aligned} \quad (17.198)$$

Here we identify the ground state wave function as the symmetric combination of the ground state wave functions of the individual wells

$$\Psi_0(x) = \frac{1}{\sqrt{2}} [\psi_0(x - a) + \psi_0(x + a)]. \quad (17.199)$$

Its energy is

$$\mathcal{E}^{(0)} = E^{(0)} - \frac{\Delta E^{(0)}}{2} = \left(\omega/2 - K e^{-\mathcal{A}_{cl}/\hbar} \right) \hbar. \quad (17.200)$$

The first excited state has the antisymmetric wave function

$$\Psi_1(x) = \frac{1}{\sqrt{2}} [\psi_0(x - a) - \psi_0(x + a)] \quad (17.201)$$

and the slightly higher energy

$$\mathcal{E}^{(1)} = E^{(0)} + \frac{\Delta E^{(0)}}{2} = \left(\omega/2 + K e^{-\mathcal{A}_{cl}/\hbar} \right) \hbar. \quad (17.202)$$

The level splitting is therefore

$$\Delta E = 2K\hbar e^{-\mathcal{A}_{cl}/\hbar}. \quad (17.203)$$

Inserting K from (17.131), we obtain the formula

$$\Delta E = 4\sqrt{3}\sqrt{\frac{\mathcal{A}_{\text{cl}}}{2\pi\hbar}}\hbar\omega e^{-\mathcal{A}_{\text{cl}}/\hbar}, \quad (17.204)$$

with $\mathcal{A}_{\text{cl}} = (2/3)a^2\omega$. When expressing the action in terms of the height of the potential barrier $V_{\text{max}} = a^2\omega^2/8 = 3\omega\mathcal{A}_{\text{cl}}/16$, the formula reads

$$\Delta E = 4\sqrt{3}\sqrt{\frac{8V_{\text{max}}}{3\pi\omega\hbar}}\hbar\omega e^{-16V_{\text{max}}/3\hbar\omega}. \quad (17.205)$$

The level splitting decreases exponentially with increasing barrier height. Note that V_{max} is related to the coupling constant of the x^4 -interaction by $V_{\text{max}} = \omega^4/16g$.

To ensure the consistency of the approximation we have to check that the assumption of a low density gas of kinks and antikinks is self-consistent. When looking at the series (17.195) for the exponential (17.196), we see that the average number of contributing terms is given by

$$\bar{N} \approx KL e^{-\mathcal{A}_{\text{cl}}/\hbar} = \frac{\Delta E}{2\hbar}L. \quad (17.206)$$

The associated average separation between kinks and antikinks is

$$\Delta L \equiv 2\hbar/\Delta E. \quad (17.207)$$

If we compare this with their size $2/\omega$, we find the ratio

$$\frac{\text{distance}}{\text{size}} \approx \frac{\hbar\omega}{\Delta E}. \quad (17.208)$$

For increasing barrier height, the level splitting decreases and the dilution increases exponentially. Thus the dilute-gas approximation becomes exact in the limit of infinite barrier height.

17.8 Fluctuation Correction to Level Splitting

Let us calculate the first fluctuation correction to the level splitting formula (17.204). For this we write the potential (17.1) as in (5.78):

ref(5.78)
lab(5.56)
est(5.77)

$$V(x) = -\frac{\omega^2}{4}x^2 + \frac{g}{4}x^4 + \frac{1}{4g}, \quad (17.209)$$

with the interaction strength

$$g \equiv \frac{\omega^2}{2a^2}. \quad (17.210)$$

Expanding the action around the classical solution, we obtain the action of the fluctuations $y(\tau) = x(\tau) - x_{\text{cl}}(\tau)$. Its quadratic part was given in Eq. (17.40) which we write as

$$\mathcal{A}_{\text{fl}}^0 = \frac{1}{2} \int d\tau d\tau' y(\tau) \mathcal{O}_\omega(\tau, \tau') y(\tau'), \quad (17.211)$$

with the functional matrix

$$\mathcal{O}_\omega(\tau, \tau') \equiv \left[-\frac{d^2}{d\tau^2} + \omega^2 \left(1 - \frac{3}{2} \frac{1}{\cosh^2[\omega(\tau - \tau_0)/2]} \right) \right]' \delta(\tau - \tau') \quad (17.212)$$

ref(14.136) associated with the Schrödinger operator for a particle in a Rosen-Morse potential (14.136). The lab(14.125)prime indicates the absence of the zero eigenvalue in the spectral decomposition of $\mathcal{O}_\omega(\tau, \tau')$. Since est(14.159)the associated mode does not perform Gaussian fluctuations, it must be removed from $y(\tau)$ and treated separately. At the semiclassical level, this was done in Subsection 17.3.1, and the zero eigenvalue appeared in the level splitting formula (17.204) as a factor (17.112). The removal gave rise to an additional effective interaction (17.110):

$$\mathcal{A}_e^{\text{eff}} = -\hbar \log \left[1 + \mathcal{A}_{\text{cl}}^{-1} \int d\tau x'_{\text{cl}}(\tau) y'(\tau) \right]. \quad (17.213)$$

With (17.88)–(17.91), this can be rewritten after a partial integration as

$$\mathcal{A}_e^{\text{eff}} = -\hbar \log \left[1 - \sqrt{\frac{3g}{\omega^3}} \int d\tau y'_0(\tau) y(\tau) \right]. \quad (17.214)$$

The interaction between the fluctuations is

$$\mathcal{A}_{\text{fl}}^{\text{int}} = \frac{g}{4} \int d\tau [y^4(\tau) + 4x_{\text{cl}}(\tau)y^3(\tau)]. \quad (17.215)$$

In the path integral, we now perform a Taylor series expansion of the exponential $e^{-(\mathcal{A}_{\text{fl}}^{\text{int}} + \mathcal{A}_e^{\text{eff}})/\hbar}$ in powers of the coupling strength g . A perturbative evaluation of the correlation functions of the fluctuations $y(\tau)$ according to the rules of Section 3.20 produces a correction factor to the path integral

$$C = \left[1 - (I_1 + I_2 + I_3) \frac{g\hbar}{\omega^3} + \mathcal{O}(g^2) \right], \quad (17.216)$$

where I_1 , I_2 , and I_3 are the dimensionless integrals running over the entire τ -axis:

$$\begin{aligned} I_1 &= \frac{\omega^3}{4\hbar^2} \int d\tau \langle y^4(\tau) \rangle_{\mathcal{O}_\omega}, \\ I_2 &= -\frac{\omega^3 g}{2\hbar^3} \int d\tau d\tau' x_{\text{cl}}(\tau) \langle y^3(\tau) y^3(\tau') \rangle_{\mathcal{O}_\omega} x_{\text{cl}}(\tau'), \\ I_3 &= -\frac{\omega^3}{\hbar^2} \sqrt{\frac{3g}{\omega^3}} \int d\tau d\tau' y'_0(\tau) \langle y(\tau) y^3(\tau') \rangle_{\mathcal{O}_\omega} x_{\text{cl}}(\tau'). \end{aligned} \quad (17.217)$$

In order to check the dimensions we observe that the classical solution (17.28) can be written with (17.210) as $x_{\text{cl}}(\tau) = \sqrt{\omega^2/2g} \tanh[\omega(\tau - \tau_0)/2]$, while $y(\tau)$ and τ have the dimensions $\sqrt{\hbar/\omega}$ and $1/\omega$, respectively. The Dirac brackets $\langle \dots \rangle_{\mathcal{O}_\omega}$ denote the expectation with respect to the quadratic fluctuations controlled by the action (17.211). Due to the absence of a zero eigenvalue, the fluctuations are harmonic. The expectation values of the various powers of $y(\tau)$ can therefore be expanded according to the Wick rule of Section 3.17 into a sum of pair contractions involving products of Green functions

$$G'_{\mathcal{O}_\omega}(\tau, \tau') = \langle y(\tau) y(\tau') \rangle_{\mathcal{O}_\omega} = \hbar \mathcal{O}_\omega^{-1}(\tau, \tau'), \quad (17.218)$$

where $\mathcal{O}_\omega^{-1}(\tau, \tau')$ denotes the inverse of the functional matrix (17.212).

The first term in (17.217) gives rise to three Wick contractions and becomes

$$I_1 = \frac{3\omega^3}{4\hbar^2} \int d\tau G'^2_{\mathcal{O}_\omega}(\tau, \tau). \quad (17.219)$$

The integrand contains an asymptotically constant term which produces a linear divergence for large L . This divergence is subtracted out as follows:

$$I_1 = L \frac{3\omega}{16} + \frac{3\omega^3}{4\hbar^2} \int d\tau \left[G'_{\mathcal{O}_\omega}{}^2(\tau, \tau) - \frac{\hbar^2}{4\omega^2} \right]. \tag{17.220}$$

The first term is part of the first-order fluctuation correction *without* the classical solution, i.e., it contributes to the constant background energy of the classical solution. It is obtained by replacing

$$G'_{\mathcal{O}_\omega}{}^2(\tau, \tau') \rightarrow \hbar G_\omega(\tau - \tau') = \frac{\hbar}{2\omega} e^{-\omega|\tau - \tau'|} \tag{17.221}$$

[recall (3.304) and (3.249)]. In the amplitudes (17.195), the background energy changes only the exponential prefactor $e^{-\omega L/2\hbar}$ to $e^{-(1+3g\hbar/16\omega^3)\omega L/2\hbar}$ and does not contribute to the level splitting. The level splitting formula receives a correction factor

$$C' = \left[1 - c_1 \frac{g\hbar}{\omega^3} + \dots \right] = \left[1 - (I'_1 + I'_2 + I'_3) \frac{g\hbar}{\omega^3} + \mathcal{O}(g^2) \right], \tag{17.222}$$

in which all contributions proportional to L are removed. Thus I_1 is replaced by its subtracted part $I'_1 \equiv I_1 - L3\omega/16$.

The integral I_2 has 15 Wick contractions which decompose into two classes:

$$I_2 \equiv I_{21} + I_{22} = -\frac{g\omega^3}{2\hbar^3} \int d\tau d\tau' \times x_{\text{cl}}(\tau) \left[6G'_{\mathcal{O}_\omega}{}^3(\tau, \tau') + 9G'_{\mathcal{O}_\omega}(\tau, \tau)G'_{\mathcal{O}_\omega}(\tau, \tau')G'_{\mathcal{O}_\omega}(\tau', \tau') \right] x_{\text{cl}}(\tau'). \tag{17.223}$$

Each of the two subintegrals I_{21} and I_{22} contains a divergence with L which can again be found via the replacement (17.221). The subtracted integrals in (17.222) are $I'_{21} = I_{21} + \omega L/8$ and $I'_{22} = I_{22} + 3\omega L/16$. Thus, altogether, the exponential prefactor $e^{-\omega L/2\hbar}$ in the amplitudes (17.195) is changed to $e^{-[1/2+(3/16-1/8-9/16)g\hbar/\omega^3]\omega L/2\hbar} = e^{-(1/2-g\hbar/2\omega^3)\omega L/2\hbar}$, in agreement with (5.258). To compare the two expressions, we have to set $\omega = \sqrt{2}$ since the present ω is the frequency at the bottom of the potential wells whereas the ω in Chapter 5 [which is set equal to 1 in (5.258)] parametrized the negative curvature at $x = 0$.

The Wick contractions of the third term lead to the finite integral

$$I_3 = I'_3 = -3 \frac{\omega^3}{\hbar^2} \sqrt{\frac{3g}{\omega^3}} \int d\tau d\tau' y'_0(\tau) G'_{\mathcal{O}_\omega}(\tau, \tau') G'_{\mathcal{O}_\omega}(\tau', \tau') x_{\text{cl}}(\tau'). \tag{17.224}$$

The correction factor (17.216) can be pictured by means of Feynman diagrams as

$$C = 1 - 3 \left(\text{diagram 1} \right) + \frac{1}{2!} \left(6 \times \text{diagram 2} + 9 \times \text{diagram 3} \right) + 3 \times \text{diagram 4} + \mathcal{O}(g^2), \tag{17.225}$$

where the vertices and lines represent the analytic expressions shown in Fig. 17.5.

For the evaluation of the integrals we need an explicit expression for $G'_{\mathcal{O}_\omega}(\tau, \tau')$. This is easily found from the results of Section 14.4.4. In Eq. (14.139), we gave the fixed-energy amplitude $(x_b|x_a)_{E_{\mathcal{R}\mathcal{N}}, E_{\mathcal{P}\mathcal{T}}}$ solving the Schrödinger equation (14.162)

$$\left(-\frac{\hbar^2}{2\mu} \frac{d^2}{dx^2} - E_{\mathcal{R}\mathcal{N}} + \frac{\hbar^2}{2\mu} - \frac{E_{\mathcal{P}\mathcal{T}}}{\cosh^2 x} \right) (x_b|x_a)_{E_{\mathcal{R}\mathcal{N}}, E_{\mathcal{P}\mathcal{T}}} = -i\hbar\delta(x_b - x_a). \tag{17.226}$$

Inserting $E_{\mathcal{PT}} = (\hbar^2/2\mu)s(s+1)$, the amplitude reads for $x_b > x_a$

$$(x_b|x_a)_{E_{\mathcal{R}\Lambda}, E_{\mathcal{PT}}} = \frac{-i\mu}{\hbar} \Gamma(m(E_{\mathcal{R}\mathcal{M}}) - s) \Gamma(s + m(E_{\mathcal{R}\mathcal{N}}) + 1) \\ \times P_s^{-m(E_{\mathcal{R}\Lambda})}(\tanh x_b) P_s^{-m(E_{\mathcal{R}\Lambda})}(-\tanh x_a), \quad (17.227)$$

with

$$m(E_{\mathcal{R}\mathcal{N}}) = \sqrt{1 - 2\mu E_{\mathcal{R}\mathcal{M}}/\hbar^2}. \quad (17.228)$$

After a variable change $x = \omega\tau/2$ and $\hbar^2/\mu = \omega^2/2$, we set $s = 2$ and insert the energy $E_{\mathcal{R}\mathcal{N}} = -3\omega^2/4$. Then the operator in Eq. (17.226) coincides with $\mathcal{O}_\omega(\tau, \tau')$ of Eq. (17.212), and we obtain the desired Green function for $\tau > \tau'$

$$G_{\mathcal{O}_\omega}(\tau, \tau') = \frac{\hbar}{\omega} \Gamma(m-2) \Gamma(m+3) P_2^{-m}(\tanh \frac{\omega\tau}{2}) P_2^{-m}(-\tanh \frac{\omega\tau'}{2}), \quad (17.229)$$

with $m = 2$. Due to translational invariance along the τ -axis, this Green function has a pole at $E_{\mathcal{R}\mathcal{N}} = -3\omega^2/4$ which must be removed before going to this energy. The result is the subtracted Green function $G'_{\mathcal{O}_\omega}(\tau, \tau')$ which we need for the perturbation expansion. The subtraction procedure is most easily performed using the formula $G'_{\mathcal{O}_\omega} = (d/dE_{\mathcal{R}\mathcal{N}})E_{\mathcal{R}\mathcal{N}} G_{\mathcal{O}_\omega}|_{E_{\mathcal{R}\mathcal{N}} = -3\omega^2/4}$. In terms of the parameter m , this amounts to

$$G'_{\mathcal{O}_\omega}(\tau, \tau') = \frac{1}{2m} \frac{d}{dm} (m^2 - 4) G_{\mathcal{O}_\omega}(\tau, \tau') \Big|_{m=2}. \quad (17.230)$$

Inserting into (17.227) the Legendre polynomials from (14.143),

$$P_2^{-m}(z) = \frac{1}{\Gamma(1+m)} \left(\frac{1+z}{1-z} \right)^{-m/2} \left[1 - \frac{3}{1+m}(1-z) + \frac{3}{(1+m)(2+m)}(1-z)^2 \right], \quad (17.231)$$

ref(14.143)
lab(x14.166)
est(14.166)

the Green function (17.230) can be written as

$$G'_{\mathcal{O}_\omega}(\tau, \tau') = \hbar [Y_0(\tau_>) y_0(\tau_<) + y_0(-\tau_>) Y_0(-\tau_<)], \quad (17.232)$$

where $\tau_>$ and $\tau_<$ are the greater and the smaller of the two times τ and τ' , respectively, and $y_0(\tau), Y_0(\tau)$ are the wave functions

$$y_0(\tau) = -2\sqrt{6\omega} P_2^{-2} \left(-\tanh \frac{\omega\tau}{2} \right) = -\sqrt{\frac{3\omega}{8}} \frac{1}{\cosh^2 \frac{\omega\tau}{2}}, \quad (17.233)$$

Figure 17.5 Vertices and lines of Feynman diagrams for correction factor C in Eq. (17.225).

$$Y_0(\tau) = \frac{1}{2\sqrt{6\omega}} \frac{1}{2\omega m} \left\{ \frac{1}{2} \left[\frac{d}{dm} (m^2 - 4)\Gamma(m-2)\Gamma(m+3) \right] P_2^{-m} \left(\tanh \frac{\omega\tau}{2} \right) + [(m^2 - 4)\Gamma(m-2)\Gamma(m+3)] \frac{d}{dm} P_2^{-m} \left(\tanh \frac{\omega\tau}{2} \right) \right\} \Big|_{m=2}. \quad (17.234)$$

From (17.231) we see that

$$\frac{d}{dm} P_2^{-m} \left(\tanh \frac{\omega\tau}{2} \right) \Big|_{m=2} = \frac{\sqrt{6}}{144} y_0(\tau) [6(3 - 2\gamma + \omega\tau) - e^{-\omega\tau}(8 + e^{-\omega\tau})], \quad (17.235)$$

where $\gamma \approx 0.5773156649$ is the Euler-Mascheroni constant (2.469). Hence

$$Y_0(\tau) = \frac{1}{12\omega^2} y_0(\tau) [e^{-\omega\tau}(e^{-\omega\tau} + 8) - 2(2 + 3\omega\tau)]. \quad (17.236)$$

For $\tau = \tau'$, the Green function is

$$G'_{\mathcal{O}_\omega}(\tau, \tau) = \frac{\hbar}{2\omega} \frac{1}{\cosh^4 \frac{\omega\tau}{2}} \left(\cosh^4 \frac{\omega\tau}{2} + \cosh^2 \frac{\omega\tau}{2} - \frac{11}{8} \right). \quad (17.237)$$

Note that an application of the Schrödinger operator (17.212) to the wave functions $Y_0(\tau)$ and $y_0(\tau)$ produces $-y_0(\tau)$ and 0, respectively. These properties can be used to construct the Green function $G'_{\mathcal{O}_\omega}(\tau, \tau')$ by a slight modification of the Wronski method of Chapter 3. Instead of the differential equation $\mathcal{O}_\omega G(\tau, \tau') = \hbar\delta(\tau - \tau')$, we must solve the projected equation

$$\mathcal{O}'_\omega G'_{\mathcal{O}_\omega}(\tau, \tau') = \hbar[\delta(\tau - \tau') - y_0(\tau)y_0(\tau')], \quad (17.238)$$

where the right-hand side is the completeness relation without the zero-eigenvalue solution:

$$\sum_{n \neq 0} y_n(\tau)y_n(\tau') = \delta(\tau - \tau') - y_0(\tau)y_0(\tau'). \quad (17.239)$$

The solution of the projected equation (17.238) is precisely given by the combination (17.232) of the solutions $Y_0(\tau)$ and $y_0(\tau)$ with the above-stated properties.

The evaluation of the Feynman integrals I_1, I_{21}, I_{22}, I_3 is somewhat tedious and is therefore described in Appendix 17A. The result is

$$I'_1 = \frac{97}{560}, \quad I'_{21} = \frac{53}{420}, \quad I'_{22} = \frac{117}{560}, \quad I_3 = \frac{49}{20}. \quad (17.240)$$

These constants yield for the correction factor (17.222)

$$C' = \left[1 - \frac{71 g \hbar}{24 \omega^3} + \mathcal{O}(g^2) \right], \quad (17.241)$$

modifying the level splitting formula (17.204) for the ground state energy to

$$\Delta E^{(0)} = 4\sqrt{3} \sqrt{\frac{\omega^3/3g}{2\pi\hbar}} \hbar\omega e^{-\omega^3/3g\hbar - 71g\hbar/24\omega^3 + \dots}. \quad (17.242)$$

This expression can be compared with the known energy eigenvalues of the lowest two double-well states. In Section 5.15, we have calculated the variational approximation $W_3(x_0)$ to the effective classical potential of the double well and obtained for small g an energy (see Fig. 5.24) which did not yet incorporate the effects of tunneling. We now add to this the level shifts $\pm\Delta E^{(0)}/2$ from Eq. (17.242) and obtain the curves also shown in Fig. 5.24. They agree reasonably well with the Schrödinger energies.

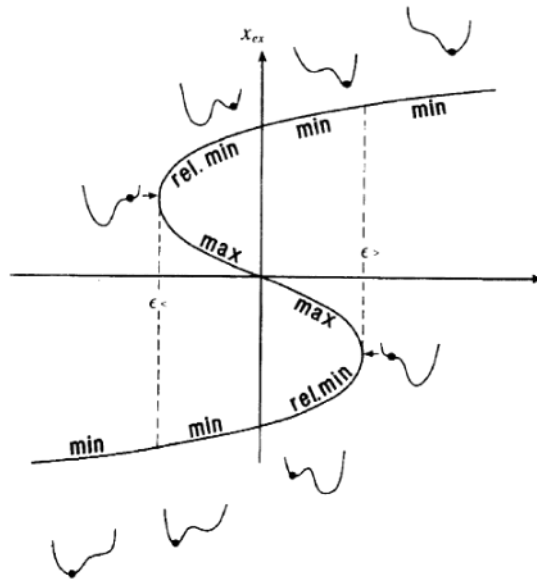

Figure 17.6 Positions of extrema x_{ex} in asymmetric double-well potential, plotted as function of asymmetry parameter ϵ . If rotated by 90° , the plot shows the typical cubic shape. Between $\epsilon_>$ and $\epsilon_<$, there are two minima and one central maximum. The branches denoted by “min” are absolute minima; those denoted by “rel min” are relative minima.

17.9 Tunneling and Decay

The previous discussion of level splitting leads us naturally to another important tunneling phenomenon of quantum theory: the decay of metastable states. Suppose that the potential is not completely symmetric. For definiteness, let us add to $V(x)$ of Eq. (17.1) a linear term which breaks the symmetry $x \rightarrow -x$:

$$\Delta V = -\epsilon \frac{x - a}{2a}. \quad (17.243)$$

For small $\epsilon > 0$, this slightly depresses the left minimum at $x = -a$. The positions of the extrema are found from the cubic equation

$$V'(x_{\text{ex}}) = \frac{\omega^2 a}{2} \left[\left(\frac{x_{\text{ex}}}{a} \right)^3 - \frac{x_{\text{ex}}}{a} - \frac{\epsilon}{\omega^2 a^2} \right] = 0. \quad (17.244)$$

They are shown in Fig. 17.6. For large ϵ , there is only one extremum, and this is always a minimum. In the region where x_{ex} has three solutions, say x_-, x_0, x_+ , the branches denoted by “rel min.” in Fig. 17.6 correspond to relative minima which lie higher than the absolute minimum. The central branch corresponds to a maximum. As ϵ decreases from large positive to large negative values, a classical particle at rest at the minimum follows the upper branch of the curve and drops to the lower branch as ϵ becomes smaller than $\epsilon_<$. Quantum-mechanically, however, there is tunneling

to the lower state before $\epsilon_<$. Tunneling sets in as soon as ϵ becomes negative, i.e., as soon as the initial minimum at x_+ comes to lie higher than the other minimum at x_- . The state whose wave packet is localized initially around x_+ decays into the lower minimum around x_- . After some finite time, the wave packet is concentrated around x_- .

A state with a finite lifetime is described analytically by an energy which lies in the lower half of the complex energy plane, i.e., which carries a negative imaginary part E^{im} . The imaginary part gives half the decay rate $\Gamma/2\hbar$. This follows directly from the temporal behavior of a wave function with an energy $E = E^{\text{re}} + iE^{\text{im}}$ which is given by

$$\psi(\mathbf{x})e^{-iEt/\hbar} = \psi(\mathbf{x})e^{-iE^{\text{re}}t/\hbar}e^{E^{\text{im}}t/\hbar} = \psi(\mathbf{x})e^{-iE^{\text{re}}t/\hbar}e^{-\Gamma t/2\hbar}. \quad (17.245)$$

The last factor leads to an exponential decay of the norm of the state

$$\int d^3x |\psi(\mathbf{x})|^2 = e^{-\Gamma t/\hbar}, \quad (17.246)$$

which shows that \hbar/Γ is the lifetime of the state. A positive sign of the imaginary part of the energy is ruled out since it would imply the state to have an exponentially growing norm.

We are now going to calculate Γ for the lowest state.⁴ If ϵ has a small negative value, the initial probability is concentrated in the potential valley around the right-hand minimum $x = x_+ \approx a$. We assume the potential barrier to be high compared to the ground state energy. Then a semiclassical treatment is adequate. In this approximation we evaluate the amplitude

$$(x_+ t_b | x_+ t_a).$$

It contains the desired information on the lifetime of the lowest state by behaving, for large $t_b - t_a$, as

$$(x_+ t_b | x_+ t_a) \sim \psi_0(0)\psi_0(0)e^{-iE^{\text{re}}(t_b-t_a)/\hbar}e^{-\Gamma(t_b-t_a)/2\hbar}.$$

As before, it is convenient to work with the Euclidean amplitude with $\tau_a = -L/2$ and $\tau_b = L/2$,

$$(x_+ L/2 | x_+ - L/2), \quad (17.247)$$

which behaves for large L as

$$(x_+ L/2 | x_+ - L/2) \sim \psi_0(0)\psi_0(0)e^{-E^{\text{re}}L/\hbar}e^{i\Gamma L/2\hbar}. \quad (17.248)$$

The classical approximation to this amplitude is dominated by the path solving the imaginary-time equation of motion which corresponds to a real-time motion in the reversed potential $-V(x)$ (see Fig. 17.7). The particle starts out at $x = x_+$ for

⁴Due to the finite lifetime this state is not stationary. For sufficiently long lifetimes, however, it is approximately stationary for a finite time.

Figure 17.7 Classical bubble solution in reversed asymmetric quartic potential for $\epsilon < 0$, starting out at the potential maximum at x_+ , crossing the valley, and returning to the maximum.

$\tau = -L/2$, traverses the minimum of $-V(x)$ at some finite value $\tau = \tau_0$, and comes back to x_+ at $\tau = L/2$. This solution is sometimes called a *bounce* solution, because of its returning to the initial point.

There exists an important application of the tunneling theory to the vaporization process of overheated water, to be discussed in Section 17.11. There the same type of solutions plays the role of *critical bubbles* triggering the phase transition. Since bounce solutions were first discussed in this context [4], we shall call them *bubble solutions* or critical bubbles.

We now proceed as in the previous section, i.e., we calculate

- a) the classical action of a bubble solution,
- b) the quadratic fluctuations around a bubble solution,
- c) the sum over infinitely many bubble solutions.

By following these three steps naively, we obtain the amplitude

$$\langle x_+ - L/2 | x_+ - L/2 \rangle = \sqrt{\frac{\omega}{\pi\hbar}} e^{-\omega L/2\hbar} \exp \left[\sqrt{\mathcal{A}_{\text{cl}}/2\pi\hbar} K' L e^{-\mathcal{A}_{\text{cl}}/\hbar} \right]. \quad (17.249)$$

Here \mathcal{A}_{cl} is the action of the bubble solution and K' collects the fluctuations of all nonzero-eigenvalue modes in the presence of the bubble solution as in (17.192):

$$K' = \sqrt{\frac{\prod_n^0 \lambda_n}{\prod_n' \lambda_n}} \Big|_L. \quad (17.250)$$

The translational invariance makes the imaginary part in the exponent proportional to the total length L of the τ -axis.

From the large- L behavior of the amplitude (17.249) we obtain the ground state energy

$$E^{(0)} = \left(\frac{\omega}{2} - \sqrt{\frac{\mathcal{A}_{\text{cl}}}{2\pi\hbar}} K' e^{-\mathcal{A}_{\text{cl}}/\hbar} \right). \quad (17.251)$$

In order to deduce the finite lifetime of the state from this formula we note that, just like the kink solution, the bubble solution has a zero-eigenvalue fluctuation

associated with the time translation invariance of the system. As before, its wave function is given by the time derivative of the bubble solution

$$y_0(\tau) = \frac{1}{\sqrt{\mathcal{A}_{\text{cl}}}} x'_{\text{cl}}(\tau). \quad (17.252)$$

In contrast to the kink solution, however, the bubble solution returns to the initial position, implying that $x_{\text{cl}}(\tau)$ has a maximum. Thus, the zero-eigenvalue mode $\propto x'_{\text{cl}}(\tau)$ contains a sign change (see Fig. 17.7). In wave mechanics, such a place is called a *node* of the wave function. A wave function with a node cannot be the ground state of the Schrödinger equation governing the fluctuations

$$\left[-\frac{d^2}{d\tau^2} + V''(x_{\text{cl}}(\tau)) \right] y_n(\tau) = \lambda_n y_n(\tau). \quad (17.253)$$

A symmetric wave function without a node must exist, which will have a lower energy than the zero-eigenvalue mode, i.e., it will have a negative eigenvalue $\lambda_{-1} < 0$. The associated wave function is denoted by $y_{-1}(\tau)$. It corresponds to a size fluctuation of the bubble solution. The nodeless wave function $y_{-1}(\tau)$ is the ground state. There can be no further negative-eigenvalue solution [5].

It is instructive to trace the origin of the negative sign within the efficient calculation method of the fluctuation determinant in Section 17.5. In contrast to the instanton treated there, the bubble solution has opposite symmetry, with an anti-symmetric translational mode $x'_{\text{cl}}(\tau)$. From this we may construct again two linearly independent solutions to find the determinant $D(\tau)$ to be used in Eq. (17.154).

The negative eigenvalue λ_{-1} enters in the calculation of the functional integral (17.46) via a fluctuation integral

$$\int \frac{d\xi_1}{\sqrt{2\pi\hbar}} e^{-(1/2\hbar)\xi_1^2\lambda_{-1}}. \quad (17.254)$$

This integral diverges. The harmonic fluctuations of the integration variable take place around a maximum; they are unstable. At first sight one might hope to obtain a correct result by a naive analytic continuation doing first the integral for $\lambda_{-1} > 0$, where it gives

$$\int \frac{d\xi_{-1}}{\sqrt{2\pi\hbar}} e^{-(1/2\hbar)\xi_{-1}^2\lambda_{-1}} = \frac{1}{\sqrt{\lambda_{-1}}}, \quad (17.255)$$

and then continuing the right-hand side analytically to negative λ_{-1} . The result would be

$$\int \frac{d\xi_{-1}}{\sqrt{2\pi\hbar}} e^{-(1/2\hbar)\xi_{-1}^2\lambda_{-1}} = \pm \frac{i}{\sqrt{|\lambda_{-1}|}}. \quad (17.256)$$

From (17.250) and (17.251) we then might expect the formula for the decay rate to be

$$\frac{1}{\hbar}\Gamma = -2i\sqrt{\frac{\mathcal{A}_{\text{cl}}}{2\pi\hbar}} K' e^{-\mathcal{A}_{\text{cl}}/\hbar} \quad (\text{wrong}), \quad (17.257)$$

Figure 17.8 Action of deformed bubble solution as function of deformation parameter ξ . The maximum at $\xi = 1$ represents the critical bubble.

with

$$K' = i|K'| = \sqrt{\frac{\prod_n^0 \lambda_n}{\prod_{n \neq 0, -1} \lambda_n}} \bigg|_L \frac{i}{\sqrt{|\lambda_{-1}|}}. \quad (17.258)$$

However, this naive manipulation does not quite give the correct result. As we shall see immediately, the error consists in a missing factor $1/2$ which has a simple physical explanation. A more careful analytic continuation is necessary to find this factor [4]. As a function of ξ , it behaves as shown in Fig. 17.8.

For a proper analytic continuation, consider a continuous sequence of paths in the functional space and parametrize it by some variable ξ . Let the trivial path

$$x(\tau) \equiv x_+ \quad (17.259)$$

correspond to $\xi = 0$, and the bubble solution

$$x(\tau) = x_{\text{cl}}(\tau) \quad (17.260)$$

to $\xi = 1$. The action of the trivial path is zero, that of the bubble solution is $\mathcal{A} = \mathcal{A}_{\text{cl}}$. As the parameter ξ increases to values > 1 , the bubble solution is deformed with a growing portion of the curve moving down towards the bottom of the lower potential valley (see Fig. 17.9). This lowers the action more and more.

There is a maximum at the bubble solution $\xi = 1$. The negative eigenvalue $\lambda_{-1} < 0$ of the fluctuation equation (17.253) is proportional to the negative curvature at the maximum. Since there exists only a single negative eigenvalue, the fluctuation determinant of the remaining modes is positive. It does not influence the process of analytic continuation. Thus we may study the analytic continuation within a simple model integral designed to have the qualitative behavior described above:

$$Z = \int_0^\infty \frac{d\xi}{\sqrt{2\pi}} e^{\lambda(\xi^2 + \alpha\xi^3)}. \quad (17.261)$$

The parameter λ stands for the negative eigenvalue λ_{-1} , whereas α is an auxiliary parameter to help perform the analytic continuation. For $\alpha > 0$, the integral is

Figure 17.9 Sequence of paths as function of parameter ξ , starting out at $\xi = 0$, with a constant solution in the metastable valley $x(\tau) \equiv x \equiv x_+$, reaching the extremal bubble solution $x(\tau) \equiv x_{\text{cl}}(\tau)$ for $\xi = 1$, and sliding more and more down towards the stable minimum for $1 < \xi \rightarrow \infty$.

stable and well defined. For $\alpha < 0$, the “Euclidean action” in the exponent $\mathcal{A} = -\lambda(\xi^2 + \alpha\xi^3)$ has a maximum at

$$\xi_m = -\frac{2}{3\alpha}. \quad (17.262)$$

Near the maximum, it has the expansion

$$\mathcal{A} = -\lambda \left[\frac{4}{27\alpha^2} - (\xi - \xi_m)^2 + \dots \right]. \quad (17.263)$$

The second term possesses a negative curvature λ which represents the negative eigenvalue λ_{-1} . The parameter α^2 plays the role of $\hbar/(-\lambda\mathcal{A}_{\text{cl}})$ in the bubble discussion, and the semiclassical expansion of the path integral corresponds to an expansion of the model integral in powers of α^2 . We want to show that the lowest two orders of this expansion yield an imaginary part

$$\text{Im } Z \sim e^{\lambda 4/27\alpha^2} \frac{1}{2} \frac{1}{\sqrt{|\lambda|}}, \quad (17.264)$$

where the exponential is the classical contribution and the factor contains the fluctuation correction. To derive (17.264), we continue the integral (17.261) analytically from $\alpha > 0$, where it is well defined, into the complex α -plane. It is convenient to introduce a new variable $t = \alpha\xi$. Then Z becomes

$$Z = \frac{1}{\alpha} \int_0^\infty \frac{dt}{\sqrt{2\pi}} \exp \left[\frac{\lambda}{\alpha^2} (t^2 + t^3) \right]. \quad (17.265)$$

Since $\lambda < 0$ this integral converges for $\alpha > 0$. To continue it to negative real values of α , we set $\alpha \equiv |\alpha|e^{i\varphi}$ and increase the angle φ from zero to $\pi/2$. While doing so,

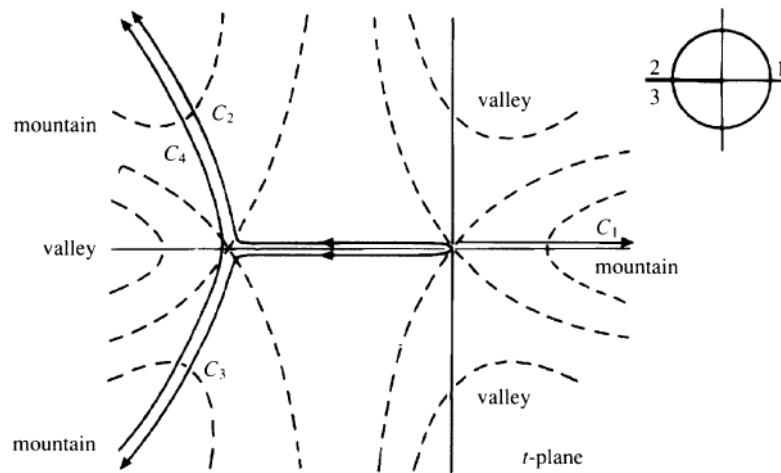

Figure 17.10 Lines of constant $\text{Re}(t^2 + t^3)$ in complex t -plane and integration contours C_i for various phase angles of α (shown in the insert) which maintain convergence of the integral (17.265).

we deform the contour in the t -plane in order to maintain convergence. Thus we introduce an auxiliary real variable t' and set

$$t = e^{i2\varphi/3} t', \quad t' \in (0, \infty). \quad (17.266)$$

The continued integral is then performed as $\int dt = e^{i2\varphi/3} \int_0^\infty dt'$. From the geometric viewpoint, the convergence is maintained for the following reason: For $\alpha > 0$, the real part of the “action” $-(\lambda/\alpha^2)(t^2 + t^3)$ has asymptotically three mountains at azimuthal angles $\varphi = 0, 2\pi/3, 4\pi/3$, and three valleys at $\varphi = \pi/3, \pi, 5\pi/3$ (see Fig. 17.10). As α is rotated by the phase $e^{i\varphi}$, these mountains rotate with $2/3$ of the angle φ anticlockwise in the t -plane. Since the contour keeps running up the same mountain, the integral continues to converge, rendering an analytic function of α . After α has been rotated to $e^{i\pi}\alpha = -\alpha$, the exponent in (17.265) takes back the original form, but the contour C runs up the mountain at $\varphi = 2\pi/3$. It does not matter which particular shape is chosen for the contour in the finite regime. We may deform the contour to the shape C_2 shown in Fig. 17.10. Next we observe that the point $-\alpha$ can also be reached by rotating α in the clockwise sense with $-\varphi$ increasing to π . In this case the final contour will run like C_3 in Fig. 17.10. The difference between the two analytic continuations is

$$\Delta Z \equiv Z(|\alpha|e^{-i\pi}) - Z(|\alpha|e^{i\pi}) = \frac{1}{|\alpha|} \int_{C_4} \frac{dt}{\sqrt{2\pi}} \exp \left\{ \frac{\lambda}{\alpha^2} (t^2 + t^3) \right\}, \quad (17.267)$$

where the contour $C_4 = C_2 - C_3$ connects the mountain at $\varphi = 4\pi/3$ with that at $\varphi = 2\pi/3$. The convergence of the combined integral is most rapid if the contour

C_4 is chosen to run along the line of steepest slope. This traverses the minimum at $t = -1$ vertically in the complex t -plane.

The fact that ΔZ is nonzero implies that the partition function has a cut in the complex α -plane along the negative real axis. Since Z is real for $\alpha > 0$, it is a real analytic function in the complex α -plane and the difference ΔZ gives a purely imaginary discontinuity across the cut:

$$\Delta Z \equiv \text{disc } Z = Z(-|\alpha| - i\eta) - Z(-|\alpha| + i\eta). \quad (17.268)$$

Let us calculate the discontinuity in the limit of small α where the dominant contribution comes from the neighborhood of the point $t = -1$. While the action at this point has a local maximum along the real t -axis, it has a local minimum along the vertical contour in the complex t -plane. For small α^2 , the integral can be found via the saddle point approximation calculating the local minimum in the quadratic approximation:

$$\begin{aligned} \text{disc } Z &\approx e^{\lambda 4/27\alpha^2} \int_{-i\infty}^{i\infty} \frac{d\xi}{\sqrt{2\pi}} e^{\lambda(\xi-\xi_0)^2} \\ &= e^{\lambda 4/27\alpha^2} \frac{i}{\sqrt{-\lambda}}. \end{aligned} \quad (17.269)$$

Due to the real analyticity of Z , the imaginary part of Z is equal to one half of this:

$$\text{Im } Z(-|\alpha| \mp i\eta) = \pm e^{\lambda 4/27\alpha^2} \frac{1}{2\sqrt{-\lambda}}. \quad (17.270)$$

The contour leading up to the extremal point adds only a real part to Z . The result (17.270) is therefore the exact leading contribution to the imaginary part in the limit $\alpha^2 \rightarrow 0$, corresponding to the semiclassical limit $\hbar \rightarrow 0$.

The exponent in (17.270) is the action of the model integral at the saddle point. The second factor produces the desired imaginary part. For a sequence of paths in functional space whose action depends on ξ as in Fig. 17.9, the result can be phrased as follows:

$$\begin{aligned} \int_0^\infty \frac{d\xi}{\sqrt{2\pi\hbar}} e^{-\mathcal{A}(\xi)/\hbar} &= \int_0^1 \frac{d\xi}{\sqrt{2\pi\hbar}} e^{-\mathcal{A}(\xi)/\hbar} + e^{-\mathcal{A}(1)/\hbar} \int_1^{1-i\infty} \frac{d\xi}{\sqrt{2\pi\hbar}} e^{-\mathcal{A}''(1)(\xi-1)^2/2\hbar} \\ &\approx \int_0^1 \frac{d\xi}{\sqrt{2\pi\hbar}} e^{-\mathcal{A}(\xi)/\hbar} + \frac{i}{2} e^{-\mathcal{A}(1)/\hbar} \frac{1}{\sqrt{-\mathcal{A}''(1)}}. \end{aligned} \quad (17.271)$$

After translating this result to the form (17.254), we conclude that the integration over the negative-eigenvalue mode

$$\int \frac{d\xi_{-1}}{\sqrt{2\pi\hbar}} e^{-\xi_{-1}^2 \lambda_{-1}/2\hbar} \quad (17.272)$$

becomes, for $\lambda_{-1} < 0$ and after a proper analytic continuation,

$$\int \frac{d\xi_{-1}}{\sqrt{2\pi\hbar}} e^{-\xi_{-1}^2 \lambda_{-1}/2\hbar} = \frac{i}{2} \frac{1}{\sqrt{|\lambda_{-1}|}}. \quad (17.273)$$

It is easy to give a physical interpretation to the factor $1/2$ appearing in this formula, in contrast to the naively continued formula (17.287). At the extremum, the classical solution, which plays the role of a critical bubble, can equally well contract or expand in size. In the first case, the path $x(\tau)$ returns towards to the original valley and the bubble disappears. In the second case, the path moves more and more towards the lower valley at $x = -x_-$, thereby transforming the system into the stable ground state. The factor $1/2$ accounts for the fact that only the *expansion* of the bubble solution produces a stable ground state, not the *contraction*.

The factor $1/2$ multiplies the naively calculated imaginary part of the partition function which becomes

$$\text{Im } Z(-|g| - i\eta) \approx \frac{1}{2} \sqrt{\mathcal{A}_{\text{cl}}/2\pi\hbar} |K'| L e^{-\mathcal{A}_{\text{cl}}/\hbar}. \quad (17.274)$$

The summation over an infinite number of bubble solutions moves the imaginary contribution to Z into the exponent as follows:

$$\text{Re } Z + \text{Im } Z = \text{Re } Z(1 + \text{Im } Z/\text{Re } Z) \xrightarrow{\text{infinite sum}} \text{Re } Z e^{\text{Im } Z/\text{Re } Z} \quad (17.275)$$

as in Eqs. (17.195), (17.196). By comparison with (17.248), we obtain the correct semiclassical *tunneling rate formula* [rather than (17.257)]:

$$\frac{1}{\hbar} \Gamma = \sqrt{\frac{\mathcal{A}_{\text{cl}}}{2\pi\hbar}} |K'| e^{-\mathcal{A}_{\text{cl}}/\hbar}, \quad (17.276)$$

where K' is the square root of the eigenvalue ratios, with the zero-eigenvalue mode removed. The prefactor has the dimension of a frequency. It defines the *bubble decay frequency*

$$\omega_{\text{att}} = \sqrt{\frac{\mathcal{A}_{\text{cl}}}{2\pi\hbar}} |K'|. \quad (17.277)$$

The exponential in (17.276) is a “quantum Boltzmann factor” which suppresses the formation of a bubble triggering the tunneling process via its expansion. The subscript indicates that the frequency plays the role of an *attempt frequency* by which the metastable state attempts to tunnel through the barrier into the stable ground state.

17.10 Large-Order Behavior of Perturbation Expansions

The above semiclassical approach of the decay rate of a metastable state has an important fundamental application. At the end of Chapter 3 we have remarked that the perturbation expansion of the anharmonic oscillator has a zero radius of convergence. This property is typical for many quantum systems. The precise form of the divergence is controlled by the tunneling rate formula (17.276), as we shall see now.

17.10.1 Growth Properties of Expansion Coefficients

As a specific, but typical, example we consider the anharmonic oscillator with the action

$$\mathcal{A} = \int_{-L/2}^{L/2} d\tau \left[\frac{\dot{x}^2}{2} - \frac{\omega^2}{2} x^2 - \frac{g}{4} x^4 \right], \quad (17.278)$$

and study the partition function as an analytic function of g . It is given by the path integral at large L (which now represents the imaginary time $\beta = 1/k_B T$, setting $\hbar = 1$)

$$Z(g) = \int \mathcal{D}x(\tau) e^{\mathcal{A}}. \quad (17.279)$$

The L -dependence of the partition function follows from the spectral representation

$$Z(g) = \sum_n e^{-E^{(n)}(g)L}, \quad (17.280)$$

where $E^{(n)}(g)$ are the energy eigenvalues of the system. In the limit $L \rightarrow \infty$, this becomes an expansion for the ground state energy $E^{(0)}(g)$. In the limit $L \rightarrow \infty$, $Z(g)$ behaves like

$$Z(g) \rightarrow e^{-E^{(0)}(g)L}, \quad (17.281)$$

exhibiting directly the ground state energy.

Since the path integral can be done exactly at the point $g = 0$, it is suggestive to expand the exponential in powers of g and to calculate the perturbation series

$$Z(g) = \sum_{k=0}^{\infty} Z_k \left(\frac{g}{\omega^3} \right)^k. \quad (17.282)$$

As shown in Section 3.20, the expansion coefficients are given by the path integrals

$$\begin{aligned} Z_k &= \frac{(-g)^k}{k!} \int \mathcal{D}x(\tau) \left[\int_{-L/2}^{L/2} d\tau x^4(\tau) \right]^k \exp \left[- \int_{-L/2}^{L/2} d\tau \left(\frac{1}{2} \dot{x}^2 + \frac{\omega^2}{2} x^2 \right) \right] \\ &= Z^{-1} \frac{(-g)^k}{k!} \left\langle \int_{-L/2}^{L/2} d\tau x^4(\tau) \right\rangle_{\omega}. \end{aligned} \quad (17.283)$$

By selecting the connected Feynman diagrams in Fig. 3.7 contributing to this path integral, we obtain the perturbation expansion in powers of g for the free energy F . In the limit $L \rightarrow \infty$, this becomes an expansion for the ground state energy $E^{(0)}(g)$, in accordance with (17.281). By following the method in Section 3.18, we find similar expansions for all excited energies $E^{(n)}(g)$ in powers of g . For $g = 0$, the energies are, of course, those of a harmonic oscillator, $E_0^{(n)} = \omega(n + 1/2)$. In general, we find the series

$$E^{(n)}(g) = \sum_{k=0}^{\infty} E_k^{(n)} \left(\frac{g}{4} \right)^k. \quad (17.284)$$

Most perturbation expansions have the grave deficiency observed in Eq. (3C.27). Their coefficients grow for large order k like a factorial $k!$ causing a vanishing radius of convergence. They can yield approximate results only for very small values of g . Then the expansion terms $E_k^{(n)} (g/4)^k$ decrease at least for an initial sequence of k -values, say for $k = 0, \dots, N$. For large k -values, the factorial growth prevails. Such series are called *asymptotic*. Their optimal evaluation requires a truncation after the smallest correction term. In general, the large-order behavior of perturbation expansions may be parametrized as

$$E_k = \gamma p^{\beta+1} k^\beta (-4a)^k (pk)! \left[1 + \frac{\gamma_1}{k} + \frac{\gamma_2}{k^2} + \dots \right], \quad (17.285)$$

where the leading term $(pk)!$ grows like

$$(pk)! = (k!)^p (p^p)^k k^{(1-p)/2} \frac{\sqrt{p}}{(2\pi)^{(p-1)/2}} [1 + \mathcal{O}(1/k)]. \quad (17.286)$$

This behavior is found by approximating $n!$ via Stirling's formula (5.204). It is easy to see that the k th term of the series (17.284) is minimal at

$$k \approx k_{\min} \equiv \frac{1}{p(a|g|)^{1/p}}. \quad (17.287)$$

This is found by applying Stirling's formula once more to $(k!)^p$ and by minimizing $\gamma(k!)^p k^{\beta'} (p^p a|g|)^k$ with $\beta' = \beta + (1-p)/2$, which yields the equation

$$p \log k + \log(p^p a|g|) + (\beta + p/2)/k + \dots = 0. \quad (17.288)$$

An equivalent way of writing (17.285) is

$$E_k = \gamma p (-4a)^k \Gamma(pk + \beta + 1) \left[1 + \frac{c_1}{pk + \beta} + \frac{c_2}{(pk + \beta)(pk + \beta - 1)} + \dots \right]. \quad (17.289)$$

The simplest example for a function with such strongly growing expansion coefficients can be constructed with the help of the exponential integral

$$E_1(g) = \int_g^\infty \frac{dt}{t} e^{-t}. \quad (17.290)$$

Defining

$$E(g) \equiv \frac{1}{g} e^{1/g} E_1(1/g) = \int_0^\infty dt \frac{1}{1+gt} e^{-t}, \quad (17.291)$$

this has the diverging expansion

$$E(g) = 1 - g + 2!g^2 - 3!g^3 + \dots + (-1)^N N!g^N + \dots \quad (17.292)$$

At a small value of g , such as $g = 0.05$, the series can nevertheless be evaluated quite accurately if truncated at an appropriate value of N . The minimal correction

is reached at $N = 1/g = 20$ where the relative error with respect to the true value $E \approx 0.9543709099$ is equal to $\Delta E/E \approx 1.14 \cdot 10^{-8}$. At a somewhat larger value $g = 0.2$, on the other hand, the optimal evaluation up to $N = 5$ yields the much larger relative error $\approx 1.8\%$, the true value being $E \approx 0.852110880$.

The integrand on the right-hand side of (17.291), the function

$$B(t) = \frac{1}{1+t}, \quad (17.293)$$

is the so-called *Borel transform* of the function $E(g)$. It has a power series expansion which can be obtained from the divergent series (17.292) for $E(g)$ by removing in each term the catastrophically growing factor $k!$. This produces the convergent series

$$B(t) = 1 - t + t^2 - t^3 + \dots, \quad (17.294)$$

which sums up to (17.293). The integral

$$F(g) = \int_0^\infty \frac{dt}{g} e^{-t/g} B(t) \quad (17.295)$$

restores the original function by reinstalling, in each term t^k , the removed $k!$ -factor.

Functions $F(g)$ of this type are called *Borel-resummable*. They possess a convergent Borel transform $B(t)$ from which $F(g)$ can be recovered with the help of the integral (17.295). The resummability is ensured by the fact that $B(t)$ has no singularities on the integration path $t \in [0, \infty)$, including a wedge-like neighborhood around it. In the above example, $B(t)$ contains only a pole at $t = -1$, and the function $E(g)$ is Borel-resummable. Alternating signs of the expansion coefficients of $F(g)$ are a typical signal for the resummability.

The best-known quantum field theory, *quantum electrodynamics*, has divergent perturbation expansions, as was first pointed out by Dyson [6]. The expansion parameter g in that theory is the *fine-structure constant*

$$\alpha = 1/137.035963(15) \approx 0.0073. \quad (17.296)$$

Fortunately, this is so small that an evaluation of observable quantities, such as the anomalous magnetic moment of the electron

$$a_e = \frac{\Delta\mu}{\mu} = \frac{1}{2} \frac{\alpha}{\pi} - 0.328\,478\,965\,7 \left(\frac{\alpha}{\pi}\right)^2 + 1.1765(13) \left(\frac{\alpha}{\pi}\right)^3 + \dots, \quad (17.297)$$

gives an extremely accurate result:

$$a_e^{\text{theor}} = (1\,159\,652\,478 \pm 140) \cdot 10^{-12}. \quad (17.298)$$

The experimental value differs from this only in the last three digits, which are 200 ± 40 . The divergence of the series sets in only after the 137th order.

A function $E(g)$ with factorially growing expansion coefficients cannot be analytic at the origin. We shall demonstrate below that it has a left-hand cut in the complex g -plane. Thus it satisfies a dispersion relation

$$E(g) = \frac{1}{2\pi i} \int_0^\infty dg' \frac{\text{disc } E(-g')}{g' + g}, \quad (17.299)$$

where $\text{disc } E(g')$ denotes the discontinuity across the left-hand cut

$$\text{disc } E(g) \equiv E(g - i\eta) - E(g + i\eta). \quad (17.300)$$

It is then easy to see that the above large-order behavior (17.289) is in one-to-one correspondence with a discontinuity which has an expansion, around the tip of the cut,

$$\text{disc } E(-|g|) = 2\pi i \gamma (a|g|)^{-(\beta+1)/p} e^{-1/(a|g|)^p} [1 + c_1(a|g|)^{1/p} + c_2(a|g|)^{2/p} + \dots]. \quad (17.301)$$

The parameters are the same as in (17.289). The one-to-one correspondence is proved by expanding the dispersion relation (17.299) in powers of $g/4$, giving

$$E_k = (-4)^k \int_0^\infty \frac{dg'}{2\pi i} \frac{1}{g'^{k+1}} \text{disc } E(-g'). \quad (17.302)$$

The expansion coefficients are given by moment integrals of the discontinuity with respect to the inverse coupling constant $1/g$. Inserting (17.301) and using the integral formula⁵

$$\int_0^\infty dg \frac{1}{|g|^{\alpha+1}} e^{-1/(a|g|)^{1/p}} = a^\alpha p \Gamma(p\alpha), \quad (17.303)$$

we indeed recover (17.289).

From the strong-coupling limit of the ground state energy of the anharmonic oscillator Eq. (5.168) we see that the discontinuity grows for large g like $g^{1/3}$. In this case, the dispersion relation (17.304) needs a subtraction and reads

$$E(g) = E(0) + \frac{g}{2\pi i} \int_0^\infty \frac{dg'}{g'} \frac{\text{disc } E(-g')}{g' + g}. \quad (17.304)$$

This does not influence the moment formula (17.302) for the expansion coefficients, except that the lowest coefficient is no longer calculable from the discontinuity. Since the lowest coefficient is known, there is no essential restriction.

17.10.2 Semiclassical Large-Order Behavior

The large-order behavior of many divergent perturbation expansions can be determined with the help of the tunneling theory developed above. Consider the potential

⁵I.S. Gradshteyn and I.M. Ryzhik, *op. cit.*, Formula 3.478.

of the anharmonic oscillator at a small negative coupling constant g (see Fig. 17.11). The minimum at the origin is obviously metastable so that the ground state has only a finite lifetime. There are barriers to the right and left of the metastable minimum, which are very high for very small negative coupling constants. In this limit, the lifetime can be calculated accurately with the semiclassical methods of the last section. The fluctuation determinant yields an imaginary part of $Z(g)$ of the form (17.270), which determines the imaginary part of the ground state energy via (17.276), which is accurate near the tip of the left-hand cut in the complex g -plane. From this imaginary part, the dispersion relation (17.302) determines the large-order behavior of the perturbation coefficients.

The classical equation of motion as a function of τ is

$$x''(\tau) - V'(x(\tau)) = 0. \quad (17.305)$$

The differential equation is integrated as in (17.26), using the first integral of motion

$$\frac{1}{2}x'^2 - \frac{1}{2}\omega^2 x^2 - \frac{g}{4}x^4 = E = \text{const}, \quad (17.306)$$

from which we find the solutions for $E = 0$

$$\tau - \tau_0 = \pm \frac{1}{\omega} \int dx \frac{1}{x \sqrt{1 - (|g|/2\omega^2)x^2}} = \mp \frac{1}{\omega} \text{arcosh} \left(\sqrt{\frac{2\omega^2}{|g|}} \frac{1}{x} \right), \quad (17.307)$$

or

$$x(\tau) = x_{\text{cl}}(\tau) \equiv \pm \sqrt{\frac{2\omega^2}{|g|} \frac{1}{\cosh[\omega(\tau - \tau_0)]}}. \quad (17.308)$$

They represent excursions towards the abysses outside the barriers and correspond precisely to the bubble solutions of the tunneling discussion in the last section. The excursion towards the abyss on the right-hand side is illustrated in Fig. 17.11. The associated action is calculated as in (17.29):

$$\begin{aligned} \mathcal{A}_{\text{cl}} &= \int_{-L/2}^{L/2} d\tau \left[\frac{1}{2}x_{\text{cl}}'^2(\tau) + V(x_{\text{cl}}(\tau)) \right] = 2 \int_0^{L/2} d\tau [x_{\text{cl}}'^2(\tau) - E] \\ &= 2 \int_0^{x_m} dx \sqrt{2(E + V)} - EL, \end{aligned} \quad (17.309)$$

where x_m is the maximum of the solution. The bubble solution has $E = 0$, so that

$$\mathcal{A}_{\text{cl}} = 2 \int_0^{x_m} dx \sqrt{2V} = \frac{4\omega^3}{3|g|}. \quad (17.310)$$

Inserting the fluctuating path $x(\tau) = x_{\text{cl}}(\tau) + y(\tau)$ into the action (17.278) and expanding it in powers of $y(\tau)$, we find an action for the quadratic fluctuations of the same form as in Eq. (17.211), but with a functional matrix

$$\begin{aligned} \mathcal{O}_\omega(\tau, \tau') &= \left[-\frac{d^2}{d\tau^2} + \omega^2 + 3gx_{\text{cl}}^2(\tau) \right]' \delta(\tau - \tau') \\ &= \left[-\frac{d^2}{d\tau^2} + \omega^2 \left(1 - \frac{6}{\cosh^2[\omega(\tau - \tau_0)]} \right) \right]' \delta(\tau - \tau'). \end{aligned} \quad (17.311)$$

Figure 17.11 Potential of anharmonic oscillator (17.278) for small negative coupling g . The ground state centered at the origin is metastable. It decays via a classical solution which makes an excursion towards the abyss as indicated by the oriented curve.

This is once more the operator of the Rosen-Morse type encountered in Eq. (17.138) with $m = \omega$, $z = 1$, and $s = 2$. The subscript ω on the operator symbol indicates the asymptotic harmonic form of the potential. The potential accommodates again two bound states with the normalized wave functions⁶ and energies (see Fig. 17.12)

$$y_0(\tau) = -\sqrt{\frac{3\omega}{2}} \frac{\sinh[\omega(\tau - \tau_0)]}{\cosh^2[\omega(\tau - \tau_0)]} \quad \text{with } \lambda_0 = 0, \quad (17.312)$$

$$y_{-1}(\tau) = \sqrt{\frac{3\omega}{4}} \frac{1}{\cosh^2[\omega(\tau - \tau_0)]} \quad \text{with } \lambda_{-1} = -3\omega^2. \quad (17.313)$$

These are the same functions as in (17.52), (17.53), apart from the fact that m is now ω rather than $\omega/2$. However, the energies are shifted with respect to the earlier case. Now the first excited state has a zero eigenvalue so that the ground state has a negative eigenvalue. This is responsible for the finite lifetime of the ground state.

The fluctuation determinant is obtained by any of the above procedures, for instance from the general formula (17.143),

$$\frac{\prod_n \lambda_n^0}{\prod_n \lambda_n} = \frac{\Gamma(\sqrt{z} - s)\Gamma(\sqrt{z} + s + 1)}{\Gamma(\sqrt{z})\Gamma(\sqrt{z} + 1)}, \quad (17.314)$$

⁶The sign of y_0 is chosen to agree with that of $x'_{c1}(\tau)$ in accordance with (17.88).

Figure 17.12 Rosen-Morse Potential for fluctuations around the classical bubble solution.

by inserting the parameters $z = 1$ and $s = 2$. The zero eigenvalue is removed by multiplying this with $(z - 1)\omega^2$, resulting in the eigenvalue ratio

$$\frac{\prod_n \lambda_n^0}{\prod'_n \lambda_n} = \lim_{z \rightarrow 1} (\sqrt{z} - 1)(\sqrt{z} + 1)\omega^2 \left[\frac{\Gamma(\sqrt{z} - 2)\Gamma(\sqrt{z} + 3)}{\Gamma(\sqrt{z})\Gamma(\sqrt{z} + 1)} \right] = -12\omega^2. \quad (17.315)$$

The negative sign due to the negative-eigenvalue solution in (17.313) accounts for the instability of the fluctuations.

Using formula (17.274), we find the imaginary part of the partition function

$$\text{Im } Z(-|g| - i\eta) \approx \sqrt{\frac{6}{\pi}} \sqrt{\frac{4\omega^3}{3|g|}} \omega L e^{-4\omega^3/3|g|} e^{-\omega L/2}. \quad (17.316)$$

After summing over all bubble solutions, as in (17.275), we obtain the imaginary part of the ground state energy

$$\text{Im } E^{(0)}(-|g| - i\eta) = -\omega \sqrt{\frac{6}{\pi}} \sqrt{\frac{4\omega^3}{3|g|}} e^{-4\omega^3/3|g|}. \quad (17.317)$$

A comparison of this with (17.301) fixes the growth parameters of the large-order perturbation coefficients to

$$a = 3/4\omega^3, \quad \beta = -\frac{1}{2}, \quad \gamma = -\frac{\omega}{\pi} \sqrt{\frac{6}{\pi}}, \quad p = 1. \quad (17.318)$$

Recalling the one-to-one correspondence between (17.301) and (17.289), we see that the large-order behavior of the perturbation coefficients of the ground state energy $E^{(0)}(g)$ is

$$E_k^{(0)} = -\frac{\omega}{\pi} \sqrt{\frac{6}{\pi}} (-3/\omega^3)^k \Gamma(k + 1/2). \quad (17.319)$$

It is just as easy to find the large- k behavior of the excited states. Their decay is triggered by a periodic classical solution with a very long but finite Euclidean period L , which moves back and forth between positions $x_< \neq 0$ and $x_> < \sqrt{2\omega^2/|g|}$. Its action is approximately given by

$$\mathcal{A}'_{\text{cl}} \approx \frac{4\omega^3}{3|g|}(1 - 12e^{-\omega L}). \quad (17.320)$$

In comparison with the limit $L \rightarrow \infty$, the Boltzmann-like factor $e^{-\mathcal{A}'_{\text{cl}}}$ of this solution is replaced by

$$e^{-\mathcal{A}'_{\text{cl}}} = e^{-\mathcal{A}_{\text{cl}}} \sum_{n=0}^{\infty} \mathcal{A}_{\text{cl}}^n \frac{12^n}{n!} e^{-n\omega L}. \quad (17.321)$$

The exponentials in the sum raise the reference energies in the imaginary part of $Z(-|g| - i\eta)$ in (17.316) from $\omega/2$ to $\omega(n+1/2)$. The imaginary parts for the energies to the n th excited states become

$$\text{Im } E^{(n)}(-|g| - i\eta) = -\frac{12^n}{n!} \omega \sqrt{\frac{6}{\pi}} \sqrt{\frac{4\omega^3}{3|g|}}^{1+2n} e^{-4\omega^3/3|g|}, \quad (17.322)$$

implying an asymptotic behavior of the perturbation coefficients:

$$E_k^{(n)} = -\frac{\omega}{\pi} \sqrt{\frac{6}{\pi}} \frac{12^n}{n!} (-3/\omega^3)^k \Gamma(k+n+1/2). \quad (17.323)$$

It is worth mentioning that within the semiclassical approximation, the dispersion integrals for the energies can be derived directly from the path integral (17.279). This can obviously be rewritten as

$$\begin{aligned} Z(g) &= \int_{-i\infty}^{i\infty} \frac{d\lambda}{2\pi i} \int_0^\infty \frac{da}{4} e^{-(ga+\lambda a)/4} \\ &\times \int \mathcal{D}x(\tau) \exp \left\{ -\int_{L/2}^{L/2} d\tau \left[\frac{1}{2}x'^2 + \frac{\omega^2}{2}x^2 - \frac{\lambda}{4}x^4 \right] \right\}. \end{aligned} \quad (17.324)$$

The integration over λ generates a δ -function $4\delta(\int d\tau x^4(\tau) - a)$ which eliminates the additionally introduced a -integration. The integral over a is easily performed. It yields a factor $1/(\lambda+g)$, so that we obtain the integral formula

$$Z(g) = \int_{-i\infty}^{i\infty} \frac{d\lambda}{2\pi i} \frac{1}{\lambda+g} Z(-\lambda). \quad (17.325)$$

The integrand has a pole at $\lambda = -g$ and a cut on the positive real λ -axis. We now deform the contour of integration in λ until it encloses the cut tightly in the clockwise sense. In the semiclassical approximation, the discontinuity across the cut is given by Eq. (17.316), i.e., with the present variable λ :

$$\text{Im } Z(-|\lambda| - i\eta) = \sqrt{\frac{6}{\pi}} \sqrt{\frac{4\omega^3}{3\lambda}} e^{-4\omega^3/3\lambda} e^{-\omega L/2}. \quad (17.326)$$

On the upper branch of the cut, $\sqrt{\lambda}$ is positive, on the lower negative. Thus we arrive at a simple dispersion integral from $\lambda = 0$ to $\lambda = \infty$:

$$Z(g) = 2\omega \int_0^\infty \frac{d\lambda}{2\pi} \frac{1}{\lambda + g} \sqrt{\frac{6}{\pi}} \sqrt{\frac{4\omega^3}{3\lambda}} e^{-4\omega^3/3\lambda} e^{-\omega L/2}. \quad (17.327)$$

For the ground state energy, this implies

$$E^{(0)}(g) = -2\omega \int_0^\infty \frac{d\lambda}{2\pi} \frac{1}{\lambda + g} \sqrt{\frac{6}{\pi}} \sqrt{\frac{4\omega^3}{3\lambda}} e^{-4\omega^3/3\lambda}. \quad (17.328)$$

Of course, this expression is just an approximation, since the integrand is valid only at small λ . In fact, the integral converges only in this approximation. If the full imaginary part is inserted, the integral diverges. We shall see below that for large λ , the imaginary part grows like $\lambda^{1/3}$. Thus a subtraction is necessary. A convergent integral representation exists for $E^{(0)}(g) - E^{(0)}(0)$. With $E^{(0)}(0)$ being equal to $\omega/2$, we find the convergent dispersion integral

$$E^{(0)}(g) = \frac{\omega}{2} + 2\omega g \int_0^\infty \frac{d\lambda}{2\pi} \frac{1}{\lambda(\lambda + g)} \sqrt{\frac{6}{\pi}} \sqrt{\frac{4\omega^3}{3\lambda}} e^{-4\omega^3/3\lambda}. \quad (17.329)$$

The subtraction is advantageous also if the initial integral converges since it suppresses the influence of the large- λ regime on which the semiclassical tunneling calculation contains no information.

After substituting $\lambda \rightarrow 4g/3t\omega^3$, the integral (17.329) is seen to become a Borel integral of the form (17.295).

By expanding $1/(\lambda + g)$ in a power series in g

$$\frac{1}{\lambda + g} = \sum_{k=0}^{\infty} (-1)^k g^k \lambda^{-k-1}, \quad (17.330)$$

we obtain the expansion coefficients as the moment integrals of the imaginary part as a function of $1/g$:

$$E_k^{(0)} = -2\omega (-4)^k \int_0^\infty \frac{d\lambda}{2\pi} \frac{1}{\lambda^{k+1}} \sqrt{\frac{6}{\pi}} \sqrt{\frac{4\omega^3}{3\lambda}} e^{-4\omega^3/3\lambda}. \quad (17.331)$$

This leads again to the large- k behavior (17.319).

The direct treatment of the path integral has the virtue that it can be generalized also to systems which do not possess a Borel-resummable perturbation series. As an example, one may derive and study the integral representation for the level splitting formula in Section 17.7.

17.10.3 Fluctuation Correction to the Imaginary Part and Large-Order Behavior

It is instructive to calculate the first nonleading term $c_1 a|g|$ in the imaginary part (17.301), which gives rise to a correction factor $1 + c_1/k$ in the large-order behavior

(17.289). As in Section 17.8, we expand the action around the classical solution. The interaction between the fluctuations $y(\tau)$ is the same as before in (17.215). The quadratic fluctuations are now governed by the differential operator

$$\mathcal{O}_\omega(\tau, \tau') = \left[-\frac{d^2}{d\tau^2} + \omega^2 \left(1 - \frac{6}{\cosh^2 \omega(\tau - \tau_0)} \right) \right]' \delta(\tau - \tau'), \quad (17.332)$$

the prime indicating the absence of the zero eigenvalue. Its removal gives rise to the factor

$$\mathcal{A}_e^{\text{eff}} = -\hbar \log \left[1 - \sqrt{\frac{3|g|}{4\omega^3}} \int d\tau y'_0(\tau) y(\tau) \right]. \quad (17.333)$$

After expanding, in the path integral, the exponential $e^{-(\mathcal{A}_h^{\text{int}} + \mathcal{A}_e^{\text{eff}})/\hbar}$ in powers of the interaction up to the second order, a perturbative evaluation of the correlation functions of the fluctuations $y(\tau)$ according to the rules of Section 3.20 yields a correction factor

$$C = \left[1 + (I_1 + I_2 + I_3) \frac{|g|\hbar}{\omega^3} + \mathcal{O}(g^2) \right], \quad (17.334)$$

with the same τ -integrals as in Eqs. (17.217), (17.219), (17.223), and (17.224), after replacing g by $|g|$. The correction parameter C has again a diagrammatic expansion (17.225), where the vertices stand for the same analytic expressions as in Fig. 17.5, except for the third vertex, which is now

$$\text{---} \times \text{---} \text{---} \text{---} \quad \sqrt{\frac{3|g|}{4\omega^3}} y'_0(\tau). \quad (17.335)$$

The lines represent the subtracted Green function

$$G'_{\mathcal{O}_\omega}(\tau, \tau') = \langle y(\tau) y(\tau') \rangle_{\mathcal{O}_\omega} = \hbar \mathcal{O}_\omega^{-1}(\tau, \tau'), \quad (17.336)$$

where $\mathcal{O}_\omega^{-1}(\tau, \tau')$ is the inverse of the functional matrix (17.332).

In contrast to the level splitting calculation in Section 17.8, only the integral I_1 requires a subtraction,

$$I_1 = \frac{3\omega^3}{4\hbar^2} \int d\tau G'_{\mathcal{O}_\omega}{}^2(\tau, \tau) = L \frac{3\omega}{16} + \frac{3\omega^3}{4\hbar^2} \int d\tau \left[G'_{\mathcal{O}_\omega}{}^2(\tau, \tau) - \frac{\hbar^2}{4\omega^2} \right], \quad (17.337)$$

and Eq. (17.334) assumes that I_1 is subtracted, i.e., I_1 should be replaced by $I'_1 \equiv I_1 - L3\omega/16$. The correction factor for the tunneling rate reads, therefore,

$$C' = \left[1 + (I'_1 + I_2 + I_3) \frac{|g|\hbar}{\omega^3} + \mathcal{O}(g^2) \right]. \quad (17.338)$$

The subtracted integral contributes only to the real part of the ground state energy which we know to be $(1/2 + 3g\hbar/16\omega^3)\hbar\omega$.

As in Section 17.8, the explicit Green function $G'_{\mathcal{O}_\omega}(\tau, \tau')$ is found from the amplitude (17.227). By a change of variables $x = \omega\tau$ and $\hbar^2/2\mu = \omega^2$, setting $s = 2$, the Schrödinger operator in (17.226) coincides with that in (17.212), provided we set $E_{\mathcal{R}\mathcal{M}} = 0$. The amplitude (17.227) then yields the Green functions for $\tau > \tau'$

$$G_{\mathcal{O}_\omega}(\tau, \tau') = \frac{\hbar}{2\omega} \Gamma(m-2)\Gamma(m+3) \times P_2^{-m}(\tanh \omega\tau) P_2^{-m}(-\tanh \omega\tau'), \quad (17.339)$$

with $m = 1$. Due to translational invariance along the τ -axis, this Green function has a pole at $E_{\mathcal{R}\mathcal{M}} = 0$ [just like the Green function (17.229)]. The pole must be removed before going to this energy, and the result is the subtracted Green function $G'_{\mathcal{O}_\omega}(\tau, \tau')$, given by

$$G'_{\mathcal{O}_\omega}(\tau, \tau') = \frac{1}{2m} \frac{d}{dm} (m^2 - 1) G_{\mathcal{O}_\omega}(\tau, \tau') \Big|_{m=1}. \quad (17.340)$$

Using (17.231), we find the subtracted Green function

$$G'_{\mathcal{O}_\omega}(\tau, \tau') = \hbar [Y_0(\tau_>) y_0(\tau_<) + y_0(-\tau_>) Y_0(-\tau_<)], \quad (17.341)$$

with

$$y_0(\tau) = 2\sqrt{\frac{3\omega}{2}} P_2^{-1}(-\tanh \omega\tau) = -\sqrt{\frac{3\omega}{2}} \frac{\sinh \omega\tau}{\cosh^2 \omega\tau}, \quad (17.342)$$

$$\begin{aligned} Y_0(\tau) &= \sqrt{\frac{2}{3\omega}} \frac{1}{8\omega m} \left\{ \frac{1}{2} \left[\frac{d}{dm} (m^2 - 1) \Gamma(m-2)\Gamma(m+3) \right] P_2^{-m}(\tanh \omega\tau) \right. \\ &\quad \left. + [(m^2 - 1)\Gamma(m-2)\Gamma(m+3)] \frac{d}{dm} P_2^{-m}(\tanh \omega\tau) \right\} \Big|_{m=1} \\ &= -\sqrt{\frac{2}{3\omega^3}} \left[\frac{3}{4} \frac{1}{\cosh \omega\tau} + \left(-\frac{3}{4} \omega\tau - \frac{1}{8} \right) \frac{\sinh \omega\tau}{\cosh^2 \omega\tau} - \frac{1}{4} e^{-\omega\tau} \right]. \end{aligned} \quad (17.343)$$

For $\tau = \tau'$

$$G'_{\mathcal{O}_\omega}(\tau, \tau) = \frac{\hbar}{2\omega} \frac{1}{\cosh^2 \omega\tau} (\cosh^2 \omega\tau - 1)(\cosh^2 \omega\tau - 1/2). \quad (17.344)$$

The evaluation of the integrals $I'_1, I_{21}, I_{22}, I_3$ proceeds as in Section 17.8 (performed in Appendix 17A), yielding [7]

$$I'_1 = -\frac{11 \cdot 29}{2^4 \cdot 5 \cdot 7}, \quad I_{21} = -\frac{71}{2^5 \cdot 3 \cdot 7}, \quad I_{22} = \frac{3 \cdot 13}{2^4 \cdot 7}, \quad I_3 = -\frac{53}{2^4 \cdot 5}. \quad (17.345)$$

The correction factor (17.338) is therefore

$$C' = \left[1 - \frac{95}{72} \frac{3|g|\hbar}{4\omega^3} + \mathcal{O}(g^2) \right]. \quad (17.346)$$

Using the one-to-one correspondence between (17.289) and (17.301), this yields the large- k behavior of the expansion coefficients of the ground state energy:

$$E_k^{(0)} = -\frac{\omega}{\pi} \sqrt{\frac{6}{\pi}} (-3/\omega^3)^k \Gamma(k+1/2) [1 - 95/72k + \dots]. \quad (17.347)$$

17.10.4 Variational Approach to Tunneling. Perturbation Coefficients to All Orders

The semiclassical calculations of tunneling amplitudes are valid only for very high barriers. It is possible to remove this limitation with the help of a variational approach [8] similar to the one described in Chapter 5. For simplicity, we discuss here only the case of an anharmonic oscillator at zero temperature. For the lowest energy levels we shall derive highly accurate imaginary parts over the entire left-hand cut in the coupling constant plane. The accuracy can be tested by inserting these imaginary parts into the dispersion relation (17.329) to recover the perturbation coefficients of the energies. These turn out to be in good agreement with the exact ones to all orders.

For the path integral of the anharmonic oscillator

$$Z(g) = \int \mathcal{D}x(\tau) \exp \left\{ - \int_{-L/2}^{L/2} d\tau \left[\frac{1}{2} \dot{x}'^2 + \frac{\omega^2}{2} x^2 + \frac{g}{4} x^4 \right] \right\}, \quad (17.348)$$

the variational energy (5.32) at zero temperature is given by

$$W_1 = \frac{\Omega}{2} + \frac{\omega^2 - \Omega^2}{2} a^2 + \frac{3g}{4} a^4, \quad (17.349)$$

ref(5.32)
lab(5.36)
est(5.43)

with $a^2 = 1/2\Omega$. We have omitted the path average argument x_0 since, by symmetry of the potential, the minimum lies at $x_0 = 0$. The energy has to be extremized in Ω^2 . This yields the cubic equation $\Omega^3 - \omega^2\Omega - 3g/2 = 0$. The physically relevant solution starts out with ω at $g = 0$ and has two branches: For $g \in (-g^{(0)}, 0)$ with $g^{(0)} = 4\omega^3/9\sqrt{3}$ [compare (5.163)], it is given by

$$\Omega = \frac{2\omega}{\sqrt{3}} \cos \left[\frac{\pi}{3} - \frac{1}{3} \arccos(-g/g^{(0)}) \right]. \quad (17.350)$$

For large negative coupling constants $g < -g^{(0)}$, the solution is

$$\Omega^{\text{re}} = \frac{\omega}{\sqrt{3}} \cosh(\gamma/3), \quad \Omega^{\text{im}} = \omega \sinh(\gamma/3); \quad \gamma = \text{arcosh}(-g/g^{(0)}). \quad (17.351)$$

In this regime, the ground state energy acquires an imaginary part

$$\text{Im } W_1 = \frac{1}{4} \Omega^{\text{i}} (1 - 1/|\Omega|^2) - \frac{3g}{4} \Omega^{\text{re}} \Omega^{\text{im}} / 2|\Omega|^4. \quad (17.352)$$

This imaginary part describes the instability of the system to *slide* down into the two abysses situated at large positive and negative x . In this regime of coupling constants, the barriers to the right and left of the origin are no obstacle to the decay since they are smaller than the zero-point energy.

In the first regime of small negative coupling constants $g \in (-g^{(0)}, 0)$, the barriers are high enough to prevent at least one long-lived ground state from sliding down. Its energy is approximately given by the minimum of (17.349). It can decay towards

the abysses via an extremal excursion across the trial potential $\Omega^2 x^2/2 + gx^4/4$. The associated bubble solution reads, according to (17.308),

$$x(\tau) = x_{\text{cl}}(\tau) \equiv \pm \sqrt{2\Omega^2/|g|} \frac{1}{\cosh[\Omega(\tau - \tau_0)]}. \quad (17.353)$$

It has the action $\mathcal{A}_{\text{cl}} = 4\Omega^3/3|g|$. Its fluctuation determinant is given by (17.315), if ω is replaced by the trial frequency Ω . Translations contribute a factor $\beta\Omega\sqrt{\mathcal{A}_{\text{cl}}/2\pi}$. Thus, the partition function has an imaginary part

$$\text{Im } Z(-|g| - i\eta) = \beta\Omega \sqrt{\frac{6}{\pi}} \sqrt{\frac{4\Omega^3}{3|g|}} e^{-\beta\Omega/2 - 4\Omega^3/3|g|}. \quad (17.354)$$

In the variational approach, this replaces the semiclassical expression (17.316), which will henceforth be denoted by $Z_{\text{sc}}^{\text{im}}(g)$.

The expression (17.354) receives fluctuation corrections. To lowest order, they produce a factor $\exp(-\langle \mathcal{A}_{\text{fl,tot}}^{\text{int}} \rangle_{\mathcal{O}_\Omega})$, where the action $\mathcal{A}_{\text{fl,tot}}^{\text{int}}$ contains the interaction terms (17.215) and (17.213) of the fluctuations, with ω replaced by Ω , plus additional terms arising from the variational ansatz. They compensate for the fact that we are using the trial potential $\Omega^2 x^2/2$ rather than the proper $\omega^2 x^2/2$ as the zeroth-order potential for the perturbation expansion. These compensation terms have the action

$$\begin{aligned} \mathcal{A}_{\text{fl,var}}^{\text{int}} &= \int_{-\infty}^{\infty} d\tau \frac{\omega^2 - \Omega^2}{2} x^2(\tau) \\ &= \int_{-\infty}^{\infty} d\tau \frac{\omega^2 - \Omega^2}{2} [x_{\text{cl}}^2(\tau) + 2x_{\text{cl}}(\tau)y(\tau) + y^2(\tau)]. \end{aligned} \quad (17.355)$$

The expectations $\langle \dots \rangle_{\mathcal{O}_\Omega}$ in the perturbation correction are calculated with respect to fluctuations governed by the operator (17.332), in which ω is replaced by Ω . As before, all correlation functions are expanded by Wick's rule into sums of products of the simple correlation functions $G'_{\mathcal{O}_\Omega}(\tau, \tau')$ of (17.336). Using the integral formula (17.54), we have

$$\int_{-\infty}^{\infty} d\tau x_{\text{cl}}^2(\tau) = 4\Omega/|g|. \quad (17.356)$$

The expectation of $\int_{-\infty}^{\infty} d\tau y(\tau)^2$ is found with the help of (17.344) as

$$\begin{aligned} \int_{-\infty}^{\infty} d\tau \langle y^2(\tau) \rangle_{\mathcal{O}_\Omega} &= L \frac{1}{2\Omega} + \frac{1}{\Omega} \int_{-\infty}^{\infty} d\tau [G'_{\mathcal{O}_\Omega}(\tau, \tau) - 1/2] \\ &= L \frac{1}{2\Omega} - \frac{7}{6\Omega^2}. \end{aligned} \quad (17.357)$$

The second term can be obtained quite simply by differentiating the logarithm of (17.314) with respect to $\Omega^2 z$.

The linearly divergent term $L/2\Omega$ contributes to the earlier-calculated term proportional to L in the integral (17.337) (with ω replaced by Ω); together they yield

L -times W_1 of (17.349). Thus we can remove a factor e^{-LW_1} from $\text{Im } Z$, write Z as $\approx \text{Re } Z e^{\text{Im } Z / \text{Re } Z} = e^{-LW_1 + \text{Im } Z / \text{Re } Z}$ [as in (17.275)], and deduce the imaginary part of the energy from the exponent.

We now go over to the cumulants in accordance with the rules of perturbation theory in Eqs. (3.483)–(3.487) involving the integrals (17.217) (with g and ω replaced by $|g|$ and Ω , respectively). Using (17.345) we find the correction factor $e^{-A_0 - A_1}$ with

$$A_0 = \frac{95}{96} \frac{|g|}{\Omega^3}, \quad A_1 = \frac{1}{2}(\omega^2 - \Omega^2) \left(\frac{4\Omega}{|g|} - \frac{7}{6\Omega^2} \right). \quad (17.358)$$

If we want to find all terms contributing to the imaginary part up to the order g , we must continue the perturbation expansion to the next order. This yields a further factor

$$\exp \left\{ \frac{1}{2} [\langle \mathcal{A}_{\text{fl,tot}}^{\text{int}2} \rangle_{\mathcal{O}_\Omega} - \langle \mathcal{A}_{\text{fl,tot}}^{\text{int}} \rangle_{\mathcal{O}_\Omega}^2] \right\} = \exp(-A_2 - A_3 - A_4), \quad (17.359)$$

with the integrals

$$\begin{aligned} A_2 &= -\frac{1}{2}(\omega^2 - \Omega^2)^2 \int d\tau d\tau' x_{\text{cl}}(\tau) \langle y(\tau) y(\tau') \rangle_{\mathcal{O}_\Omega} x_{\text{cl}}(\tau'), \\ A_3 &= -(\omega^2 - \Omega^2) \sqrt{\frac{3|g|}{4\Omega^3}} \int d\tau d\tau' y'_0(\tau) \langle y(\tau) y(\tau') \rangle_{\mathcal{O}_\Omega} x_{\text{cl}}(\tau'), \\ A_4 &= (\omega^2 - \Omega^2) |g| \int d\tau d\tau' x_{\text{cl}}(\tau) \langle y(\tau) y^3(\tau') \rangle_{\mathcal{O}_\Omega} x_{\text{cl}}(\tau'). \end{aligned} \quad (17.360)$$

Performing the Wick contractions in the correlation functions, the integrals are conveniently rewritten as

$$\begin{aligned} A_2 &= -\frac{1}{2}(\omega^2 - \Omega^2)^2 \frac{1}{\Omega|g|} a_2, \\ A_3 &= -(\omega^2 - \Omega^2) \frac{1}{\Omega^2} a_3, \\ A_4 &= (\omega^2 - \Omega^2) \frac{1}{\Omega^2} a_4, \end{aligned} \quad (17.361)$$

where a_2, a_3, a_4 are given by

$$\begin{aligned} a_2 &= |g| \Omega \int d\tau d\tau' x_{\text{cl}}(\tau) G'_{\mathcal{O}_\Omega}(\tau, \tau') x_{\text{cl}}(\tau'), \\ a_3 &= \Omega^2 \sqrt{\frac{3|g|}{4\Omega^3}} \int d\tau d\tau' y'_0(\tau) G'_{\mathcal{O}_\Omega}(\tau, \tau') x_{\text{cl}}(\tau'), \\ a_4 &= 3|g| \Omega^2 \int d\tau d\tau' x_{\text{cl}}(\tau) G'_{\mathcal{O}_\Omega}(\tau, \tau') G'_{\mathcal{O}_\Omega}(\tau', \tau') x_{\text{cl}}(\tau'). \end{aligned} \quad (17.362)$$

In terms of these, the imaginary part of the energy reads

$$\begin{aligned} \text{Im } E(-|g| - i\eta) &= -\Omega \sqrt{\frac{6}{\pi}} \sqrt{\frac{4\Omega^3}{3|g|}} e^{-4\Omega^3/3|g| - c_1 3|g|/4\Omega^3} \\ &\times \exp \left[-\frac{\omega^2 - \Omega^2}{2} \left(\frac{4\Omega}{|g|} - \frac{7}{6\Omega^2} - 2\frac{a_3 - a_4}{\Omega^2} \right) + \frac{(\omega^2 - \Omega^2)^2}{2\Omega|g|} a_2 \right], \end{aligned} \quad (17.363)$$

evaluated at the Ω -value (17.350).

To best visualize the higher-order effect of fluctuations, we factorize (17.363) into the semiclassical part (17.317) and a correction factor $\varepsilon_i(g)$,

$$\text{Im } E(-|g| - i\eta) = -\omega \sqrt{\frac{6}{\pi}} \sqrt{\frac{4\omega^3}{3|g|}} e^{-4\omega^3/3|g|} \varepsilon_i(g), \tag{17.364}$$

where

$$\begin{aligned} \varepsilon_i(g) = & \left(\frac{\Omega}{\omega}\right)^{5/2} \exp \left[-4 \frac{\Omega^3 - \omega^3}{3|g|} - c_1 \frac{3|g|}{4\Omega^3} \right. \\ & \left. - \frac{\omega^2 - \Omega^2}{2} \left(\frac{4\Omega}{|g|} - \frac{7}{6\Omega^2} - 2 \frac{a_3 - a_4}{\Omega^2} \right) + \frac{(\omega^2 - \Omega^2)^2}{2\Omega|g|} a_2 \right]. \end{aligned} \tag{17.365}$$

The calculation of the integrals (17.362) proceeds as in Appendix 17A, yielding

Figure 17.13 Reduced imaginary part of lowest three energy levels of anharmonic oscillator for negative couplings plotted against $g' \equiv g/\omega^3$. The semiclassical limit corresponds to $\varepsilon_i \equiv 1$. The small- $|g'|$ branch is due to tunneling, the large- $|g'|$ branch to direct decay (sliding). Solid and dotted curves show the imaginary parts of the variational approximations W_1 and W_3 , respectively; dashed straight lines indicate the exactly known slopes.

$$a_2 = -1, a_3 = 3/4, a_4 = 1/12.$$

The result is shown in Fig. 17.13. The slope of $\varepsilon_i(g)$ at $g = 0$ maintains the first-order value $c_1 3/4 = 95/96$, i.e., the additional terms in the exponent of (17.365) cancel each other to first order in g .

There exists a short derivation of this result using the same method as in the ref(5.190) derivation of Eq. (5.190). We take the fluctuation-corrected semiclassical approxi- lab(5.r0) est(5.149)

mation at the frequency ω

$$\operatorname{Im} E(-|g| - i\eta) = -\omega \sqrt{\frac{6}{\pi}} \sqrt{\frac{4\omega^3}{3|g|}} e^{-4\omega^3/3|g| - 3c_1|g|/4\omega^3}, \quad (17.366)$$

move the ω -dependent prefactor into the exponent with the help of the logarithm, replace everywhere ω by $\sqrt{\Omega^2 - (\Omega^2 - \omega^2)} = \sqrt{\Omega^2 - gr^2/2}$ with $r^2 = 2(\Omega^2 - \omega^2)/g$, and expand the exponent in powers of g including all orders of g to which the exponent of (17.366) is known (treating r as a quantity of order unity). This leads again to (17.364) with (17.365).

The imaginary part is inserted into the dispersion relation (17.329) and yields for positive g the energy

$$E^{(0)}(g) = \frac{\omega}{2} + 2\omega g \int_0^\infty \frac{d\lambda}{2\pi} \frac{1}{\lambda(\lambda + g)} \sqrt{\frac{6}{\pi}} \sqrt{\frac{4\omega^3}{3\lambda}} e^{-4\omega^3/3\lambda} \varepsilon_i(\lambda). \quad (17.367)$$

Expanding the integrand in powers of g gives an integral formula for the perturbation coefficients analogous to (17.331). Its evaluation yields the numbers shown in Table 17.1. They are compared with exact previous larger-order values (17.319) which follow from $\varepsilon_i \equiv 1$. The improvement of our knowledge on the imaginary part of the energy makes it possible to extend the previous large-order results to low orders. Even the lowest coefficient with $k = 1$ is reproduced very well [9].

The high degree of accuracy of the low-order coefficients is improved further by going to the higher variational approximation W_3 of Eq. (5.192) and extracting from it the imaginary part $\operatorname{Im} W_3(0)$ at zero temperature [10]. When continuing the coupling constant g to the sliding regime, we obtain the dotted curve in Fig. 17.13. It merges rather smoothly into the tunneling branch at $g \approx -0.24$. Plotting the merging regime with more resolution, we find two closely lying intersections at $g' = -0.229$ and $g' = -0.254$. We choose the first of these to cross over from one branch to the other. After inserting the imaginary part into the integral (17.331), we obtain the fifth column in Table 17.1. For $k = 1$, the accuracy is now better than 0.05%. To make the approximation completely consistent, the tunneling amplitude should also be calculated to the corresponding order. This would yield a further improvement in the low-order coefficients.

It is instructive to test the accuracy of our low-order results by evaluating the dispersion relation (17.367) for the g -dependent ground state energy $E^{(0)}(g)$. The results shown in Fig. 17.14 compare well with the exact curves. They are only slightly worse than the original Feynman-Kleinert approximation W_1 evaluated at positive values of g . We do not show the approximation W_3 since it is indistinguishable from the exact energy on this plot.

The approximation obtained from the dispersion relation has the advantage of possessing the properly diverging power series expansion and a reliable information on the analytic cut structure in the complex g -plane. Also here, the third-order result $E_{\text{var3+disp}}^{(0)}$ based on the imaginary part of W_3 for $g < 0$ is so accurate that it cannot be distinguished from the exact ones on the plot.

Table 17.1 Comparison between exact perturbation coefficients, semiclassical ones, and those obtained from moment integrals over the imaginary parts consisting of (17.363) in the tunneling regime and the analytic continuation of the variational approximations W_1 and W_3 in the sliding regime. An alternating sign $(-1)^{k-1}$ is omitted and ω is set equal to 1.

k	E_k	E_k^{sc}	$E_k^{\text{var1+disp}}$	$E_k^{\text{var3+disp}}$

10	24478940700	29437435332	24420208763	24703889150

The strong-coupling behavior is well reproduced by our curves. Recall the limiting expression for the middle curve given in Eq. (5.77) and the exact one (5.226) with the coefficients of Table 5.9.

The calculation of the imaginary part in the sliding regime can be accelerated by removing from the perturbation coefficients the portion which is due to the imaginary part of the tunneling amplitude. By adding the energy associated with this portion in the form of a dispersion relation it is possible to find variational approximations which for positive coupling constants are not only numerically accurate but which also have power series expansions with the correct large-order behavior [which was not the case for the earlier approximations $W_N(g)$].

The entire treatment can be generalized to excited states. The variational energies are then replaced by the minima of the expressions derived in Section 5.19,

$$W_1^{(n)} = \Omega n_2 + \frac{\omega^2 - \Omega^2 n_2}{2} \frac{1}{\Omega} + \frac{g n_4}{4 \Omega^2}, \quad (17.368)$$

with $n_2 = n + 1/2$ and $n_4 = (3/2)(n^2 + n + 1/2)$. The optimal Ω -values are given by the solutions (17.350), (17.351), with $g^{(0)}$ replaced by $g^{(n)} = 2n_2/3\sqrt{3}n_4$. For $g \in (-g^{(n)}, 0)$, the energies are real; for $g < -g^{(n)}$ they possess the imaginary part

$$\text{Im } W_1^{(n)} = \frac{1}{2} \Omega^i \left(1 - \frac{\omega^2}{|\Omega|^2} \right) n_2 - \frac{g}{2} \Omega^{\text{re}} \Omega^{\text{im}} \frac{n_4}{|\Omega|^4}. \quad (17.369)$$

For $g \in (-g^{(n)}, 0)$, the imaginary part arises from the bubble solution. In the semiclassical limit it produces a factor $12^n \mathcal{A}_{\text{cl}}^n / n!$ for $n > 0$ as in Eq. (17.322) (with ω replaced by Ω). Also here, the variational approach can easily be continued higher order approximations W_2, W_3, \dots .

Figure 17.14 Energies of anharmonic oscillator as function of $g' \equiv g/\omega^3$, obtained from variational imaginary part, and the dispersion relation (17.328) as a function of the coupling constant g . Comparison is made with the exact curve and the Feynman-Kleinert variational energy for $g > 0$.

To first order in g , the imaginary part is known from a WKB calculation [11]. It reads

$$\text{Im } E^{(n)}(-|g| - i\eta) = -\frac{12^n}{n!} \omega \sqrt{\frac{6}{\pi}} \sqrt{\frac{4\omega^3}{3|g|}}^{1+2n} e^{-4\omega^3/3|g| - c_1^{(n)} 3|g|/4\omega^3}, \quad (17.370)$$

with the slope parameter

$$c_1^{(n)} = \frac{d\varepsilon_i^{(n)}}{d(g/\omega^3)} = \left(\frac{95}{96} + \frac{29}{16}n + \frac{17}{16}n^2 \right) \omega^{-3}. \quad (17.371)$$

Following the procedure described after Eq. (17.366), we obtain from this a variational expression for the imaginary part which generalizes Eq. (17.364) to any n :

$$\text{Im } E^{(n)}(-|g| - i\eta) = -\frac{12^n}{n!} \omega \sqrt{\frac{6}{\pi}} \sqrt{\frac{4\omega^3}{3|g|}}^{1+2n} e^{-4\omega^3/3|g| \varepsilon_i^{(n)}(g)}, \quad (17.372)$$

with a correction factor

$$\varepsilon_i^{(n)}(g) = \left(\frac{\Omega}{\omega} \right)^{3n+5/2} \exp \left[-4 \frac{\Omega^3 - \omega^3}{3|g|} - c_1^{(n)} \frac{3|g|}{4\Omega^3} - \frac{\omega^2 - \Omega^2}{2} \left(\frac{4\Omega}{|g|} - \frac{3n + 5/2}{\Omega^2} \right) - \frac{(\omega^2 - \Omega^2)^2}{2\Omega|g|} \right]. \quad (17.373)$$

Figure 17.15 Reduced imaginary part of ground state energy of anharmonic oscillator from variational perturbation theory plotted for small negative g against $\log(-g/4)$. The fat curve is the analytic continuation of the strong-coupling expansion (5.226) with the expansion coefficients up to the 22nd order listed in Table 5.9. The thin curve is the divergent semiclassical expansion of the contribution of the classical solution in Eq. (17.374).

Inserting for Ω the optimal value $\Omega^{(n)}$, we obtain the solid curves shown in Fig. 17.13. Their slopes have the exact values (17.371).

The sliding regime for the excited states can be obtained from an analytic continuation of the variational energies. For $n = 1, 2$ the resulting imaginary parts are shown as dotted curves in Fig. 17.13. They merge smoothly with the corresponding tunneling branches obtained from W_1 .

If we extend the variational evaluation of the perturbation expansions to high orders in g , we find the imaginary part over the left-hand cut extending deeper and deeper into the regime dominated by the classical solution and the fluctuations around it [10]. This is shown in the double-logarithmic plot of Fig. 17.15.

The result may be compared with the the divergent semiclassical expansion around the classical solution [13]

$$\log \varepsilon^i(g) = -\frac{4}{3g} + k_1 \frac{g}{4} + k_2 \left(\frac{g}{4}\right)^2 + \dots \quad (17.374)$$

also plotted in Fig. 17.15. The coefficients are listed in Table 17.2.

Table 17.2 Coefficients k_n of semiclassical expansion (17.374) around classical solution.

1	2	3	4	5

The inclusion of finite temperatures is possible by summing over the imaginary parts of the energies weighted by a Boltzmann factor with these energies. This opens the road to applications in many branches of physics where tunneling phenomena are relevant.

It will be interesting to generalize this procedure to quantum field theories, where it can give rise to the development of much more efficient resummation techniques for perturbation series. One will be able to set up system-dependent basis functions in terms of which these series possess a convergent re-expansion. The critical exponents of the $O(N)$ -symmetric φ^4 -theory should then be calculable from the presently known five-loop results [14] with a much greater accuracy than before.

17.10.5 Convergence of Variational Perturbation Expansion

The knowledge of the discontinuity across the left-hand makes it possible to understand roughly the convergence properties of the variational perturbation expansion developed in Section 5.14. The ground state energy satisfies the subtracted dispersion relation [compare (17.299)]

$$E^{(0)}(g) = \frac{\omega}{2} - \frac{g}{2\pi i} \int_0^{-\infty} \frac{dg'}{g'} \frac{\text{disc } E^{(0)}(g')}{g' - g}, \quad (17.375)$$

where $\text{disc } E^{(0)}(g')$ denotes the discontinuity across the left-hand cut in the complex g -plane. An expansion of the integrand in powers of g yields the perturbation series

$$E^{(0)}(g) = \omega \sum_{k=0}^N E_k^{(0)} \left(\frac{g}{4\omega^3} \right)^k. \quad (17.376)$$

The associated variational energy has the form [compare (5.206)]

$$W_N^\Omega(g) = \Omega \sum_{k=0}^N \varepsilon_k^{(0)} \left(\frac{g}{4\Omega^3} \right)^k. \quad (17.377)$$

It is obtained from (17.376) by the replacement (5.188) and a re-expansion in powers of g . In the present context, we write this replacement as

$$\omega \longrightarrow \Omega(1 - \sigma\hat{g})^{1/2}, \quad (17.378)$$

where \hat{g} is the dimensionless coupling constant g/Ω^3 , and

$$\sigma = \Omega(\Omega^2 - 1)/g \quad (17.379)$$

[recall Eqs. (5.213) and (5.208)].

There is a simple way of obtaining the same re-expansion from the dispersion relation (17.375). Introducing the dimensionless coupling constant $\bar{g} \equiv g/\omega^3$, the replacement (17.378) amounts to

$$\bar{g} \longrightarrow \tilde{g}(\hat{g}) \equiv \frac{\hat{g}}{(1 - \sigma\hat{g})^{3/2}}. \quad (17.380)$$

Since Eq. (17.375) represents an energy, it can be written as ω times a dimensionless function of \bar{g} . Apart from the replacement (17.380) in the argument, it receives an overall factor $\Omega/\omega = (1 - \sigma\hat{g})^{1/2}$. We introduce the reduced energies

$$\hat{E}(\hat{g}) \equiv E(g)/\Omega, \quad (17.381)$$

which depends only on the reduced coupling constant \hat{g} , the dispersion relation (17.375) for $E^{(0)}(g)$ implies a dispersion relation for $\hat{E}^{(0)}(\hat{g})$:

$$\hat{E}^{(0)}(\hat{g}) = (1 - \sigma\hat{g})^{1/2} \left[\frac{1}{2} + \frac{\tilde{g}(\hat{g})}{2\pi i} \int_0^{-\infty} \frac{d\bar{g}' \operatorname{disc} \bar{E}^{(0)}(\bar{g}')}{\bar{g}' \bar{g}' - \tilde{g}(\hat{g})} \right]. \quad (17.382)$$

The resummed perturbation series is obtained from this by an expansion in powers of $\hat{g}/4$ up to order N .

It should be emphasized that only the truncation of the expansion causes a difference between the two expressions (17.375) and (17.382), since \bar{g} and \tilde{g} are the same numbers, as can be verified by inserting (17.379) into the right-hand side of (17.380).

To find the re-expansion coefficients we observe that the expression (17.382) satisfies a dispersion relation in the complex \hat{g} -plane. If C denotes the cuts in this plane and $\operatorname{disc}_C E(\hat{g})$ is the discontinuity across these cuts, the dispersion relation reads

$$\hat{E}^{(0)}(\hat{g}) = \frac{1}{2} + \frac{\hat{g}}{2\pi i} \int_C \frac{d\hat{g}' \operatorname{disc}_C \hat{E}^{(0)}(\hat{g}')}{\hat{g}' - \hat{g}}. \quad (17.383)$$

We have changed the argument of the energy from \bar{g} to \hat{g} since this will be the relevant variable in the sequel.

When expanding the denominator in the integrand in powers of $\hat{g}/4$, the expansion coefficients $\varepsilon_l^{(0)}$ are found to be moment integrals with respect to the inverse coupling constant $1/\hat{g}$ [compare (17.302)]:

$$\varepsilon_k^{(0)} = -\frac{4^k}{2\pi i} \int_C \frac{d\hat{g}}{\hat{g}^{k+1}} \operatorname{disc}_C \hat{E}^{(0)}(\hat{g}). \quad (17.384)$$

In the complex \hat{g} -plane, the integral (17.382) has in principle cuts along the contours $C_1, C_{\bar{1}}, C_2, C_{\bar{2}}$, and C_3 , as shown in Fig. 17.16. The first four cuts are the images of the left-hand cut in the complex g -plane; the curve C_3 is due to the square root of $1 - \sigma\hat{g}$ in the mapping (17.380) and the prefactor of (17.382).

Let $\bar{D}(\bar{g})$ abbreviate the reduced discontinuity in the original dispersion relation (17.375):

$$\bar{D}(\bar{g}) \equiv \operatorname{disc} \bar{E}^{(0)}(\bar{g}) = 2i \operatorname{Im} \bar{E}^{(0)}(\bar{g} - i\eta), \quad \bar{g} \leq 0. \quad (17.385)$$

Then the discontinuities across the various cuts are

$$\operatorname{disc}_{C_{1,\bar{1},2,\bar{2}}} \hat{E}^{(0)}(\hat{g}) = (1 - \sigma\hat{g})^{1/2} \bar{D}(\hat{g}(1 - \sigma\hat{g})^{-3/2}), \quad (17.386)$$

Figure 17.16 Cuts in complex \hat{g} -plane whose moments with respect to inverse coupling constant determine re-expansion coefficients. The cuts inside the shaded circle happen to be absent due to the convergence of the strong-coupling expansion for $g > g_s$.

$$\begin{aligned} \text{disc}_{C_3} \hat{E}^{(0)}(\hat{g}) &= -2i(\sigma\hat{g} - 1)^{1/2} \\ &\times \left[\frac{1}{2} - \int_0^\infty \frac{d\bar{g}'}{2\pi} \frac{\hat{g}(\sigma\hat{g} - 1)^{-3/2}}{\bar{g}'^2 + \hat{g}^2(\sigma\hat{g} - 1)^{-3}} \bar{D}(-\bar{g}') \right]. \end{aligned} \quad (17.387)$$

For small negative \bar{g} , the discontinuity is given by the semiclassical limit (17.317):

$$\bar{D}(\bar{g}) \approx -2i\sqrt{\frac{6}{\pi}}\sqrt{\frac{4}{-3\bar{g}}}e^{4/3\bar{g}}. \quad (17.388)$$

We denote by $\varepsilon_k^{(0)}(C_i)$ the contributions of the different cuts to the integral (17.384) for the coefficients. After inserting (17.388) into Eq. (17.386), we obtain from the cut along C_1 the semiclassical approximation

$$\varepsilon_k^{(0)}(C_1) \approx -24^k \int_{C_1} \frac{d\hat{g}}{2\pi} \frac{1}{\hat{g}^{k+1}} \sqrt{\frac{6}{\pi}} \sqrt{-\frac{4(1 - \sigma\hat{g})^{5/2}}{3\hat{g}}} e^{4(1 - \sigma\hat{g})^{3/2}/3\hat{g}}. \quad (17.389)$$

For the k th term S_k of the series this yields an estimate

$$S_k \propto \left[\int_{C_\gamma} \frac{d\gamma}{2\pi} e^{f_k(\gamma)} \right] (\sigma\hat{g})^k, \quad (17.390)$$

where $f_k(\gamma)$ is the function of $\gamma \equiv \sigma\hat{g}$

$$f_k(\gamma) = -\left(k + \frac{3}{2}\right) \log(-\gamma) + \frac{4\sigma}{3\gamma}(1 - \gamma)^{3/2}. \quad (17.391)$$

For large k , the integral may be evaluated via the saddle point approximation of Subsection 4.2.1. The extremum of $f_k(\gamma)$ satisfies the equation

$$-k + \frac{3}{2} = \frac{4\sigma}{3\gamma}(1 - \gamma)^{1/2}(1 + \frac{1}{2}\gamma), \quad (17.392)$$

which is solved by

$$\gamma \xrightarrow[k \rightarrow \infty]{} \gamma_k = -4\sigma/3k. \quad (17.393)$$

At the extremum, $f_k(\gamma)$ has the value

$$f_k \xrightarrow[k \rightarrow \infty]{} k \log(3k/4e\sigma) - 2\sigma. \quad (17.394)$$

The constant -2σ in this limiting expression arises when expanding the second term of Eq. (17.391) into a Taylor series, $(4\sigma/3\gamma)(1-\gamma)^{3/2} = 4\sigma/3\gamma_k - 2\sigma + \dots$. Only the first two terms survive the large- k limit.

Thus, to leading order in k , the k th term of the re-expanded series becomes

$$S_k \propto e^{-2\sigma} \left(\frac{-3k}{e} \right)^k \left(\frac{\hat{g}}{4} \right)^k. \quad (17.395)$$

The corresponding re-expansion coefficients are

$$\varepsilon_k^{(0)} \propto e^{-2\sigma} E_k^{(0)}. \quad (17.396)$$

They have the remarkable property of growing in precisely the same manner with k as the initial expansion coefficients $E_k^{(0)}$, except for an overall suppression factor $e^{-2\sigma}$. This property was found empirically in Fig. 5.20b.

In order to estimate the convergence of the variational perturbation expansion, we note that with

$$\sigma = \frac{\Omega(\Omega^2 - 1)}{g} \quad (17.397)$$

and \hat{g} from (5.213), we have

$$\sigma \hat{g} = 1 - \frac{1}{\Omega^2}. \quad (17.398)$$

For large Ω , this expression is smaller than unity. Hence the powers $(\sigma \hat{g})^k$ alone yield a convergent series. An optimal re-expansion of the energy can be achieved by choosing, for a given large maximal order N of the expansion, a parameter σ proportional to N :

$$\sigma \approx \sigma_N \equiv cN. \quad (17.399)$$

Inserting this into (17.391), we obtain for large $k = N$

$$f_N(\gamma) \approx N \left[-\log(-\gamma) + \frac{4c}{3\gamma}(1-\gamma)^{3/2} \right]. \quad (17.400)$$

The extremum of this function lies at

$$1 + \frac{4c}{3\gamma}(1-\gamma)^{1/2}(1 + \frac{1}{2}\gamma) = 0. \quad (17.401)$$

The constant c is now chosen in such a way that the large exponent proportional to N in the exponential function $e^{f_N(\gamma)}$ due to the first term in (17.400) is canceled by an equally large contribution from the second term, i.e., we require at the extremum

$$f_N(\gamma) = 0. \quad (17.402)$$

The two equations (17.401) and (17.402) are solved by

$$\gamma = -0.242\,964\,029\,973\,520 \dots, \quad c = 0.186\,047\,272\,987\,975 \dots. \quad (17.403)$$

In contrast to the extremal γ in Eq. (17.393) which dominates the large- k limit, the extremal γ of the present limit, in which k is also large but of the order of N , remains finite (the previous estimate holds for $k \gg N$). Accordingly, the second term $(4c/3\gamma)(1-\gamma)^{3/2}$ in $f_N(\gamma)$ contributes in full, not merely via the first two Taylor expansion terms of $(1-\gamma)^{3/2}$, as it did in (17.394).

Since $f_N(\gamma)$ vanishes at the extremum, the N th term in the re-expansion has the order of magnitude

$$S_N \propto (\sigma_N \hat{g}_N)^N = \left(1 - \frac{1}{\Omega_N^2}\right)^N. \quad (17.404)$$

According to (17.397) and (17.399), the frequency Ω_N grows for large N like

$$\Omega_N \sim \sigma_N^{1/3} g^{1/3} \sim (cNg)^{1/3}. \quad (17.405)$$

As a consequence, the last term of the series decreases for large N like

$$S_N(C_1) \propto \left[1 - \frac{1}{(\sigma_N g)^{2/3}}\right]^N \approx e^{-N/(\sigma g)^{2/3}} \approx e^{-N^{1/3}/(cg)^{2/3}}. \quad (17.406)$$

This estimate does not yet explain the convergence of the variational perturbation expansion in the strong-coupling limit observed in Figs. 5.21 and 5.22. For the contribution of the cut C_1 to S_N , the derivation of such a behavior requires including a little more information into the estimate. This information is supplied by the empirically observed property, that the best Ω_N -values lie for finite N on a curve [recall Eq. (5.211)]:

$$\sigma_N \sim cN \left(1 + \frac{6.85}{N^{2/3}}\right). \quad (17.407)$$

Thus the asymptotic behavior (17.399) receives, at a finite N , a rather large correction. By inserting this σ_N into $f_N(\gamma)$ of (17.400), we find an extra exponential factor

$$\begin{aligned} e^{\Delta f_N} &\approx \exp \left[N \frac{4c}{3} \frac{(1-\gamma)^{3/2}}{\gamma} \frac{6.85}{N^{2/3}} \right] \\ &= \exp \left[-N \log(-\gamma) \frac{6.85}{N^{2/3}} \right] \approx e^{-9.7N^{1/3}}. \end{aligned} \quad (17.408)$$

This reduces the size of the last term due to the cut C_1 in (17.406) to

$$S_N(C_1) \propto e^{-[9.7+(cg)^{-2/3}]N^{1/3}}, \tag{17.409}$$

which agrees with the convergence seen in Figs. 5.21 and 5.22.

There is no need to evaluate the effect of the shift in the extremal value of γ caused by the correction term in (17.407), since this would be of second order in $1/N^{2/3}$.

How about the contributions of the other cuts? For $C_{\bar{1}}$, the integrals in (17.384) run from $\hat{g} = -2/\sigma$ to $-\infty$ and decrease like $(-2/\sigma)^{-k}$. The associated last term $S_N(C_{\bar{1}})$ is of the negligible order $e^{-N \log N}$. For the cuts $C_{2,\bar{2},3}$, the integrals (17.384) start at $\hat{g} = 1/\sigma$ and have therefore the leading behavior

$$\varepsilon_k^{(0)}(C_{2,\bar{2},3}) \sim \sigma^k. \tag{17.410}$$

This implies a contribution to the N th term in the re-expansion of the order of

$$S_N(C_{2,\bar{2},3}) \sim (\sigma\hat{g})^N, \tag{17.411}$$

which decreases merely like (17.406) and does not explain the empirically observed convergence in the strong-coupling limit. As before, an additional information produces a better estimate. The cuts in Fig. 17.16 do not really reach the point $\sigma\hat{g} = 1$. There exists a small circle of radius $\Delta\hat{g} > 0$ in which $\hat{E}^{(0)}(\hat{g})$ has no singularities at all. This is a consequence of the fact unused up to this point that the strong-coupling expansion (5.231) converges for $g > g_s$. For the reduced energy, this expansion reads:

$$\hat{E}^{(0)}(\hat{g}) = \left(\frac{\hat{g}}{4}\right)^{1/3} \left\{ \alpha_0 + \alpha_1 \left[\frac{\hat{g}}{4\omega^3} \frac{1}{(1-\sigma\hat{g})^{3/2}} \right]^{-2/3} + \alpha_2 \left[\frac{\hat{g}}{4\omega^3} \frac{1}{(1-\sigma\hat{g})^{3/2}} \right]^{-4/3} + \dots \right\}. \tag{17.412}$$

The convergence of (5.231) for $g > g_s$ implies that (17.412) converges for all $\sigma\hat{g}$ in a neighborhood of the point $\sigma\hat{g} = 1$ with a radius

$$\Delta(\sigma\hat{g}) \sim \left(\frac{\hat{g}}{-\bar{g}_s}\right)^{2/3} = \left\{ \frac{1}{-\sigma\bar{g}_s} [1 + \Delta(\sigma\hat{g})] \right\}^{2/3}, \tag{17.413}$$

where $\bar{g}_s \equiv g_s/\omega^3$. For large N , $\Delta(\sigma\hat{g})$ goes to zero like $1/(N|\bar{g}_s|c)^{2/3}$. Thus the integration contours of the moment integrals (17.384) for the contributions $\varepsilon_k^{(0)}(C_i)$ of the other cuts do not begin at the point $\sigma\hat{g} = 1$, but a little distance $\Delta(\sigma\hat{g})$ away from it. This generates an additional suppression factor

$$(\sigma\hat{g})^{-N} \sim [1 + \Delta(\sigma\hat{g})]^{-N}. \tag{17.414}$$

Let us set $-\bar{g}_s = |\bar{g}_s| \exp(i\varphi_s)$ and $x_s \equiv (-\hat{g}/\bar{g}_s)^{2/3} = -|x_s| \exp(i\theta)$, and introduce the parameter $a \equiv 1/[|\bar{g}_s|c]^{2/3}$. Since there are two complex conjugate contributions we obtain, for large N a last term of the re-expanded series the order of

$$S_N(C_{2,\bar{2},3}) \approx e^{-N^{1/3}a \cos \theta} \cos(N^{1/3}a \sin \theta). \tag{17.415}$$

Figure 17.17 Theoretically obtained convergence behavior of N th approximants for α_0 , to be compared with the empirically found behavior in Fig. 5.21.

Figure 17.18 Theoretically obtained oscillatory behavior around exponentially fast asymptotic approach of α_0 to its exact value as a function of the order N of the approximant, to be compared with the empirically found behavior in Fig. 5.22, averaged between even and odd orders.

By choosing

$$|\bar{g}_s| \sim 0.160, \quad \theta \sim -0.467, \tag{17.416}$$

we obtain the curves shown in Figs. 17.17 and 17.18 which agree very well with the observed Figs. 5.21 and 5.22. Their envelope has the asymptotic falloff $e^{-9.23N^{1/3}}$.

Let us see how the positions of the leading Bender-Wu singularities determined by (17.416) compare with what we can extract directly from the strong-coupling series (5.231) up to order 22. For a pair of square root singularities at $x_s = -|x_s| \exp(\pm i\theta)$, the coefficients of a power series $\sum \alpha_n x^n$ have the asymptotic ratios $R_n \equiv \alpha_{n+1}/\alpha_n \sim$

Figure 17.19 Comparison of ratios R_n between successive expansion coefficients of strong-coupling expansion (dots) with ratios R_n^{as} of expansion of superposition of two singularities at $g = 0.156 \times \exp(\pm 0.69)$ (crosses).

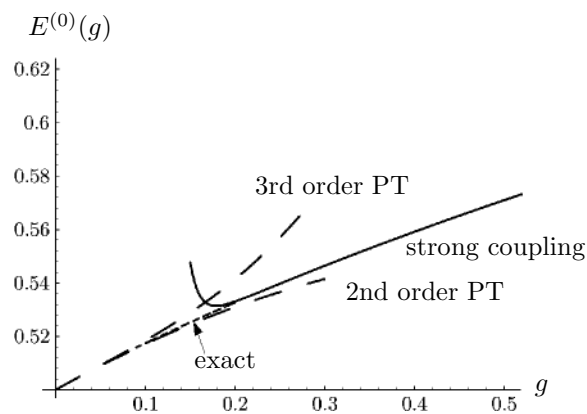

Figure 17.20 Strong-coupling expansion of ground state energy in comparison with exact values and perturbative results of 2nd and 3rd order. The convergence radius in $1/g$ is larger than $1/0.2$.

$R_n^{\text{as}} \equiv -\cos[(n+1)\theta + \delta]/|x_s| \cos(n\theta + \delta)$. In Fig. 17.19 we have plotted these ratios against the ratios R_n obtained from the coefficients α_n of Table 5.9. For large n , the agreement is good if we choose

$$|x_s| = 1/0.117, \quad \theta = -0.467, \quad (17.417)$$

with an irrelevant phase angle $\delta = -0.15$. The angle θ is in excellent agreement with the value found in (17.416). From $|x_s|$ we obtain $|\bar{g}_s| = 4|1/x_s|^{3/2} = 0.160$, again in excellent agreement with (17.416).

This convergence radius is compatible with the heuristic convergence of the strong-coupling series up to order 22, as can be seen in Fig. 17.19 by comparing the curves resulting from the series with the exact curve.

It is possible to extend the convergence proof to the more general divergent power series discussed in Section 5.17, whose strong-coupling expansions have the more general growth parameters p and q [15]. The convergence is assured for $1/2 < 2/q < 1$ [16]. If the interaction of the anharmonic oscillator is $\int d\tau x^n(\tau)$ with $n \neq 4$, the dimensionless expansion parameter for the energies is $g/\omega^{n/2+1}$ rather than g/ω^3 . Then $q = n/2 + 1$, such that for $n \geq 6$ the convergence is lost. This can be verified by trying to resum the expansions for the ground state energies of $n = 6$ and $n = 8$, for example. For $n = 6$, the cut in Fig. 17.16 becomes circular such that there is no more shaded circle C_3 in which the strong-coupling series converges.

17.11 Decay of Supercurrent in Thin Closed Wire

An important physical application of the above tunneling theory explains the temperature behavior of the resistance of a thin⁷ superconducting wire. The superconducting state is described by a complex order parameter $\psi(z)$ depending on the spatial variable z along the wire. We then speak of an *order field*. The variable z plays the role of the Euclidean time τ in the previous sections. We shall consider a closed wire where $\psi(z)$ satisfies the periodic boundary condition

$$\psi(z) = \psi(z + L). \quad (17.418)$$

The energy density of the system is described approximately by a *Ginzburg-Landau expansion* in powers of ψ and its gradients containing only the terms

$$\varepsilon(z) = |\partial_z \psi(z)|^2 + m^2 |\psi(z)|^2 + \frac{g}{4} |\psi(z)|^4. \quad (17.419)$$

The total fluctuating energy is given by the functional

$$E[\psi^*, \psi] = \int_{-L/2}^{L/2} dz \varepsilon(z), \quad (17.420)$$

⁷A superconducting wire is called *thin* if it is much smaller than the coherence length to be defined in Eq. (17.425).

and the probability of each fluctuation is determined by the Boltzmann factor $\exp\{-E[\psi^*, \psi]/k_B T\}$. The parameter m^2 in front of $|\psi(z)|^2$ is called the *mass term* of the field. It vanishes at the critical temperature T_c and behaves near T_c like

$$m^2 \approx m_0^2 \left(\frac{T}{T_c} - 1 \right). \quad (17.421)$$

Below T_c , the square mass is negative and the wire becomes superconducting. One can easily estimate, that each term in the Landau expansion is of the order of $|1 - T/T_c|^2$ and any higher expansion term in (17.419) would be smaller than that by at least a power $|1 - T/T_c|^{1/2}$.

The partition function of the system is given by the path integral

$$Z = \int \mathcal{D}\psi^*(z) \mathcal{D}\psi(z) e^{-E[\psi^*, \psi]/k_B T}. \quad (17.422)$$

If T does not lie too close to T_c [although close enough to justify the Landau expansion, i.e., the neglect of higher expansion terms in (17.419) suppressed by a factor $|1 - T/T_c|^{1/2}$], this path integral can be treated semiclassically in the way described earlier in this chapter [17].

The basic microscopic mechanism responsible for the phenomenon of superconductivity will be irrelevant for the subsequent discussion. Let us only recall the following facts: A superconductor is a metal at low temperatures whose electrons near the surface of the Fermi sea overcome their Coulomb repulsion due to *phonon exchange*. This enables them to form bound states between two electrons of opposite spin orientations in a relative *s*-wave, the celebrated *Cooper pairs*.⁸ The attraction which binds the Cooper pairs is extremely weak. This is why the temperature has to be very small to keep the pairs from being destroyed by thermal fluctuations. The critical temperature T_c , where the pairs break up, is related to the binding energy of the Cooper pairs by $E_{\text{pair}} = k_B T_c$. The field-theoretic process called phonon exchange is a way of describing the accumulation of positive ions along the path of an electron which acts as an attractive potential wake upon another electron while screening the Coulomb repulsion. The attraction is very weak and leads to a bound state only in the *s*-wave (the centrifugal barrier $\propto l(l+1)/r^2$ preventing the formation of a bound state in higher partial waves). The potential between the electrons may well be approximated by a δ -function potential $V(x) \approx -g\delta(r)$. The critical temperature T_c , usually a few degrees Kelvin, is found to satisfy the characteristic exponential relation

$$T_c k_B = \mu e^{-1/g}. \quad (17.423)$$

The parameter μ denotes the upper energy cutoff of the phonon spectrum $T_D k_B$, where T_D is the Debye temperature of the lattice vibration.

⁸We consider here only with old-fashioned superconductivity which sets in below a very small critical temperature of a few-degree Kelvin. The physics of the recently discovered high-temperature superconductors is at present not sufficiently understood to be discussed along the same lines.

Figure 17.21 Renormalization group trajectories in the g, μ plane of superconducting electrons (g =attractive coupling constant, μ =Debye temperature, $k_B = 1$). Curves with same T_c imply identical superconducting properties. The renormalization group determines the reparametrizations of a fixed superconductive system along any of these curves.

An important result of the theory, confirmed by experiment, is that all T -dependent characteristic equilibrium properties of the superconductor near T_c depend only on the single parameter T_c . Thus, many quite different systems with different microscopic parameters $\mu \equiv T_D$ and g will have the *same* superconducting properties (see Fig. 17.21). The critical temperature is an important prototype for the understanding of the so-called *dimensionally transmuted coupling constant* in quantum field theories, which plays a completely analogous role in specifying the system. In quantum field theory, an arbitrary mass parameter μ is needed to define the coupling strength of a renormalized theory and physical quantities depend only on the combination⁹

$$M_c = \mu e^{-1/g(\mu)}. \quad (17.424)$$

The set of all changes μ which are accompanied by a simultaneous change of $g(\mu)$ such as to stay on a fixed curve with M_c from the *renormalization group*. The curve $\mu, g(\mu)$ is called the *renormalization group trajectory* [16].

If one works in natural units with $\hbar = k_B = M = 1$, the critical temperature corresponds to a length of $\approx 1000 \text{ \AA}$. This length sets the scale for the spatial correlations of the Cooper pairs near the critical point via the relation

$$\xi(T) = \frac{\text{const.}}{T_c} \left(1 - \frac{T}{T_c}\right)^{-1/2} \approx 1000 \text{ \AA} \left(1 - \frac{T}{T_c}\right)^{-1/2}. \quad (17.425)$$

⁹In quantum chromodynamics, this dimensionally transmuted coupling constant is of the order of the pion mass and usually denoted by Λ .

The Cooper pairs are much larger than the lattice spacing, which is of the order of 1\AA . Their size is determined by the ratio $\hbar^2 k_F / m_e \pi k_B T_c$, where k_F is the wave number of electrons of mass m_e on the surface of the Fermi sphere. The temperature T_c in conventional superconductors of the order of 1 K corresponds to $1/11604.447\text{ eV}$. Thus the thermal energy $k_B T_c$ is smaller than the atomic energy $E_H = 27.210\text{ eV}$ (recall the atomic units defined on p. 13.7) by a factor 2.345×10^{-3} , and we find that $\hbar^2 / m_e \pi k_B T_c$ is of the order of $10^2 a_H^2$. Since a_H is of the order of $1/k_F$, we estimate the size of the Cooper pairs as being roughly 100 times larger than the lattice spacing.

This justifies **a posteriori** the δ -function approximation for the attractive potential, whose range is just a few lattice spacings, i.e., much smaller than $\xi(T)$. The presence of such large bound states causes the superconductor to be coherent over the large distance $\xi(T)$. For this reason, $\xi(T)$ is called the *coherence length*.

Similar Cooper pairs exist in other low-temperature fermion systems such as ^3He , where they give rise to the phenomenon of *superfluidity*. There, the interatomic potential contains a hard repulsive core for $r < 2.7\text{\AA}$. This prevents the formation of an *s*-wave bound state. In addition it produces a strong spin-spin correlation in the almost fully degenerate Fermi liquid, with a preference of parallel spin configurations. Because of the necessary antisymmetry of the pair wave function of the electrons, this amounts to a repulsion in any even partial wave. For this reason, Cooper pairs can only exist in the *p*-wave spin triplet state. The binding energy is much weaker than in a superconductor, suppressing the critical temperature by roughly a factor thousand. Experimentally, one finds $T_c = 27\text{mK}$ at a pressure of $p = 35\text{ bar}$. Since the masses of the ^3He atoms are larger than those of the electrons by about the same factor thousand, the coherence length ξ has the same order of magnitude in both systems, i.e., $1/T_c$ has the same length when measured in units of \AA .

The theoretical description of the behavior of the condensate is greatly simplified by re-expressing the fundamental Euclidean action in terms of a Cooper *pair field* which is the composite field

$$\psi_{\text{pair}}(\mathbf{x}) = \psi_e(\mathbf{x})\psi_e(\mathbf{x}). \quad (17.426)$$

Such a change of field variables can easily be performed in a path integral formulation of the field theory. The method is very similar to the introduction of the auxiliary field $\varphi(\mathbf{x})$ in the polymer field theory of Section 15.12. Since this subject has been treated extensively elsewhere¹⁰ we shall not go into details. The partition function of the system reads

$$Z = \int \mathcal{D}\psi_e^*(\mathbf{x}) \mathcal{D}\psi_e(\mathbf{x}) e^{-\mathcal{A}[\psi_e^*, \psi_e]}. \quad (17.427)$$

¹⁰The way to describe the pair formation by means of path integrals is explained in H. Kleinert, *Collective Quantum Fields*, Fortschr. Phys. 26, 565 (1978) (<http://www.physik.fu-berlin.de/~kleinert/55>).

By going from integration variables ψ_e to ψ_{pair} , we can derive the alternative pair partition function

$$Z = \int \mathcal{D}\psi_{\text{pair}}^*(\mathbf{x}) \mathcal{D}\psi_{\text{pair}}(\mathbf{x}) e^{-\mathcal{A}[\psi_{\text{pair}}^*, \psi_{\text{pair}}]}, \quad (17.428)$$

where ψ_{pair} is the Cooper pair field (17.426).

In general, the new action is very complicated. For temperatures close to T_c , however, it can be expanded in powers of the field ψ_{pair} and its derivatives, leading to a Landau expansion of the type (17.419). For static fields the Euclidean field action is

$$\begin{aligned} \mathcal{A}[\psi_{\text{pair}}^*, \psi_{\text{pair}}] &= E/k_B T = \frac{1}{k_B T} \int d^3x \varepsilon(\mathbf{x}) \\ &= \frac{1}{k_B T} \int d^3x \left[\left(-\log \frac{\mu}{T} + \frac{1}{g^2} \right) |\psi_{\text{pair}}|^2 + \frac{1}{2T_c^2} |\psi_{\text{pair}}|^4 + \frac{1}{T_c^2} |\nabla \psi_{\text{pair}}|^2 + \dots \right], \end{aligned} \quad (17.429)$$

where the dots denote the omitted higher powers of ψ_{pair} and of their derivatives, each accompanied by an additional factor $1/T_c$.

Let us discuss the path integral (17.429) first in the classical limit. We observe that with the critical temperature (17.423), the mass term in the energy can be written as

$$-\log \frac{T_c}{T} |\psi_{\text{pair}}|^2 \sim - \left(1 - \frac{T}{T_c} \right) |\psi_{\text{pair}}|^2. \quad (17.430)$$

It has the “wrong sign” for $T < T_c$, so that the field has no stable minimum at $\psi_{\text{pair}} = 0$. It fluctuates around one of the infinitely many nonzero values with the fixed absolute value

$$|\psi_{\text{pair},0}| = T_c \sqrt{1 - \frac{T}{T_c}}. \quad (17.431)$$

It is then useful to take a factor $T_c (1 - T/T_c)^{1/2}$ out of the field ψ_{pair} , define

$$\psi(\mathbf{x}) \equiv \psi_{\text{pair}}(\mathbf{x}) \frac{1}{T_c (1 - T/T_c)^{1/2}}, \quad (17.432)$$

and write the renormalized energy density as

$$\varepsilon(\mathbf{x}) = |\nabla \psi|^2 - |\psi|^2 + \frac{1}{2} |\psi|^4. \quad (17.433)$$

Here we have made use of the coherence length (17.425) to introduce a dimensionless space variable \mathbf{x} , replacing $\mathbf{x} \rightarrow \mathbf{x} \xi$. We also have dropped an overall energy density factor proportional to $(1 - T/T_c)^2 T_c^2$.

In the rescaled form (17.433), the minimum of the energy lies at $|\psi_0| = 1$, where it has the density

$$\varepsilon = \varepsilon_c = -1/2. \quad (17.434)$$

The negative energy accounts for the binding of the Cooper pairs in the condensate (in the present natural units) and is therefore called the *condensation energy*. In terms of (17.433), the partition function in equilibrium can be written as

$$Z = \int \mathcal{D}\psi^*(\mathbf{x})\mathcal{D}\psi(\mathbf{x})e^{-(1/T)\int d^3x\varepsilon(\mathbf{x})}. \quad (17.435)$$

We are now prepared to discuss the flow properties of an electric current of the system carried by the Cooper pairs. It is carried by the divergenceless pair current [compare (1.102)]

$$\mathbf{j}(\mathbf{x}) = \frac{1}{2i}\psi^*(\mathbf{x})\overleftrightarrow{\nabla}\psi(\mathbf{x}) \quad (17.436)$$

associated with the transport of the number of pairs, apart from a charge factor of the pairs, which is equal to twice the electron charge.

The important question to be understood by the theory is: How can this current become “super”, and stay alive for a very long time (in practice ranging from hours to years, as far as the patience of the experimentalist may last) [18]. To see this let us set up a current in a long circular wire and assume that the wire thickness is much smaller than the coherence length $\xi(T)$. Then transverse variations of the pair field $\psi(\mathbf{x})$ are strongly suppressed with respect to longitudinal ones (by the gradient terms $|\nabla\psi(\mathbf{x})|^2$ in the Boltzmann factor) and the system depends mainly on the coordinate z *along* the wire, so that the above formalism can be applied. If the cross section of the wire is absorbed into the inverse temperature prefactor in the Boltzmann factor in (17.435), we may simply study the partition function (17.435) for a one-dimensional problem along the z -axis. The energy density (17.433) is precisely of the form announced in the beginning in Eq. (17.419). It is convenient to decompose the complex field $\psi(z)$ into polar coordinates

$$\psi(z) = \rho(z)e^{i\gamma(z)}, \quad (17.437)$$

in terms of which the energy density reads

$$\varepsilon(z) = -\rho^2 + \frac{1}{2}\rho^4 + \rho_z^2 + \rho^2\gamma_z^2, \quad (17.438)$$

where the subscript z indicates a derivative with respect to z . The field equations are

$$j(z) = \rho^2(z)\gamma_z(z) = \text{const} \quad (17.439)$$

and

$$\rho_{zz} = -\rho + \rho^3 + \frac{j^2}{\rho^3}. \quad (17.440)$$

Figure 17.22 Potential $V(\rho) = -\rho^2 + \rho^4/2 - j^2/\rho^2$ showing barrier in superconducting wire to the left of ρ_0 to be penetrated if the supercurrent is to relax.

If z is reinterpreted as an imaginary “time”, the latter equation can be interpreted as describing the mechanical motion of a mass point at the position $\rho(z)$ moving as a function of the “time” z in the potential

$$-V(\rho) \equiv \rho^2 - \frac{1}{2}\rho^4 + \frac{j^2}{\rho^2}, \quad (17.441)$$

which is the potential shown in Fig. 17.22 turned upside down.

Certainly, the time-sliced path integral in ρ would suffer from the phenomenon of path collapse described in Chapter 8. At the level of the semiclassical approximation to be performed here, however, this does not happen. There are two types of extremal solutions. The trivial solutions are

$$\gamma(z) = kz, \quad \rho(z) \equiv \rho_0 = \sqrt{1 - k^2}. \quad (17.442)$$

Since the wire is closed, the phase $\gamma(z)$ has to be periodic over the total length L of the wire. This implies the quantization of the wave number k ,

$$k_n = \frac{2\pi}{L}n, \quad n = 0, \pm 1, \pm 2, \dots \quad (17.443)$$

The current associated with these solutions is

$$j = \rho_0^2 k = (1 - k^2)k. \quad (17.444)$$

Figure 17.23 The condensation energy as function of velocity parameter $k_n = 2\pi n/L$.

As a function of k , this has an absolute maximum at the so-called *critical current* j_c , i.e.,

$$|j| < j_c \equiv \frac{2}{3\sqrt{3}}. \quad (17.445)$$

No solution of the field equations can carry a larger current than this. The critical wave number is

$$k_c \equiv \frac{1}{\sqrt{3}}, \quad (17.446)$$

and the energy density:

$$e_c(k) = V(\rho_0) = -\frac{1}{2}(1 - k^2)^2. \quad (17.447)$$

It is plotted in Fig. 17.23. Note that the k -values (17.446) for which a supercurrent can exist between the turning points. The energy $e_c(k)$ represents the negative condensation energy of the state in the presence of the current. For $k \rightarrow 0$ it goes against the current-free value (17.434).

We can now understand why all states of current j_n smaller than j_c are, in fact, “super” in the sense of having an extremely long lifetime. At each value of k_n , the wire carries a metastable current which can only decay by a slow tunneling. To see this, we picture the field configuration as a spiral of radius ρ wound around the wire with the azimuthal angle representing the phase $\gamma(z) = k_n z$ (see Fig. 17.24). At zero temperature, the size ρ of the order parameter is frozen at ρ_0 and the winding number is *absolutely stable* on topological grounds. Then, each metastable state with wave number k_n has an infinite lifetime. If the current is to relax by one unit of n it is necessary that at some place z , thermal fluctuations carry $\rho(z)$ to zero. There

Figure 17.24 Order parameter $\Delta(z) = \rho(z)e^{i\gamma(z)}$ of superconducting thin circular wire neglecting fluctuations. The order parameter is pictured as a spiral of radius ρ_0 and pitch $\partial\gamma(z)/\partial z = 2\pi n/L$ winding around the wire. At $T = 0$, the supercurrent is absolutely stable since the winding number n is fixed topologically.

the phase becomes undefined and may slip by 2π . At the typical low temperatures of these systems, such *phase slips* are extremely rare. To have a local excursion of $\rho(z)$ to $\rho \approx 0$ at one place z , with an appreciable measure in the functional integral (17.435), it must start from a nontrivial solution of the equations of motion which carries $\rho(z)$ as closely as possible to zero. From our experience with the mechanical motion of a mass point in a potential such as $-V(\rho)$ of Eq. (17.441), it is easily realized that there exists such a solution. It carries $\rho(z)$ from $\rho_0 = \sqrt{1 - k^2}$ at $z = -\infty$ across the potential barrier to the small value $\rho_1 = \sqrt{2}k$ and back once more across the barrier to ρ_0 at $z = \infty$ (see Fig. 17.25). Using the first integral of

Figure 17.25 Extremal excursion of order parameter in superconducting wire. It corresponds to a mass point starting out at ρ_0 , rolling under the influence of “negative gravity” up the mountain unto the point $\rho_1 = \sqrt{2}k$, and returning back to ρ_0 , with the variable z playing the role of a time variable.

motion of the differential equation (17.440), the law of energy conservation

$$\frac{1}{2}\rho_z^2 - \frac{1}{2}V(\rho) = E = -\frac{1}{2}V(\rho_0) = \frac{1}{4}\rho_0(\rho_0 + 2\rho_1) \quad (17.448)$$

leads to the equation

$$\rho_z = \sqrt{2E + V(\rho)}. \quad (17.449)$$

This is solved by the integral

$$\begin{aligned} z - z_1 &= \sqrt{2} \int_{\rho_1}^{\rho} \frac{\rho d\rho}{\sqrt{\rho^6 - 2\rho^4 + 4E\rho^2 - 2j^2}} \\ &= \frac{1}{\sqrt{2}} \int_{\rho_1^2}^{\rho^2} \frac{d\rho^2}{\sqrt{(\rho^2 - \rho_1^2)(\rho^2 - \rho_0^2)}}, \end{aligned} \quad (17.450)$$

yielding

$$z - z_1 = -\frac{2}{\sqrt{2(\rho_0^2 - \rho_1^2)}} \operatorname{arctanh} \sqrt{\frac{\rho^2 - \rho_1^2}{\rho_0^2 - \rho_1^2}}. \quad (17.451)$$

Inverting this, we find the bubble solution

$$\rho_{\text{cl}}^2(z) = 1 - k^2 - \frac{\omega^2/2}{\cosh^2[\omega(z - z_1)/2]}, \quad (17.452)$$

where

$$\omega = \sqrt{2(\rho_0^2 - \rho_1^2)} \quad (17.453)$$

is the curvature of $V(\rho)$ close to ρ_0 , i.e.,

$$V(\rho) \approx \omega^2(\rho - \rho_0)^2 + \dots \quad (17.454)$$

The extra energy of the bubble solution is

$$E_{\text{cl}} = \int_0^L dz [e(\rho_{\text{cl}}) - e_c(k)] = \frac{4}{3}\omega = \frac{4}{3}\sqrt{2(1 - 3k^2)}. \quad (17.455)$$

The explicit solution (17.452) reaches the point of smallest ρ at z_1 , where its value is

$$\rho_1 \equiv \rho(z_1) = \sqrt{2}k. \quad (17.456)$$

This value is still nonzero and does not yet permit a phase slip. However, we shall now demonstrate that quadratic fluctuations around the solution (17.456) do, in fact, to reduce the current. For this, we insert the fluctuating order field

$$\rho(z) = \rho_{\text{cl}}(z) + \delta\rho(z) \quad (17.457)$$

Figure 17.26 Infinitesimal translation of critical bubble yields antisymmetric wave function of zero energy ρ'_{cl} solving differential equation (17.509). Since this wave function has a node, there must be a negative-energy bound state.

into the free energy. With ρ_{cl} being extremal, the lowest variation of E is of second order in $\delta\rho(z)$

$$\delta^2 E = \int_0^L dz \delta\rho(z) [-\partial_z^2 + V''(\rho)] \delta\rho(z). \quad (17.458)$$

This expression is not positive definite as can be verified by studying the eigenvalue problem

$$[-\partial_z^2 + V''(\rho_{cl})] \psi_n(z) = \left[-\partial_z^2 - 1 + 3\rho_{cl}^2 - 3\frac{j^4}{\rho_{cl}^4} \right] \psi_n(z) = \lambda_n \psi_n(z). \quad (17.459)$$

The potential $V''(\rho_{cl}(z))$ has asymptotically the value ω^2 . When approaching $z = z_1$ from the right, it develops a minimum at a negative value (see Fig. 17.26). After that it goes again against ω^2 . The energy eigenvalues λ_0 and λ_{-1} lie as indicated in the figure. The fact that there is precisely one negative eigenvalue λ_{-1} can be proved without an explicit solution by the same physical argument that was used to show the instability of the fluctuation problem (17.253): A small temporal translation of the classical solution corresponds to a wave function which has no energy and a zero implying the existence of precisely one lower wave function with $\lambda_{-1} < 0$ and no zero.

The negative eigenvalue makes the critical bubble solution unstable against contraction or expansion. The former makes the fluctuation return to the spiral classical solution (17.452) of Fig. 17.24, the second removes one unit from the winding number of the spiral and reduces the supercurrent. For the precise calculation of the

decay rate, the reader is referred to the references quoted at the end of the chapter. Here we only give the final result which is [19]

$$\text{rate} = \text{const} \times L \omega(k) e^{-E_{cl}/k_B T}, \quad (17.460)$$

with the k -dependent prefactor

Figure 17.27 Logarithmic plot of resistance of thin superconducting wire as function of temperature at current $0.2\mu\text{A}$ in comparison with experimental data (vertical axis is normalized by the Ohmic resistance $R_n = 0.5\Omega$ measured at $T > T_c$, see papers quoted at end of chapter).

$$\omega(k) = 2|\lambda'_{-1}| \frac{(1 - 3k^2)^{7/4}}{(1 - k^2)^{1/2}} \exp \left[-\frac{3\sqrt{2}k}{\sqrt{1 - 3k^2}} \arctan \left(\frac{\sqrt{1 - 3k^2}}{\sqrt{2}k} \right) \right], \quad (17.461)$$

where

$$\lambda'_{-1} \equiv -\frac{1}{2} \left\{ \left[(1 + k^2)^2 + 3(1 - 3k^2)^2 \right]^{1/2} - (1 + k^2) \right\} < 0 \quad (17.462)$$

is the negative eigenvalue of the fluctuations in the complex field $\psi(z)$ [which is not directly related to λ_{-1} of Eq. (17.459) and requires a separate discussion of the initial path integral (17.435)]. This complicated-looking expression has a simple quite accurate approximation which had previously been deduced from a numerical evaluation of the fluctuation determinant [20]:

$$\omega(k) \approx (1 - \sqrt{3}k)^{15/4} (1 + k^2/4). \quad (17.463)$$

Both expressions vanish at the critical value $k = k_c = 1/\sqrt{3}$.

The resistance of a thin superconducting wire following from this calculation is compared with experimental data in Fig. 17.27.

17.12 Decay of Metastable Thermodynamic Phases

A generalization of this decay mechanism can be found in the first-order phase transitions of many-particle systems. These possess some order parameter with an effective potential which has two minima corresponding to two different thermodynamic phases. Take, for instance, water near the boiling point. At the boiling temperature, the liquid and gas phases have the same energy. This situation corresponds to the symmetric potential. At a slightly higher temperature, the liquid phase is overheated and becomes metastable. The potential is now slightly asymmetric. The decay of the overheated phase proceeds by the formation of critical bubbles [4]. Their outside consists of the metastable water phase, their inside is filled with vapor lying close to the stable minimum of the potential. The radius of the critical bubble is determined by the equilibrium between the gain in volume energy and the cost in surface energy. If σ is the surface tension and ϵ the difference in energy density, the energy of bubble solution depends on the radius as follows:

$$E \propto \sigma 4\pi R^2 - \epsilon \frac{4\pi}{3} R^3. \quad (17.464)$$

A plot of this energy in Fig. 17.28 looks just like that of the action $\mathcal{A}(\xi)$ in Fig. 17.8. Thus the role of the deformation parameter ξ is played here by the bubble radius R .

Figure 17.28 Bubble energy as function of its radius R .

At the critical bubble, the energy has a maximum. The fluctuations of the critical bubble must therefore have a negative eigenvalue. This negative eigenvalue mode accounts for the fact that the critical bubble is unstable against expansion and contraction. When expanding, the bubble transforms the entire liquid into the stable gas phase. When contracting, the bubble disappears and the liquid remains in the overheated phase. Only the first half of the fluctuations have to be counted when calculating the lifetime of the overheated phase.

It is instructive to take a comparative look at the instability of a critical bubble to see how the different spatial dimensions modify the properties of the solution. We shall discuss first the case of three space dimensions. As in the case of superconductivity, the description of the liquid-vapor phase transition makes use of a space-dependent order parameter, the real order field $\varphi(\mathbf{x})$. The two minima of the

potential $V(\varphi)$ describe the two phases of the system. The kinetic term \mathbf{x}'^2 in the path integral is now a field gradient term $[(\partial_{\mathbf{x}}\varphi(\mathbf{x}))^2]$ which ensures finite correlations between neighboring field configurations. The Euclidean action controlling the fluctuations is therefore of the form

$$\mathcal{A}[\varphi] = \int d^3x \left\{ \frac{1}{2} [\nabla\varphi(\mathbf{x})]^2 + V(\varphi) \right\}, \quad (17.465)$$

where $V(\varphi)$ is the same potential as in Eq. (17.1), but it is extended by the asymmetric energy (17.243). Within classical statistics, the thermal fluctuations are controlled by the path integral for the partition function

$$Z = \int \mathcal{D}\varphi(\mathbf{x}) e^{-\mathcal{A}[\varphi]/T}. \quad (17.466)$$

Here T is the temperature measured in multiples of the Boltzmann constant k_B . The path integral $\int \mathcal{D}\varphi(\mathbf{x})$ is defined by cutting the three-dimensional space into small cubes of size ϵ and performing one field integration at each point.

The critical bubble extremizes the action. Assuming spherical symmetry, the bubble satisfies in D dimensions the classical Euler-Lagrange field equation

$$\left(-\frac{d^2}{dr^2} - \frac{D-1}{r} \frac{d}{dr} \right) \varphi_{\text{cl}} + V'(\varphi_{\text{cl}}(r)) = 0. \quad (17.467)$$

This differs from the equation (17.305) for the one-dimensional bubble solution by the extra gradient term $-[(D-1)/r]\partial_r\varphi_{\text{cl}}(r)$. Such a term is an obstacle to an exact solution of the equation via the energy conservation law (17.306). The relevant qualitative properties of the solution can nevertheless be seen in a similar way as for the bubble solution. As in Fig. 17.11 we plot the reversed potential and imagine the solution $\varphi(r)$ to describe the motion of a mass point in this potential with $-r$ playing the role of a “time”. Setting $\varphi_{\text{cl}}(r) = x(-t)$, the field equation (17.467) takes the form

$$\ddot{x}(t) - \frac{D-1}{t} \dot{x}(t) - V'(x(t)) = 0. \quad (17.468)$$

In this notation, the second term, i.e., the term $-[(D-1)/r]\partial_r\varphi_{\text{cl}}(r)$ in (17.467) plays the role of a negative “friction” accelerating motion of the particle along $x(t)$. This effect decreases with time like $1/t$. With our everyday experience of mechanical systems, the qualitative behavior of the solution can immediately be plotted qualitatively as shown in Fig. 17.29. For $D=1$, the energy conservation makes the particle reach the right-hand zero of the potential. For $D>1$, the “antifriction” makes the trajectory overshoot. At $r=0$, the solution is closest to the stable minimum (the maximum of the reversed potential) on the left-hand side. In the superheated water system, this corresponds to the inside of the bubble being filled with vapor. As r moves outward in the bubble, the state moves closer to the metastable state, i.e., it becomes more and more liquid. The antifriction term has the effect that the

Figure 17.29 Qualitative behavior of critical bubble solution as function of its radius.

point of departure on the left-hand side lies energetically below the final value of the metastable state.

Consider now the fluctuations of such a critical bubble in $D = 3$ dimensions. Suppose that the field deviates from the solution of the field equation (17.467) by $\delta\varphi(\mathbf{x})$. The deviations satisfy the differential equation

$$\left[-\frac{d^2}{dr^2} - \frac{2}{r} \frac{d}{dr} + \frac{\hat{L}^2}{r^2} + V''(\varphi_{cl}(r)) \right] \delta\varphi(\mathbf{x}) = \lambda \delta\varphi(\mathbf{x}), \quad (17.469)$$

where \hat{L}^2 is the differential operator of orbital angular momentum (in units $\hbar = 1$). Taking advantage of rotational invariance, we expand $\delta\varphi(\mathbf{x})$ into eigenfunctions of angular momentum φ_{nlm} , the spherical harmonics $Y_{lm}(\hat{\mathbf{x}})$:

$$\phi(\mathbf{x}) = \sum_{nlm} \varphi_{nlm}(r) Y_{lm}(\hat{\mathbf{x}}). \quad (17.470)$$

The coefficients φ_{nlm} satisfy the radial differential equation

$$\left[-\frac{d^2}{dr^2} - \frac{2}{r} \frac{d}{dr} + \frac{l(l+1)}{r^2} + V''(\varphi_{cl}(r)) \right] \varphi_{nlm}(r) = \lambda_{nl} \varphi_{nlm}(r), \quad (17.471)$$

with

$$V''(\varphi_{\text{cl}}(r)) = -\frac{\omega^2}{2} + \frac{3\omega^2}{2a^2}\varphi_{\text{cl}}^2(r). \quad (17.472)$$

One set of solutions is easily found, namely those associated with the translational motion of the classical solution. Indeed, if we take the bubble at the origin,

$$\varphi_{\text{cl}}(\mathbf{x}) = \varphi_{\text{cl}}(r), \quad (17.473)$$

to another place $\mathbf{x} + \mathbf{a}$, we find, to lowest order in \mathbf{a} ,

$$\begin{aligned} \varphi_{\text{cl}}(\mathbf{x} + \mathbf{a}) &= \varphi_{\text{cl}}(\mathbf{x}) + \mathbf{a}\partial_{\mathbf{x}}\varphi_{\text{cl}}(\mathbf{x}) \\ &= \varphi_{\text{cl}}(r) + \mathbf{a}\hat{\mathbf{x}}\partial_r\varphi_{\text{cl}}(r). \end{aligned} \quad (17.474)$$

But $\hat{\mathbf{x}}$ is just the Cartesian way of writing the three components of the spherical harmonics $Y_{1m}(\hat{x})$. If we introduce the *spherical components* of a vector as follows

$$\begin{pmatrix} x_0 \\ x_1 \\ x_{-1} \end{pmatrix} \equiv \begin{pmatrix} x_3 \\ (x_1 + ix_2)/\sqrt{2} \\ -(x_1 - ix_2)/\sqrt{2} \end{pmatrix}, \quad (17.475)$$

we see that

$$\hat{x}_m = \sqrt{\frac{4\pi}{3}}Y_{1m}(\hat{\mathbf{x}}). \quad (17.476)$$

Thus, $\delta\varphi(\mathbf{x}) = \mathbf{a}\hat{\mathbf{x}}\partial_r\varphi(\mathbf{x})$ must be a solution of Eq. (17.469) with zero eigenvalue λ . This can easily be verified directly: The factor $\hat{\mathbf{x}}$ causes \hat{L}^2 to have the eigenvalue 2, and the accompanying radial derivative $\delta\varphi(\mathbf{x}) = \partial_r\varphi_{\text{cl}}(r)$ is a solution of Eq. (17.471) for $l = 1$ and $\lambda_{nl} = 0$, as is seen by differentiating the Euler-Lagrange equation (17.467) with respect to r . Choosing the principal quantum number of these translational modes to be $n = 1$, we assign the three components of $\hat{\mathbf{x}}\partial_r\varphi_{\text{cl}}(r)$ to represent the eigenmodes $\varphi_{1,1,m}$.

As long as the bubble radius is large compared to the thickness of the wall, which is of the order $1/\omega$, the $1/r^2$ -terms will be very small. There exists then an entire family of solutions $\varphi_{1lm}(\mathbf{x})$ with all possible values of l which all have approximately the same radial wave function $\partial_r\varphi_{\text{cl}}(r)$. Their eigenvalues are found by a perturbation expansion. The perturbation consists in the centrifugal barrier but with the $l = 1$ barrier subtracted since it is already contained in the derivative $\partial_r\varphi_{\text{cl}}(r)$, i.e.,

$$V_{\text{pert}} = [l(l+1) - 2]/2r^2. \quad (17.477)$$

The bound-state wave functions φ_{1lm} are normalizable and differ appreciably from zero only in the neighborhood of the bubble wall. To lowest approximation, the perturbation expansion produces therefore an energy

$$\lambda_{nl} \approx \frac{l(l+1) - 2}{r_c^2}, \quad (17.478)$$

where r_c is the radius of the critical bubble. As a consequence, the lowest $l = 0$ eigenstate has a negative energy

$$\lambda_{00} \approx -\frac{1}{r_c^2}. \quad (17.479)$$

Physically, this single $l = 0$ -mode corresponds to an infinitesimal radial vibration of the bubble. As already explained above it is not astonishing that a radial vibration has a negative eigenvalue. The critical bubble lies at a maximum of the action. Expansion or contraction is energetically favorable. Since $Y_{00}(\mathbf{x})$ is a constant, the wave function is proportional to $(d/dr)\varphi_{cl}(r)$ itself without an angular factor. This is seen directly by performing an infinitesimal radial contraction

$$\varphi_{cl}((1 - \epsilon)r) = \varphi_{cl}(r) - \epsilon r \partial_r \varphi_{cl}(r). \quad (17.480)$$

The variation $r \partial_r \varphi_{cl}(r)$ is almost zero except in the vicinity of the critical radius r_c , so that $r \partial_r \varphi_{cl}(r) \approx r_c \partial_r \varphi_{cl}(r)$ which is the above wave function. Being the ground state of the Schrödinger equation (17.469), it should be denoted by $\varphi_{000}(r)$. Since it solves approximately the Schrödinger equation (17.471) with $l = 1$, it also solves this equation approximately with $l = 0$ and the energy (17.479).

Finally let us point out that in $D > 1$ dimensions, the value of the negative eigenvalue can be calculated very simply from a phenomenological consideration of the bubble action. Since the inside of the bubble is very close to the true ground state of the system whose energy density lies lower than that of the metastable one by ϵ , the volume energy of a bubble of an arbitrary radius R is

$$E_V = -S_D \frac{R^D}{D} \epsilon, \quad (17.481)$$

where $S_D R^{D-1}$ is the surface of the bubble and $S_D R^D / D$ its volume. The surface energy can be parametrized as

$$E_S = S_D R^{D-1} \sigma, \quad (17.482)$$

where σ is a constant proportional to the surface tension. Adding the two terms and differentiating with respect to R , we obtain a critical bubble radius at

$$R = r_c = (D - 1)\sigma/\epsilon, \quad (17.483)$$

with a critical bubble energy

$$E_c = \frac{S_D}{D} R_c^{D-1} \sigma = \frac{S_D}{D(D-1)} R_c^D \epsilon = \frac{S_D}{D} (D-1)^{D-1} \frac{\sigma^D}{\epsilon^{D-1}}. \quad (17.484)$$

The second derivative with respect to the radius R is, at the critical radius,

$$\left. \frac{d^2 E}{dR^2} \right|_{R=r_c} = -DE_c \frac{D-1}{r_c^2}. \quad (17.485)$$

Identifying the critical bubble energy E_c with the classical Euclidean action \mathcal{A}_{cl} we find the variation of the bubble action as

$$\delta^2 \mathcal{A}_{\text{cl}} \approx -\frac{1}{2}(\delta R)^2 D \mathcal{A}_{\text{cl}} \frac{D-1}{r_c^2}. \quad (17.486)$$

We now express the dilational variation of the bubble radius in terms of the normal coordinate of (17.470). The normalized wave function is obviously

$$\varphi_{000}(r) = \frac{\partial_r \varphi_{\text{cl}}(r)}{\sqrt{\int d^D x (\partial_r \varphi_{\text{cl}})^2}}. \quad (17.487)$$

But the expression under the square root is exactly D times the action of the critical bubble

$$\int d^D x (\partial_r \varphi_{\text{cl}})^2 = D \mathcal{A}_{\text{cl}}. \quad (17.488)$$

To prove this we introduce a scale factor s into the solution of the bubble and evaluate the action

$$\begin{aligned} \tilde{\mathcal{A}}_{\text{cl}} &= \int d^D x \left\{ \frac{1}{2} [(\partial_r \varphi_{\text{cl}}(sr))^2 + V(\varphi_{\text{cl}}(sr))] \right\} \\ &= \frac{1}{s^D} \int d^D x \left\{ \frac{s^2}{2} [\partial_r \varphi_{\text{cl}}(r)]^2 + V(\varphi_{\text{cl}}(r)) \right\}. \end{aligned} \quad (17.489)$$

Since $\tilde{\mathcal{A}}_{\text{cl}}$ is extremal at $s = 1$, it has to satisfy

$$\left. \frac{\partial \tilde{\mathcal{A}}_{\text{cl}}}{\partial s} \right|_{s=1} = 0, \quad (17.490)$$

or

$$\int d^D x \left\{ (D-2) \frac{1}{2} [\partial_r \varphi_{\text{cl}}]^2 + DV(\varphi_{\text{cl}}(r)) \right\} = 0. \quad (17.491)$$

Hence

$$\int d^D x V(\varphi_{\text{cl}}(r)) = -\frac{D-2}{D} \int d^D x \frac{1}{2} [\partial_r \varphi_{\text{cl}}(r)]^2, \quad (17.492)$$

implying that

$$\begin{aligned} \mathcal{A}_{\text{cl}} &= \left(\frac{1}{2} - \frac{D-2}{2D} \right) \int d^D x [\partial_r \varphi_{\text{cl}}(r)]^2 \\ &= \frac{1}{D} \int d^D x [\partial_r \varphi_{\text{cl}}(r)]^2. \end{aligned} \quad (17.493)$$

With (17.487), the φ_{000} contribution to $\delta\varphi(\mathbf{x})$ reads

$$\delta\varphi(\mathbf{x}) = \xi_{000} \varphi_{000}(r) = \xi_{000} \frac{\partial_r \varphi}{\sqrt{D \mathcal{A}_{\text{cl}}}}, \quad (17.494)$$

and we arrive at

$$\delta R = \frac{\xi_{000}}{\sqrt{D\mathcal{A}_{\text{cl}}}}. \quad (17.495)$$

Inserting this into (17.486) shows that the second variation of the Euclidean action $\delta^2\mathcal{A}_{\text{cl}}$ can be written in terms of the normal coordinates associated with the normalized fluctuation wave function φ_{000} as

$$\delta^2\mathcal{A}_{\text{cl}} = -\xi_{000}^2 \frac{D-1}{2r_c^2}. \quad (17.496)$$

From this relation, we read off the negative eigenvalue

$$\lambda_{00} = -\frac{D-1}{2r_c^2}. \quad (17.497)$$

For $D = 3$, this is in agreement with the $D = 3$ value (17.479). For general D , the eigenvalue corresponding to (17.479) would have been derived with the arguments employed there from the derivative term $-[(D-1)/r]d/dr$ in the Lagrangian and would also have resulted in (17.497).

All other multipole modes φ_{nlm} have a positive energy. Close to the bubble wall (as compared with the radius), the classical solutions $(1/r)\varphi_{nlm}(r)$ can be taken approximately from the solvable one-dimensional equation

$$\left[-\frac{1}{2} \frac{d^2}{dr^2} + \frac{\omega^2}{2} \left(1 - \frac{3}{2} \frac{1}{\cosh^2[\omega(r-r_c)/2]} \right) \right] \left(\frac{1}{r} \varphi_{nlm} \right) \approx \tilde{\lambda}_n \left(\frac{1}{r} \varphi_{nlm} \right). \quad (17.498)$$

The wave functions with $n = 0$ are

$$\varphi_{0lm} \approx \sqrt{\frac{3\omega}{8}} \frac{1}{\cosh^2[\omega(r-r_c)/2]}, \quad (17.499)$$

and have the eigenvalues

$$\lambda_{0l} \approx \frac{l(l+1)-2}{2r_c^2}. \quad (17.500)$$

The $n = 1$ -bound states are

$$\varphi_{1lm} \approx \sqrt{\frac{3\omega}{4}} \frac{\sinh[\omega(r-r_c)/2]}{\cosh^2[\omega(r-r_c)/2]}, \quad (17.501)$$

with eigenvalues

$$\lambda_{1l} \approx \frac{3}{8}\omega^2 + \frac{l(l+2)-2}{2r_c^2}. \quad (17.502)$$

Figure 17.30 Decay of metastable false vacuum in Minkowski space. It proceeds as a shock wave which after some time traverses the world almost with light velocity, converting the false into the true vacuum.

17.13 Decay of Metastable Vacuum State in Quantum Field Theory

The theory of decay presented in the last section has an interesting quantum field-theoretic application. Consider a metastable scalar field system in a D -dimensional Euclidean spacetime at temperature zero. At a fixed time, there will be a certain average number of bubbles, regulated by the “quantum Boltzmann factor” $\exp(-\mathcal{A}_{\text{cl}}/\hbar)$. If the bubble gas is sufficiently dilute (i.e., if the distances between bubbles is much larger than the radii), each bubble is described quite accurately by the classical solution. In Minkowski space, a Euclidean radius $r = \sqrt{\mathbf{x}^2 + c^2\tau^2}$ corresponds to $r = \sqrt{\mathbf{x}^2 - c^2t^2}$, where c is the light velocity. The critical bubble has therefore the spacetime behavior

$$\varphi_{\text{cl}}(\mathbf{x}, t) = \varphi_{\text{cl}}(r = \sqrt{\mathbf{x}^2 - c^2t^2}). \quad (17.503)$$

From the above discussion in Euclidean space we know that φ will be equal to the metastable false vacuum in the outer region $r > r_c$, i.e., for

$$\mathbf{x}^2 - c^2t^2 > r_c^2. \quad (17.504)$$

The inside region

$$\mathbf{x}^2 - c^2t^2 < r_c^2 \quad (17.505)$$

contains the true vacuum state with the lower energy. Thus a critical bubble in spacetime has the hyperbolic structure drawn in Fig. 17.30. Therefore, the Euclidean critical bubble describes in Minkowski space the growth of a bubble as a function of time. The bubble starts life at some time $t = r_c/c$ and expands almost instantly to a radius of order r_c . The position of the shock wave is described by

$$\mathbf{x}^2 - c^2t^2 = r_c^2. \quad (17.506)$$

This implies that a shock wave that runs through space with a velocity

$$v = \frac{|\mathbf{x}|}{t} = \frac{c}{\sqrt{1 - r_c^2/c^2 t^2}} \quad (17.507)$$

and converts the metastable into the stable vacuum — a global catastrophe. A Euclidean bubble centered at another place \mathbf{x}_b, τ_b would correspond to the same process starting at \mathbf{x}_b and a time

$$t_b = r_c/c + \tau_b. \quad (17.508)$$

A finite time after the creation of a bubble, of the order r_c/c , the velocity of the shock wave approaches the speed of light (in many-body systems the speed of sound). Thus, we would hardly be able to see precursors of such a catastrophe warning us ahead of time. We would be annihilated with the present universe before we could even notice.

17.14 Crossover from Quantum Tunneling to Thermally Driven Decay

For completeness, we discuss here the difference between a decay caused by a quantum-mechanical tunneling process at $T = 0$, and a pure thermally driven decay at large temperatures. Consider a one-dimensional system possessing, at some place x_* , a high potential barrier, much higher than the thermal energy $k_B T$, with a shape similar to Fig. 17.10. Let the well to the left of the barrier be filled with a grand-canonical ensemble of noninteracting particles of mass M in a nearly perfect equilibrium. Their distribution of momenta and positions in phase space is governed by the Boltzmann factor $e^{-\beta[p^2/2M+V(x)]}$. The rate, at which the particles escape across the barrier, is given by the classical statistical integral

$$\Gamma_{\text{cl}} = Z_{\text{cl}}^{-1} \int dx \int \frac{dp}{2\pi\hbar} e^{-\beta[p^2/2M+V(x)]} \delta(x - x_*) \frac{p}{M} \Theta(p), \quad (17.509)$$

where Z_{cl} is the classical partition function

$$Z_{\text{cl}} = \int dx \int \frac{dp}{2\pi\hbar} e^{-\beta[p^2/2M+V(x)]}. \quad (17.510)$$

The step function $\Theta(p)$ selects the particles running to the right across the top of the potential barrier. Performing the phase space path integral in (17.509) yields

$$\Gamma_{\text{cl}} = \frac{Z_{\text{cl}}^{-1}}{2\pi\hbar\beta} e^{-V(x_*)}. \quad (17.511)$$

If the metastable minimum of the potential is smooth, $V(x)$ can be replaced approximately in the neighborhood of x_0 by the harmonic expression

$$V(x) \approx \frac{M}{2} \omega_0^2 (x - x_0)^2. \quad (17.512)$$

The classical partition function is then given approximately by

$$Z_{\text{cl}} \approx \frac{1}{\hbar\beta\omega_0}, \quad (17.513)$$

and the decay rate follows the simple formula

$$\Gamma_{\text{cl}} \approx \frac{\omega_0}{2\pi} e^{-\beta V(x_*)}. \quad (17.514)$$

Let us compare this result with the decay rate due to pure quantum tunneling. In the limit of small temperatures, the decay proceeds from the ground state, and the partition function is approximately equal to

$$Z \approx e^{-\beta(E^{(0)} - i\hbar\Gamma/2)}. \quad (17.515)$$

The decay rate is given by the small imaginary part of the partition function:

$$\Gamma \xrightarrow{T \rightarrow 0} \frac{2 \operatorname{Im} Z}{\hbar\beta \operatorname{Re} Z}. \quad (17.516)$$

In contrast to this, the thermal rate formula (17.511) implies for the high-temperature regime, where Γ becomes equal to Γ_{cl} , the relation:

$$\Gamma \xrightarrow{T \rightarrow \infty} \frac{\omega_* \operatorname{Im} Z_{\text{cl}}}{\pi \operatorname{Re} Z_{\text{cl}}}. \quad (17.517)$$

The frequency ω_* is determined by the curvature of the potential at the top of the barrier, where it behaves like

$$V(x) \approx -\frac{M}{2}\omega_*^2(x - x_*)^2. \quad (17.518)$$

The relation (17.517) follows immediately by calculating in the integral (17.510) the contribution of the neighborhood of the top of the barrier in the saddle point approximation. As in the integral, this is done (17.261) by rotating the contour of integration which starts at $x = x_*$ into the upper complex half-plane. Writing $x = x_* + iy$ this leads to the following integral:

$$\operatorname{Im} Z_{\text{cl}} \approx \int_0^\infty \frac{dy}{\sqrt{2\pi\hbar^2\beta/M}} e^{-\beta[V(x_*) + \frac{M}{2}\omega_*^2 y^2]} \approx \frac{1}{2\hbar\beta\omega_*} e^{-\beta V(x_*)}. \quad (17.519)$$

Since the real part is given by (17.513) we find the ratio

$$\frac{\operatorname{Im} Z_{\text{cl}}}{\operatorname{Re} Z_{\text{cl}}} \approx \frac{\omega_0}{2\omega_*} e^{-\beta V(x_*)}, \quad (17.520)$$

so that (17.511) is equivalent to (17.517).

The two formulas (17.516) and (17.517) are derived for the two extreme regimes $T \gg T_0$ and $T \ll T_0$, respectively, where T_0 denotes the characteristic temperature

associated with the curvature of the potential at the metastable minimum $T_0 = \hbar\omega_0/k_B$. Numerical studies have shown that the applicability extends into the close neighborhood of T_0 on each side of the temperature axis. The crossover regime is quite small, of the order $\mathcal{O}(\hbar^{3/2})$.

Note that given the knowledge of the imaginary parts of all excited states, which can be obtained as in Section 17.9, it will be possible to calculate the average lifetime of a metastable state at all temperatures without the restrictions of the semiclassical approximation. This remains to be done.

Appendix 17A Feynman Integrals for Fluctuation Correction

For the integral (17.219) we obtain with (17.237) immediately the result stated in Eq. (17.240)

$$I'_1 = \frac{97}{560}. \tag{17A.1}$$

To calculate the remaining three double integrals I_{21}, I_{22}, I_3 in (17.223) and (17.224) we observe that because of the symmetry of the Green function $G_{\mathcal{O}_\omega}(\tau, \tau')$ in τ, τ' the measure of integration can be rewritten as $2 \int_{-\infty}^{\infty} d\tau \int_{-\infty}^t d\tau'$. We further introduce the dimensionless classical functions

$$\begin{aligned} \tilde{x}_{\text{cl}}(\tau) &\equiv \sqrt{\frac{g}{2\omega^2}} x_{\text{cl}}(\tau) = \tanh(\tau/2), \\ \tilde{y}_0(\tau) &\equiv \sqrt{\frac{8}{3\omega}} y_0(\tau) = \frac{1}{\cosh^2(\omega\tau/2)}, \end{aligned} \tag{17A.2}$$

use natural units with $\omega = 1, g = 1$, since these quantities cancel in all integrals, and define

$$\begin{aligned} x_{\text{G}}(\tau) &\equiv \tilde{x}_{\text{cl}}(\tau) G_{\mathcal{O}_\omega}(\tau, \tau) \\ x_{\text{KG}}(\tau) &\equiv \left[\int_{-\infty}^{\tau} G_{\mathcal{O}_\omega}(\tau, \tau') x_{\text{G}}(\tau') d\tau' \right]_{\text{A}} \\ x_{\text{K3G}}(\tau) &\equiv \left[\int_{-\infty}^{\tau} G_{\mathcal{O}_\omega}^3(\tau, \tau') x_{\text{G}}(\tau') dt' \right]_{\text{A}}, \end{aligned} \tag{17A.3}$$

where the subscript A denotes the antisymmetric part in τ . Because of the antisymmetry of x_{cl} , the symmetric part gives no contribution to the integrals which can be written as

$$I_{21} = 6 \int_0^{\infty} d\tau \tilde{x}_{\text{cl}}(\tau) x_{\text{K3G}}(\tau), \tag{17A.4}$$

$$I_{22} = 9 \int_0^{\infty} d\tau x_{\text{G}}(\tau) x_{\text{KG}}(\tau), \tag{17A.5}$$

$$I_3 = 24 \int_0^{\infty} d\tau y'_0(\tau) x_{\text{KG}}(\tau). \tag{17A.6}$$

When evaluating the integrals in (17A.3) the antisymmetry of $y_0(\tau)$ is useful. We easily find

$$x_{\text{KG}}(\tau) = \frac{1}{4} \frac{12\tau + \tanh(\tau/2)}{12\cosh^2(\tau/2)}. \tag{17A.7}$$

Inserting this into I_{22} and I_3 we encounter integrals of two types

$$\int_0^{\infty} d\tau \sinh^m(\tau/2)/\cosh^n(\tau/2) \quad \text{and} \quad \int_0^{\infty} \tau \sinh^m(\tau/2)/\cosh^n(\tau/2).$$

The former can be performed with the help of formula (17.54), the latter require integrations by parts of the type

$$\int_0^\infty f(\tau/2) \tanh \frac{\tau}{2} d\tau = - \int_0^\infty f'(\tau/2) \ln(2 \cosh \frac{\tau}{2}) d\tau, \tag{17A.8}$$

which lead to a finite sum of integrals of the first type plus integrals of the type¹¹

$$\int_0^\infty \log \cosh(\tau/2) \sinh^m(\tau/2) / \cosh^n(\tau/2).$$

These, in turn, are equal to $-\partial_\nu \int_0^\infty d\tau \sinh^m(\tau/2) / \cosh^{\nu+1}(\tau/2)$ so that it is evaluated again via (17.54). After performing the subtraction in I_{22} we obtain the values given in Eq. (17.240).

The evaluation of the integral I_{21} is more tedious since we must integrate over the third power of the Green function, which is itself a lengthy function of τ . It is once more useful to exploit the symmetry properties of the integrand. We introduce the abbreviations

$$\begin{aligned} f_n^{S/A}(\tau) &\equiv \frac{1}{2} [H_R^n(\tau) \pm H_R^n(-\tau)] y_0^{3-n}(\tau), \\ F_n^{S/A}(\tau) &\equiv \int_0^\tau f_n^{S/A}(\tau') \tilde{x}_{cl}(\tau') d\tau', \\ N_n &\equiv \int_0^\infty H_R^n(\tau) y_0^{3-n}(\tau) \tilde{x}_{cl}(\tau) d\tau, \end{aligned} \tag{17A.9}$$

and find x_{K3G} in the form

$$\begin{aligned} x_{K3G}(\tau) &= f_3^A(\tau) [N_0 - F_0^S(\tau)] + 3f_2^A(\tau) [N_1 - F_1^S(\tau)] + 3f_1^A(\tau) [N_2 - F_2^S(\tau)] \\ &\quad + 3f_2^S(\tau) F_1^A(\tau) + 3f_1^S(\tau) F_2^A(\tau) + f_0^S(\tau) F_3^A(\tau), \end{aligned} \tag{17A.10}$$

with

$$N_0 = \frac{3}{32}, \quad N_1 = -\frac{7}{128}, \quad N_2 = \frac{203}{512} - \frac{\log 2}{2}. \tag{17A.11}$$

Explicitly:

$$\begin{aligned} x_{K3G}(\tau) &= \frac{\operatorname{sech}^7 \frac{\tau}{2}}{3 \cdot 2^9} \left[3\tau \left(58 \cosh \frac{\tau}{2} - 27 \cosh \frac{3\tau}{2} - 3 \cosh \frac{5\tau}{2} \right) \right. \\ &\quad - \left(753 \sinh \frac{\tau}{2} + 48 \sinh \frac{3\tau}{2} + 22 \sinh \frac{5\tau}{2} + \sinh \frac{7\tau}{2} \right) \\ &\quad + 36 \cosh \frac{\tau}{2} \ln(2 \cosh \frac{\tau}{2}) (6\tau + 8 \sinh \tau + \sinh 2\tau) \\ &\quad \left. - 108 \cosh \frac{\tau}{2} \left(\int_0^\tau d\tau' \tau' \tanh \frac{\tau'}{2} \right) \right]. \end{aligned} \tag{17A.12}$$

The integrals to be performed are of the same types as before, except for the one involving the last term which requires one further partial integration:

$$\begin{aligned} - \int_0^\infty d\tau \tilde{x}_{cl}(\tau) \operatorname{sech}^6 \frac{\tau}{2} \int_0^\tau d\tau' \tau' \tanh \frac{\tau'}{2} &= \frac{1}{3} \int_0^\infty d\tau \frac{d}{d\tau} \left[\operatorname{sech}^6 \frac{\tau}{2} \right] \int_0^\tau d\tau' \tau' \tanh \frac{\tau'}{2} \\ &= -\frac{1}{3} \int_0^\infty d\tau \operatorname{sech}^6 \frac{\tau}{2} \tau \tanh \frac{\tau}{2} = -\frac{16}{135}. \end{aligned} \tag{17A.13}$$

¹¹I.S. Gradshteyn and I.M. Ryzhik, *op. cit.*, Formulas 2.417.

After the necessary subtraction of the divergent term we find the value of I_{21} given in Eq. (17.240).

The final result for the first coefficient of the Taylor expansion of the subtracted fluctuation factor C' in Eq. (17.222) is therefore

$$c_1 = \frac{71}{24} \approx 2.958. \quad (17A.14)$$

This number was calculated in Ref. [13] by solving the Schrödinger equation [21].

With the help of the WKB approximation he derived a recursion relation for the higher coefficients c_k of the expansion of C' :

$$C' = \left[1 - c_1 \frac{g\hbar}{\omega^3} - c_2 \left(\frac{g\hbar}{\omega^3} \right)^2 - c_3 \left(\frac{g\hbar}{\omega^3} \right)^3 + \dots \right]. \quad (17A.15)$$

From this he calculated the next nine coefficients

$$c_2 = \frac{315}{32} \approx 9.84376, \quad c_3 = \frac{65953}{1152} \approx 57.2509. \quad (17A.16)$$

Their large behavior is

$$c_k \sim \frac{9}{\pi} \left(\frac{3}{2} \right)^k k! [\ln(6k) + \gamma]. \quad (17A.17)$$

Notes and References

The path integral theory of tunneling was first discussed by

A.I. Vainshtein, *Decaying Systems and the Divergence of Perturbation Series*, Novosibirsk Report (1964), in Russian (unpublished),

and in the context of the nucleation of first-order phase transitions by

J.S. Langer, *Ann. Phys.* **41**, 108 (1967).

The subject was studied further in the field-theoretic literature:

M.B. Voloshin, I.Y. Kobzarev, L.B. Okun, *Yad. Fiz.* **20**, 1229 (1974); *Sov. J. Nucl. Phys.* **20**, 644 (1975);

Nonequilibrium Quantum Statistics

Quantum statistics described by the theoretical tools of the previous chapters is quite limited. The physical system under consideration must be in thermodynamic equilibrium, with a constant temperature enforced by a thermal reservoir. In this situation, partition function and the density matrix can be calculated from an analytic continuation of quantum-mechanical time evolution amplitudes to an imaginary time $t_b - t_a = -i\hbar/k_B T$. In this chapter we want to go beyond such equilibrium physics and extend the path integral formalism to nonequilibrium time-dependent phenomena. The tunneling processes discussed in Chapter 17 belong really to this class of phenomena, and their full understanding requires the theoretical framework of this chapter. In the earlier treatment this was circumvented by addressing only certain quasi-equilibrium questions. These were answered by applying the equilibrium formalism to the quantum system at positive coupling constant, which guaranteed perfect equilibrium, and extending the results to the quasi-equilibrium situation analytic continuation to small negative coupling constants.

Before we can set up a path integral formulation capable of dealing with true nonequilibrium phenomena, some preparatory work is useful based on the traditional tools of operator quantum mechanics.

18.1 Linear Response and Time-Dependent Green Functions for $T \neq 0$

If the deviations of a quantum system from thermal equilibrium are small, the easiest description of nonequilibrium phenomena proceeds via the *theory of linear response*. In operator quantum mechanics, this theory is introduced as follows. First, the system is assumed to have a time-independent Hamiltonian operator \hat{H} . The ground state is determined by the Schrödinger equation, evolving as a function of time according to the equation

$$|\Psi_S(t)\rangle = e^{-i\hat{H}t}|\Psi_S(0)\rangle \quad (18.1)$$

(in natural units with $\hbar = 1$, $k_B = 1$). The subscript S denotes the Schrödinger picture.

Next, the system is slightly disturbed by adding to \hat{H} a time-dependent external interaction,

$$\hat{H} \rightarrow \hat{H} + \hat{H}^{\text{ext}}(t), \quad (18.2)$$

where $\hat{H}^{\text{ext}}(t)$ is assumed to set in at some time t_0 , i.e., $\hat{H}^{\text{ext}}(t)$ vanishes identically for $t < t_0$. The disturbed Schrödinger ground state has the time dependence

$$|\Psi_S^{\text{dist}}(t)\rangle = e^{-i\hat{H}t}\hat{U}_H(t)|\Psi_S(0)\rangle, \quad (18.3)$$

where $\hat{U}_H(t)$ is the time translation operator in the Heisenberg picture. It satisfies the equation of motion

$$i\dot{\hat{U}}_H(t) = \hat{H}_H^{\text{ext}}(t)\hat{U}_H(t), \quad (18.4)$$

with¹

$$\hat{H}_H^{\text{ext}}(t) \equiv e^{i\hat{H}t}\hat{H}^{\text{ext}}(t)e^{-i\hat{H}t}. \quad (18.5)$$

To lowest-order perturbation theory, the operator $\hat{U}_H(t)$ is given by

$$\hat{U}_H(t) = 1 - i \int_{t_0}^t dt' \hat{H}_H^{\text{ext}}(t') + \dots. \quad (18.6)$$

In the sequel, we shall assume the onset of the disturbance to lie at $t_0 = -\infty$. Consider an arbitrary time-independent Schrödinger observable \hat{O} whose Heisenberg representation has the time dependence

$$\hat{O}_H(t) = e^{i\hat{H}t}\hat{O}e^{-i\hat{H}t}. \quad (18.7)$$

Its time-dependent expectation value in the disturbed state $|\Psi_S^{\text{dist}}(t)\rangle$ is given by

$$\begin{aligned} \langle \Psi_S^{\text{dist}}(t) | \hat{O} | \Psi_S^{\text{dist}}(t) \rangle &= \langle \Psi_S(0) | \hat{U}_H^\dagger(t) e^{i\hat{H}t} \hat{O} e^{-i\hat{H}t} \hat{U}_H(t) | \Psi_S(0) \rangle \\ &\approx \langle \Psi_S(0) | \left(1 + i \int_{-\infty}^t dt' \hat{H}_H^{\text{ext}}(t') + \dots \right) \hat{O}_H(t) \\ &\quad \times \left(1 - i \int_{-\infty}^t dt' \hat{H}_H^{\text{ext}}(t') + \dots \right) | \Psi_S(0) \rangle \\ &= \langle \Psi_H | \hat{O}_H(t) | \Psi_H \rangle - i \langle \Psi_H | \int_{-\infty}^t dt' [\hat{O}_H(t), \hat{H}_H^{\text{ext}}(t')] | \Psi_H \rangle + \dots \end{aligned} \quad (18.8)$$

We have identified the time-independent Heisenberg state with the time-dependent Schrödinger state at zero time in the usual manner, i.e., $|\Psi_H\rangle \equiv |\Psi_S(0)\rangle$. Thus the expectation value of \hat{O} deviates from equilibrium by

$$\begin{aligned} \delta \langle \Psi_S(t) | \hat{O} | \Psi_S(t) \rangle &\equiv \langle \Psi_S^{\text{dist}}(t) | \hat{O}(t) | \Psi_S^{\text{dist}}(t) \rangle - \langle \Psi_S(t) | \hat{O}(t) | \Psi_S(t) \rangle \\ &= -i \int_{-\infty}^t dt' \langle \Psi_H | [\hat{O}_H(t), \hat{H}_H^{\text{ext}}(t')] | \Psi_H \rangle. \end{aligned} \quad (18.9)$$

¹Note that after the replacements $H \rightarrow H_0$, $H_H^{\text{ext}} \rightarrow H_I^{\text{int}}$, Eq. (18.4) coincides with the equation for the time evolution operator in the interaction picture to appear in Section 18.7. In contrast to that section, however, the present interaction is a nonpermanent artifact to be set equal to zero at the end, and H is the complicated total Hamiltonian, not a simple free one. This is why we do not speak of an interaction picture here.

If the left-hand side is transformed into the Heisenberg picture, it becomes

$$\delta\langle\Psi_S(t)|\hat{O}|\Psi_S(t)\rangle = \delta\langle\Psi_H|\hat{O}_H(t)|\Psi_H\rangle = \langle\Psi_H|\delta\hat{O}_H(t)|\Psi_H\rangle,$$

so that Eq. (18.9) takes the form

$$\langle\Psi_H|\delta\hat{O}_H(t)|\Psi_H\rangle = -i\int_{-\infty}^t dt' \langle\Psi_H|[\hat{O}_H(t), \hat{H}_H^{\text{ext}}(t')]|\Psi_H\rangle. \quad (18.10)$$

It is useful to use the retarded Green function of the operators $\hat{O}_H(t)$ and $\hat{H}_H(t')$ in the state $|\Psi_H\rangle$ [compare (3.40)]:

$$G_{OH}^R(t, t') \equiv \Theta(t - t')\langle\Psi_H|[\hat{O}_H(t), \hat{H}_H(t')]|\Psi_H\rangle. \quad (18.11)$$

Then the deviation from equilibrium is given by the integral

$$\langle\Psi_H|\delta\hat{O}_H(t)|\Psi_H\rangle = -i\int_{-\infty}^{\infty} dt' G_{OH}^R(t, t'). \quad (18.12)$$

Suppose now that the observable $\hat{O}_H(t)$ is capable of undergoing oscillations. Then an external disturbance coupled to $\hat{O}_H(t)$ will in general excite these oscillations. The simplest coupling is a linear one, with an interaction energy

$$\hat{H}^{\text{ext}}(t) = -\hat{O}_H(t)\delta j(t), \quad (18.13)$$

where $j(t)$ is some external source. Inserting (18.13) into (18.12) yields the linear-response formula

$$\langle\Psi_H|\delta\hat{O}_H(t)|\Psi_H\rangle = i\int_{-\infty}^{\infty} dt' G_{OO}^R(t, t')\delta j(t'), \quad (18.14)$$

where G_{OO}^R is the retarded Green function of two operators \hat{O} :

$$G_{OO}^R(t, t') = \Theta(t - t')\langle\Psi_H|[\hat{O}_H(t), \hat{O}_H(t')]|\Psi_H\rangle. \quad (18.15)$$

At frequencies where the Fourier transform of $G_{OO}(t, t')$ is singular, the slightest disturbance causes a large response. This is the well-known resonance phenomenon found in any oscillating system. Whenever the external frequency ω hits an eigenfrequency, the Fourier transform of the Green function diverges. Usually, the eigenfrequencies of a complicated N -body system are determined by calculating (18.15) and by finding the singularities in ω .

It is easy to generalize this description to a thermal ensemble at a nonzero temperature. The principal modification consists in the replacement of the ground state expectation by the thermal average

$$\langle\hat{O}\rangle_T \equiv \frac{\text{Tr}(e^{-\hat{H}/T}\hat{O})}{\text{Tr}(e^{-\hat{H}/T})}.$$

Using the free energy

$$F = -T \log \text{Tr} (e^{-\hat{H}/T}),$$

this can also be written as

$$\langle \hat{O} \rangle_T = e^{F/T} \text{Tr} (e^{-\hat{H}/T} \hat{O}). \quad (18.16)$$

In a grand-canonical ensemble, \hat{H} must be replaced by $\hat{H} - \mu \hat{N}$ and F by its grand-canonical version F_G (see Section 1.17). At finite temperatures, the linear-response formula (18.14) becomes

$$\delta \langle \hat{O}(t) \rangle_T = i \int_{-\infty}^{\infty} dt' G_{OO}^R(t, t') \delta j(t'), \quad (18.17)$$

where $G_{OO}^R(t, t')$ is the *retarded Green function at nonzero temperature* defined by [recall (1.306)]

$$G_{OO}^R(t, t') \equiv G_{OO}^R(t - t') \equiv \Theta(t - t') e^{F/T} \text{Tr} \left\{ e^{-\hat{H}/T} [\hat{O}_H(t), \hat{O}_H(t')] \right\}. \quad (18.18)$$

In a realistic physical system, there are usually many observables, say $\hat{O}_H^i(t)$ for $i = 1, 2, \dots, l$, which perform coupled oscillations. Then the relevant retarded Green function is some $l \times l$ matrix

$$G_{ij}^R(t, t') \equiv G_{ij}^R(t - t') \equiv \Theta(t - t') e^{F/T} \text{Tr} \left\{ e^{-\hat{H}/T} [\hat{O}_H^i(t), \hat{O}_H^j(t')] \right\}. \quad (18.19)$$

After a Fourier transformation and diagonalization, the singularities of this matrix render the important physical information on the resonance properties of the system.

The retarded Green function at $T \neq 0$ occupies an intermediate place between the real-time Green function of field theories at $T = 0$, and the imaginary-time Green function used before to describe thermal equilibria at $T \neq 0$ (see Subsection 3.8.2). The Green function (18.19) depends both on the real time and on the temperature via an imaginary time.

18.2 Spectral Representations of Green Functions for $T \neq 0$

The retarded Green functions are related to the imaginary-time Green functions of equilibrium physics by an analytic continuation. For two arbitrary operators \hat{O}_H^1 , \hat{O}_H^2 , the latter is defined by the thermal average

$$G_{12}(\tau, 0) \equiv G_{12}(\tau) \equiv e^{F/T} \text{Tr} \left[e^{-\hat{H}/T} \hat{T}_\tau \hat{O}_H^1(\tau) \hat{O}_H^2(0) \right], \quad (18.20)$$

where $\hat{O}_H(\tau)$ is the *imaginary-time Heisenberg operator*

$$\hat{O}_H(\tau) \equiv e^{\hat{H}\tau} \hat{O} e^{-\hat{H}\tau}. \quad (18.21)$$

To see the relation between $G_{12}(\tau)$ and the retarded Green function $G_{12}^R(t)$, we take a complete set of states $|n\rangle$, insert them between the operators \hat{O}^1 , \hat{O}^2 , and expand $G_{12}(\tau)$ for $\tau \geq 0$ into the spectral representation

$$G_{12}(\tau) = e^{F/T} \sum_{n,n'} e^{-E_n/T} e^{(E_n - E_{n'})\tau} \langle n | \hat{O}^1 | n' \rangle \langle n' | \hat{O}^2 | n \rangle. \quad (18.22)$$

Since $G_{12}(\tau)$ is periodic under $\tau \rightarrow \tau + 1/T$, its Fourier representation contains only the discrete Matsubara frequencies $\omega_m = 2\pi mT$:

$$\begin{aligned} G_{12}(\omega_m) &= \int_0^{1/T} d\tau e^{i\omega_m \tau} G_{12}(\tau) \\ &= e^{F/T} \sum_{n,n'} e^{-E_n/T} \left(1 - e^{(E_n - E_{n'})/T} \right) \langle n | \hat{O}^1 | n' \rangle \langle n' | \hat{O}^2 | n \rangle \\ &\quad \times \frac{-1}{i\omega_m - E_{n'} + E_n}. \end{aligned} \quad (18.23)$$

The retarded Green function satisfies no periodic (or antiperiodic) boundary condition. It possesses Fourier components with *all* real frequencies ω :

$$\begin{aligned} G_{12}^R(\omega) &= \int_{-\infty}^{\infty} dt e^{i\omega t} \Theta(t) e^{F/T} \text{Tr} \left\{ e^{-\hat{H}/T} \left[\hat{O}_H^1(t), \hat{O}_H^2(0) \right]_{\mp} \right\} \\ &= e^{F/T} \int_0^{\infty} dt e^{i\omega t} \sum_{n,n'} \left[e^{-E_n/T} e^{i(E_n - E_{n'})t} \langle n | \hat{O}^1 | n' \rangle \langle n' | \hat{O}^2 | n \rangle \right. \\ &\quad \left. \mp e^{-E_{n'}/T} e^{-i(E_n - E_{n'})t} \langle n | \hat{O}^2 | n' \rangle \langle n' | \hat{O}^1 | n \rangle \right]. \end{aligned} \quad (18.24)$$

In the second sum we exchange n and n' and perform the integral, after having attached to ω an infinitesimal positive-imaginary part $i\eta$ to ensure convergence [recall the discussion after Eq. (3.84)]. The result is

ref(3.84)
lab(3.50)
est(3.50)

$$\begin{aligned} G_{12}^R(\omega) &= e^{F/T} \sum_{n,n'} e^{-E_n/T} \left[1 - e^{(E_n - E_{n'})/T} \right] \langle n | \hat{O}^1 | n' \rangle \langle n' | \hat{O}^2 | n \rangle \\ &\quad \times \frac{i}{\omega - E_{n'} + E_n + i\eta}. \end{aligned} \quad (18.25)$$

By comparing this with (18.23) we see that the thermal Green functions are obtained from the retarded ones by replacing [1]

$$\frac{i}{\omega - E_{n'} + E_n + i\eta} \rightarrow \frac{-1}{i\omega_m - E_{n'} + E_n}. \quad (18.26)$$

A similar procedure holds for fermion operators \hat{O}^i (which are not observable). There are only two changes with respect to the boson case. First, in the Fourier expansion of the imaginary-time Green functions, the bosonic Matsubara frequencies ω_m in (18.23) become fermionic. Second, in the definition of the retarded Green

functions (18.19), the commutator is replaced by an anticommutator, i.e., the retarded Green function of fermion operators \hat{O}_H^i is defined by

$$G_{ij}^R(t, t') \equiv G_{ij}^R(t - t') \equiv \Theta(t - t') e^{F/T} \text{Tr} \left\{ e^{-\hat{H}/T} [\hat{O}_H^i(t), \hat{O}_H^j(t')]_{\mp} \right\}. \quad (18.27)$$

These changes produce an opposite sign in front of the $e^{(E_n - E_{n'})/T}$ -term in both of the formulas (18.23) and (18.25). Apart from that, the relation between the two Green functions is again given by the replacement rule (18.26).

At this point it is customary to introduce the *spectral function*

$$\begin{aligned} \rho_{12}(\omega') &= (1 \mp e^{-\omega'/T}) e^{F/T} \\ &\times \sum_{n, n'} e^{-E_n/T} 2\pi \delta(\omega - E_{n'} + E_n) \langle n | \hat{O}^1 | n' \rangle \langle n' | \hat{O}^2 | n \rangle, \end{aligned} \quad (18.28)$$

where the upper and the lower sign hold for bosons and fermions, respectively. Under an interchange of the two operators it behaves like

$$\rho_{12}(\omega') = \mp \rho_{12}(-\omega'). \quad (18.29)$$

Using this spectral function, we may rewrite the Fourier-transformed retarded and thermal Green functions as the following spectral integrals:

$$G_{12}^R(\omega) = \int_{-\infty}^{\infty} \frac{d\omega'}{2\pi} \rho_{12}(\omega') \frac{i}{\omega - \omega' + i\eta}, \quad (18.30)$$

$$G_{12}(\omega_m) = \int_{-\infty}^{\infty} \frac{d\omega'}{2\pi} \rho_{12}(\omega') \frac{-1}{i\omega_m - \omega'}. \quad (18.31)$$

These equations show how the imaginary-time Green functions arise from the retarded Green functions by a simple analytic continuation in the complex frequency plane to the discrete Matsubara frequencies, $\omega \rightarrow i\omega_m$. The inverse problem of reconstructing the retarded Green functions in the entire upper half-plane of ω from the imaginary-time Green functions defined only at the Matsubara frequencies ω_m is not solvable in general but only if other information is available [2]. For instance, the sum rules for canonical fields to be derived later in Eq. (18.66) with the ensuing asymptotic condition (18.67) are sufficient to make the continuation unique [3].

ref(18.66)
lab(18.41)
est(18.59)

Going back to the time variables t and τ , the Green functions are

$$G_{12}^R(t) = \Theta(t) \int_{-\infty}^{\infty} \frac{d\omega'}{2\pi} \rho_{12}(\omega') e^{-i\omega' t}, \quad (18.32)$$

$$G_{12}(\tau) = \int_{-\infty}^{\infty} \frac{d\omega'}{2\pi} \rho_{12}(\omega') T \sum_{\omega_m} e^{-i\omega_m \tau} \frac{-1}{i\omega_m - \omega'}. \quad (18.33)$$

The sum over even or odd Matsubara frequencies on the right-hand side of $G_{12}(\tau)$ was evaluated in Section 3.3 for bosons and fermions as

$$\begin{aligned} T \sum_n e^{-i\omega_m \tau} \frac{-1}{i\omega_m - \omega} &= G_{\omega, e}^p(\tau) = e^{-\omega(\tau - 1/2T)} \frac{1}{2 \sin(\omega/2T)} \\ &= e^{-\omega\tau} (1 + n_\omega) \end{aligned} \quad (18.34)$$

and

$$\begin{aligned} T \sum_n e^{-i\omega_m \tau} \frac{-1}{i\omega_m - \omega} &= G_{\omega,e}^a(\tau) = e^{-\omega(\tau-1/2T)} \frac{1}{2 \cos(\omega/2T)} \\ &= e^{-\omega\tau} (1 - n_\omega), \end{aligned} \quad (18.35)$$

with the Bose and Fermi distribution functions [see (3.93), (7.542), (7.544)]

$$n_\omega = \frac{1}{e^{\omega/T} \mp 1}, \quad (18.36)$$

respectively.

18.3 Other Important Green Functions

In studying the dynamics of systems at finite temperature, several other Green functions are useful whose spectral functions we shall now derive.

In complete analogy with the retarded Green functions for bosonic and fermionic operators, we may introduce their counterparts, the so-called *advanced Green functions* (compare page 38)

$$G_{12}^A(t, t') \equiv G_{12}^A(t - t') = -\Theta(t' - t) e^{F/T} \text{Tr} \left\{ e^{-\hat{H}/T} \left[\hat{O}_H^1(t), \hat{O}_H^2(t') \right]_{\mp} \right\}. \quad (18.37)$$

Their Fourier transforms have the spectral representation

$$G_{12}^A(\omega) = \int_{-\infty}^{\infty} \frac{d\omega'}{2\pi} \rho_{12}(\omega') \frac{i}{\omega - \omega' - i\eta}, \quad (18.38)$$

differing from the retarded case (18.30) only by the sign of the $i\eta$ -term. This makes the Fourier transforms vanish for $t > 0$, so that the time-dependent Green function has the spectral representation [compare (18.32)]

$$G_{12}^A(t) = -\Theta(-t) \int_{-\infty}^{\infty} \frac{d\omega}{2\pi} \rho_{12}(\omega) e^{-i\omega t}. \quad (18.39)$$

By subtracting retarded and advanced Green functions, we obtain the thermal expectation value of commutator or anticommutator:

$$C_{12}(t, t') = e^{F/T} \text{Tr} \left\{ e^{-\hat{H}/T} \left[\hat{O}_H^1(t), \hat{O}_H^2(t') \right]_{\mp} \right\} = G_{12}^R(t, t') - G_{12}^A(t, t'). \quad (18.40)$$

Note the simple relations:

$$G_{12}^R(t, t') = \Theta(t - t') C_{12}(t, t'), \quad (18.41)$$

$$G_{12}^A(t, t') = -\Theta(t' - t) C_{12}(t, t'). \quad (18.42)$$

When inserting the spectral representations (18.30) and (18.39) of $G_{12}^R(t)$ and $G_{12}^A(t)$ into (18.40), and using the identity (1.328),

$$\frac{i}{\omega - \omega' + i\eta} - \frac{i}{\omega - \omega' - i\eta} = 2\frac{\eta}{(\omega - \omega')^2 + \eta^2} = 2\pi\delta(\omega - \omega'), \quad (18.43)$$

we obtain the spectral integral representation for the commutator function:²

$$C_{12}(t) = \int_{-\infty}^{\infty} \frac{d\omega}{2\pi} \rho_{12}(\omega) e^{-i\omega t}. \quad (18.44)$$

Thus a knowledge of the commutator function $C_{12}(t)$ determines directly the spectral function $\rho_{12}(\omega)$ by its Fourier components

$$C_{12}(\omega) = \rho_{12}(\omega). \quad (18.45)$$

An important role in studying the dynamics of a system in a thermal environment is played by the time-ordered Green functions. They are defined by

$$G_{12}(t, t') \equiv G_{12}(t - t') = e^{F/T} \text{Tr} \left[e^{-\hat{H}/T} \hat{T} \hat{O}_H^1(t) \hat{O}_H^2(t') \right]. \quad (18.46)$$

Inserting intermediate states as in (18.23) we find the spectral representation

$$\begin{aligned} G_{12}(\omega) &= \int_{-\infty}^{\infty} dt e^{i\omega t} \Theta(t) e^{F/T} \text{Tr} \left\{ e^{-\hat{H}/T} \hat{O}_H^1(t) \hat{O}_H^2(0) \right\} \\ &+ \int_{-\infty}^{\infty} dt e^{i\omega t} \Theta(-t) e^{F/T} \text{Tr} \left\{ e^{-\hat{H}/T} \hat{O}_H^2(t) \hat{O}_H^1(0) \right\} \\ &= e^{F/T} \int_0^{\infty} dt e^{i\omega t} \sum_{n, n'} e^{-E_n/T} e^{i(E_n - E_{n'})t} \langle n | \hat{O}_H^1 | n' \rangle \langle n' | \hat{O}_H^2 | n \rangle \\ &\pm e^{F/T} \int_{-\infty}^0 dt e^{i\omega t} \sum_{n, n'} e^{-E_n/T} e^{-i(E_n - E_{n'})t} \langle n | \hat{O}_H^2 | n' \rangle \langle n' | \hat{O}_H^1 | n \rangle. \end{aligned} \quad (18.47)$$

Interchanging again n and n' , this can be written in terms of the spectral function (18.28) as

$$G_{12}(\omega) = \int_{-\infty}^{\infty} \frac{d\omega'}{2\pi} \rho_{12}(\omega') \left[\frac{1}{1 \mp e^{-\omega'/T}} \frac{i}{\omega - \omega' + i\eta} + \frac{1}{1 \mp e^{\omega'/T}} \frac{i}{\omega - \omega' - i\eta} \right]. \quad (18.48)$$

Let us also write down the spectral decomposition of a further operator expression complementary to $C_{12}(t)$ of (18.40), in which boson or fermion fields appear with the “wrong” commutator:

$$A_{12}(t - t') \equiv e^{F/T} \text{Tr} \left\{ e^{-\hat{H}/T} \left[\hat{O}_H^1(t), \hat{O}_H^2(t') \right]_{\pm} \right\}. \quad (18.49)$$

²Due to the relation (18.41), the same representation is found by dropping the factor $\Theta(t)$ in (18.32).

This function characterizes the size of fluctuations of the operators O_H^1 and O_H^2 . Inserting intermediate states, we find

$$\begin{aligned} A_{12}(\omega) &= \int_{-\infty}^{\infty} dt e^{i\omega t} e^{F/T} \text{Tr} \left\{ e^{-\hat{H}/T} \left[\hat{O}_H^1(t), \hat{O}_H^2(0) \right]_{\pm} \right\} \\ &= e^{F/T} \int_{-\infty}^{\infty} dt e^{i\omega t} \sum_{n,n'} \left[e^{-E_n/T} e^{i(E_n - E_{n'})t} \langle n | \hat{O}_H^1 | n' \rangle \langle n' | \hat{O}_H^2 | n \rangle \right. \\ &\quad \left. \pm e^{-E_{n'}/T} e^{-i(E_n - E_{n'})t} \langle n | \hat{O}_H^2 | n' \rangle \langle n' | \hat{O}_H^1 | n \rangle \right]. \end{aligned} \quad (18.50)$$

In the second sum we exchange n and n' and perform the integral, which runs now over the entire time interval and gives therefore a δ -function:

$$\begin{aligned} A_{12}(\omega) &= e^{F/T} \sum_{n,n'} e^{-E_n/T} \left[1 \pm e^{(E_n - E_{n'})/T} \right] \langle n | \hat{O}_H^1 | n' \rangle \langle n' | \hat{O}_H^2 | n \rangle \\ &\quad \times 2\pi \delta(\omega - E_{n'} + E_n). \end{aligned} \quad (18.51)$$

In terms of the spectral function (18.28), this has the simple form

$$A_{12}(\omega) = \int_{-\infty}^{\infty} \frac{d\omega'}{2\pi} \tanh^{\mp 1} \frac{\omega'}{2T} \rho_{12}(\omega') 2\pi \delta(\omega - \omega') = \tanh^{\mp 1} \frac{\omega}{2T} \rho_{12}(\omega). \quad (18.52)$$

Thus the expectation value (18.49) of the “wrong” commutator has the time dependence

$$A_{12}(t, t') \equiv A_{12}(t - t') = \int_{-\infty}^{\infty} \frac{d\omega}{2\pi} \rho_{12}(\omega) \tanh^{\mp 1} \frac{\omega}{2T} e^{-i\omega(t-t')}. \quad (18.53)$$

There exists another way of writing the spectral representation of the various Green functions. For retarded and advanced Green functions G_{12}^R , G_{12}^A , we decompose in the spectral representations (18.30) and (18.38) according to the rule (1.329):

$$\frac{i}{\omega - \omega' \pm i\eta} = i \left[\frac{\mathcal{P}}{\omega - \omega'} \mp i\pi \delta(\omega - \omega') \right], \quad (18.54)$$

where \mathcal{P} indicates principal value integration across the singularity, and write

$$G_{12}^{R,A}(\omega) = i \int_{-\infty}^{\infty} \frac{d\omega'}{2\pi} \rho_{12}(\omega') \left[\frac{\mathcal{P}}{\omega - \omega'} \mp i\pi \delta(\omega - \omega') \right]. \quad (18.55)$$

Inserting (18.54) into (18.48) we find the alternative representation of the time-ordered Green function

$$G_{12}(\omega) = i \int_{-\infty}^{\infty} \frac{d\omega'}{2\pi} \rho_{12}(\omega') \left[\frac{\mathcal{P}}{\omega - \omega'} - i\pi \tanh^{\mp 1} \frac{\omega}{2T} \delta(\omega - \omega') \right]. \quad (18.56)$$

The term proportional to $\delta(\omega - \omega')$ in the spectral representation is commonly referred to as the *absorptive* or *dissipative part* of the Green function. The first term proportional to the principal value is called the *dispersive* or *fluctuation part*.

The relevance of the spectral function $\rho_{12}(\omega')$ in determining both the *fluctuation part* as well as the *dissipative part* of the time-ordered Green function is the content of the important *fluctuation-dissipation theorem*. In more detail, this may be restated as follows: The common spectral function $\rho_{12}(\omega')$ of the commutator function in (18.44), the retarded Green function in (18.30), and the *fluctuation part* of the time-ordered Green function in (18.56) determines, after being multiplied by a factor $\tanh^{\mp 1}(\omega'/2T)$, the *dissipative part* of the time-ordered Green function in Eq. (18.56).

The three Green functions $-iG_{12}(\omega)$, $-iG_{12}^R(\omega)$, and $-iG_{12}^A(\omega)$ have the same real parts. By comparing Eqs. (18.30) and (18.31) we found that retarded and advanced Green functions are simply related to the imaginary-time Green function via an analytic continuation. The spectral decomposition (18.56) shows this is not true for the time-ordered Green function, due to the extra factor $\tanh^{\mp 1}(\omega/2T)$ in the absorptive term.

Another representation of the time-ordered Green is useful. It is obtained by expressing $\tanh^{\mp 1}$ in terms of the Bose and Fermi distribution functions (18.36) as $\tanh^{\mp 1} = 1 \pm 2n_\omega$. Then we can decompose

$$G_{12}(\omega) = \int_{-\infty}^{\infty} \frac{d\omega'}{2\pi} \rho_{12}(\omega') \left[\frac{i}{\omega - \omega' + i\eta} \pm 2\pi n_\omega \delta(\omega - \omega') \right]. \quad (18.57)$$

18.4 Hermitian Adjoint Operators

If the two operators $\hat{O}_H^1(t)$, $\hat{O}_H^2(t)$ are Hermitian adjoint to each other,

$$\hat{O}_H^2(t) = [\hat{O}_H^1(t)]^\dagger, \quad (18.58)$$

the spectral function (18.28) can be rewritten as

$$\begin{aligned} \rho_{12}(\omega') &= (1 \mp e^{-\omega'/T}) e^{F/T} \\ &\times \sum_{n,n'} e^{-E_n/T} 2\pi \delta(\omega' - E_{n'} + E_n) |\langle n | \hat{O}_H^1(t) | n' \rangle|^2. \end{aligned} \quad (18.59)$$

This shows that

$$\begin{aligned} \rho_{12}(\omega') \omega' &\geq 0 && \text{for bosons,} \\ \rho_{12}(\omega') &\geq 0 && \text{for fermions.} \end{aligned} \quad (18.60)$$

This property permits us to derive several useful inequalities between various diagonal Green functions in Appendix 18A.

Under the condition (18.58), the expectation values of anticommutators and commutators satisfy the time-reversal relations

$$G_{12}^A(t, t') = \mp G_{21}^R(t', t)^*, \quad (18.61)$$

$$A_{12}(t, t') = \pm A_{21}(t', t)^*, \quad (18.62)$$

$$C_{12}(t, t') = \mp C_{21}(t', t)^*. \quad (18.63)$$

$$G_{12}(t, t') = \pm G_{21}(t', t)^*. \quad (18.64)$$

Examples are the corresponding functions for creation and annihilation operators which will be treated in detail below. More generally, these properties hold for any interacting nonrelativistic particle fields $\hat{O}_H^1(t) = \hat{\psi}_{\mathbf{p}}(t)$, $\hat{O}_H^2(t) = \hat{\psi}_{\mathbf{p}}^\dagger(t)$ of a specific momentum \mathbf{p} .

Such operators satisfy, in addition, the canonical equal-time commutation rules at each momentum

$$[\hat{\psi}_{\mathbf{p}}(t), \hat{\psi}_{\mathbf{p}}^\dagger(t)] = 1 \quad (18.65)$$

(see Sections 7.6, 7.9). Using (18.40), (18.44) we derive from this *spectral function sum rule*:

$$\int_{-\infty}^{\infty} \frac{d\omega'}{2\pi} \rho_{12}(\omega') = 1. \quad (18.66)$$

For a canonical free field with $\rho_{12}(\omega') = 2\pi\delta(\omega' - \omega)$, this sum rule is of course trivially fulfilled. In general, the sum rule ensures the large- ω behavior of imaginary-time, retarded, and advanced Green functions of canonically conjugate field operators to be the same as for a free particle, i.e.,

$$G_{12}(\omega_m) \xrightarrow{\omega_m \rightarrow \infty} \frac{i}{\omega_m}, \quad G_{12}^{A,R}(\omega) \xrightarrow{\omega \rightarrow \infty} \frac{1}{\omega}. \quad (18.67)$$

18.5 Harmonic Oscillator Green Functions for $T \neq 0$

As an example, consider a single harmonic oscillator of frequency Ω or, equivalently, a free particle at a point in the second-quantized field formalism (see Chapter 7). We shall start with the second representation.

18.5.1 Creation Annihilation Operators

The operators $\hat{O}_H^1(t)$ and $\hat{O}_H^2(t)$ are the creation and annihilation operators in the Heisenberg picture

$$\hat{a}_H^\dagger(t) = \hat{a}^\dagger e^{i\Omega t}, \quad \hat{a}_H(t) = \hat{a} e^{-i\Omega t}. \quad (18.68)$$

The eigenstates of the Hamiltonian operator

$$\hat{H} = \frac{1}{2} (\hat{p}^2 + \Omega^2 \hat{x}^2) = \frac{\omega}{2} (\hat{a}^\dagger \hat{a} + \hat{a} \hat{a}^\dagger) = \omega \left(\hat{a}^\dagger \hat{a} \pm \frac{1}{2} \right) \quad (18.69)$$

are

$$|n\rangle = \frac{1}{\sqrt{n!}} (\hat{a}^\dagger)^n |0\rangle, \quad (18.70)$$

with the eigenvalues $E_n = (n \pm 1/2)\Omega$ for $n = 0, 1, 2, 3, \dots$ or $n = 0, 1$, if \hat{a}^\dagger and \hat{a} commute or anticommute, respectively [compare Eq. (7.564)]. In the second-quantized field interpretation the energies are $E_n = n\Omega$ and the final Green functions

are the same. The spectral function $\rho_{12}(\omega')$ is trivial to calculate. The Schrödinger operator $\hat{O}^2 = \hat{a}^\dagger$ can connect the state $|n\rangle$ only to $\langle n+1|$, with the matrix element $\sqrt{n+1}$. The operator $\hat{O}^1 = \hat{a}$ does the opposite. Hence we have

$$\rho_{12}(\omega') = 2\pi\delta(\omega' - \Omega)(1 \mp e^{-\Omega/T})e^{F/T} \sum_{n=0}^{\infty,0} e^{-(n\pm 1/2)\Omega/T}(n+1). \tag{18.71}$$

Now we make use of the explicit partition functions of the oscillator whose paths satisfy periodic and antiperiodic boundary conditions:

$$Z_\Omega \equiv e^{-F/T} = \sum_{n=0}^{\infty,1} e^{-(n\pm 1/2)\Omega/T} = \left\{ \begin{array}{l} [2 \sinh(\Omega/2T)]^{-1} \\ 2 \cosh(\Omega/2T) \end{array} \right. \text{ for } \left. \begin{array}{l} \text{bosons} \\ \text{fermions} \end{array} \right\}. \tag{18.72}$$

These allow us to calculate the sums in (18.71) as follows

$$\begin{aligned} \sum_{n=0}^{\infty} e^{-(n+1/2)\Omega/T}(n+1) &= \left(-T \frac{\partial}{\partial \Omega} + \frac{1}{2}\right) e^{-F/T} = (1 \mp e^{-\Omega/T})^{-1} e^{-F/T}, \\ \sum_{n=0}^0 e^{-(n-1/2)\Omega/T}(n+1) &= e^{\Omega/2T} = (1 + e^{-\Omega/T})^{-1} e^{-F/T}. \end{aligned} \tag{18.73}$$

The spectral function $\rho_{12}(\omega')$ of the a single oscillator quantum of frequency Ω is therefore given by

$$\rho_{12}(\omega') = 2\pi\delta(\omega' - \Omega). \tag{18.74}$$

With it, the retarded and imaginary-time Green functions become

$$G_\Omega^R(t, t') = \Theta(t - t')e^{-\Omega(t-t')}, \tag{18.75}$$

$$G_\Omega(\tau, \tau') = -T \sum_{m=-\infty}^{\infty} e^{-i\omega_m(\tau-\tau')} \frac{1}{i\Omega_m - \Omega} \tag{18.76}$$

$$= e^{-\Omega(\tau-\tau')} \begin{cases} 1 \pm n_\Omega \\ \pm n_\Omega \end{cases} \text{ for } \begin{cases} \tau \geq \\ < \end{cases} \tau', \tag{18.77}$$

with the average particle number n_Ω of (18.36). The commutation function, for instance, is by (18.44) and (18.74):

$$C_{12}(t, t') = e^{-i\Omega(t-t')}, \tag{18.78}$$

and the correlation function of the “wrong commutator” is from (18.53) and (18.74):

$$A_\Omega(t, t') = \tanh^{\mp 1} \frac{\Omega}{2T} e^{-i\Omega(t-t')}. \tag{18.79}$$

Of course, these harmonic-oscillator expressions could have been obtained directly by starting from the defining operator equations. For example, the commutator function

$$C_\Omega(t, t') = e^{F/T} \text{Tr} \left\{ e^{-\hat{H}/T} [\hat{a}_H(t), \hat{a}_H^\dagger(t')]_{\mp} \right\} \tag{18.80}$$

turn into (18.78) by using the commutation rule at different times

$$[\hat{a}_H(t), \hat{a}_H^\dagger(t')] = e^{-i\Omega(t-t')}, \quad (18.81)$$

which follows from (18.68). Since the right-hand side is a c -number, the thermodynamic average is trivial:

$$e^{F/T} \text{Tr} (e^{-\hat{H}/T}) = 1. \quad (18.82)$$

After this, the relations (18.41), (18.42) determine the retarded and advanced Green functions

$$G_\Omega^R(t-t') = \Theta(t-t')e^{-i\Omega(t-t')}, \quad G_\Omega^A(t-t') = -\Theta(t'-t)e^{-i\Omega(t-t')}. \quad (18.83)$$

For the Green function at imaginary times

$$G_\Omega(\tau, \tau') \equiv e^{F/T} \text{Tr} \left[e^{-\hat{H}/T} \hat{T}_\tau \hat{a}_H(\tau) \hat{a}_H^\dagger(\tau') \right], \quad (18.84)$$

the expression (18.77) is found using [see (18.85)]

$$\begin{aligned} \hat{a}_H^\dagger(\tau) &\equiv e^{\hat{H}\tau} \hat{a}^\dagger e^{-\hat{H}\tau} = \hat{a}^\dagger e^{\Omega\tau}, \\ \hat{a}_H(\tau) &\equiv e^{\hat{H}\tau} \hat{a} e^{-\hat{H}\tau} = \hat{a} e^{-\Omega\tau}, \end{aligned} \quad (18.85)$$

and the summation formula (18.73).

The “wrong” commutator function (18.79) can, of course, be immediately derived from the definition

$$A_{12}(t-t') \equiv e^{F/T} \text{Tr} \left\{ e^{-\hat{H}/T} \left[\hat{a}_H(t), \hat{a}_H^\dagger(t') \right]_\pm \right\} \quad (18.86)$$

and (18.68), by inserting intermediate states.

For the temporal behavior of the time-ordered Green function we find from (18.48)

$$G_\Omega(\omega) = \left(1 \mp e^{-\Omega/T}\right)^{-1} G_\Omega^R(\omega) + \left(1 \mp e^{\Omega/T}\right)^{-1} G_\Omega^A(\omega), \quad (18.87)$$

and from this by a Fourier transformation

$$\begin{aligned} G_\Omega(t, t') &= \left(1 \mp e^{-\Omega/T}\right)^{-1} \Theta(t-t')e^{-i\Omega(t-t')} - \left(1 \mp e^{\Omega/T}\right)^{-1} \Theta(t'-t)e^{-i\Omega(t-t')} \\ &= \left[\Theta(t-t') \pm (e^{\Omega/T} \mp 1)^{-1}\right] e^{-i\Omega(t-t')} = [\Theta(t-t') \pm n_\Omega] e^{-i\Omega(t-t')}. \end{aligned} \quad (18.88)$$

The same result is easily obtained by directly evaluating the defining equation using (18.68) and inserting intermediate states:

$$\begin{aligned} G_\Omega(t, t') &\equiv G_\Omega(t-t') = e^{F/T} \text{Tr} \left[e^{-\hat{H}/T} \hat{T} \hat{a}_H(t) \hat{a}_H^\dagger(t') \right] \\ &= \Theta(t-t') \langle \hat{a} \hat{a}^\dagger \rangle e^{-i\Omega(t-t')} \pm \Theta(t'-t) \langle \hat{a}^\dagger \hat{a} \rangle e^{-i\Omega(t-t')} \\ &= \Theta(t-t') (1 \pm n_\Omega) e^{-i\Omega(t-t')} \pm \Theta(t'-t) n_\Omega e^{-i\Omega(t-t')}, \end{aligned} \quad (18.89)$$

which is the same as (18.88). For the correlation function with a and a^\dagger interchanged,

$$\bar{G}_\Omega(t, t') \equiv G_\Omega(t - t') = e^{F/T} \text{Tr} \left[e^{-\hat{H}/T} \hat{T} \hat{a}_H^\dagger(t) \hat{a}_H(t') \right], \quad (18.90)$$

we find in this way

$$\begin{aligned} \bar{G}_\Omega(t, t') &= \Theta(t - t') \langle \hat{a}^\dagger \hat{a} \rangle e^{-i\Omega(t-t')} \pm \Theta(t' - t) \langle \hat{a} \hat{a}^\dagger \rangle e^{-i\Omega(t-t')} \\ &= \Theta(t - t') n_\Omega e^{-i\Omega(t-t')} \pm \Theta(t' - t) (1 \pm n_\Omega) e^{-i\Omega(t-t')}, \end{aligned} \quad (18.91)$$

in agreement with (18.64).

18.5.2 Real Field Operators

From the above expressions it is easy to construct the corresponding Green functions for the position operators of the harmonic oscillator $\hat{x}(t)$. It will be useful to keep the discussion more general by admitting oscillators which are not necessarily mass points in space but can be field variables. Thus we shall use, instead of $\hat{x}(t)$, the symbol $\varphi(t)$, and call this a field variable. As in Eq. (7.295) we decompose the field as

$$\hat{x}(t) = \sqrt{\frac{\hbar}{2M\Omega}} \left[\hat{a} e^{-i\Omega t} + \hat{a}^\dagger e^{i\Omega t} \right]. \quad (18.92)$$

In this section we use physical units. The commutator function (18.40) is directly

$$C(t, t') \equiv \langle [\hat{\varphi}(t), \hat{\varphi}(t')]_{\mp} \rangle_\rho = -\frac{\hbar}{2M\Omega} 2i \sin \Omega(t - t'), \quad (18.93)$$

implying a spectral function [recall (18.44)]

$$\rho(\omega') = \frac{1}{2M\Omega} 2\pi [\delta(\omega' - \Omega) - \delta(\omega' + \Omega)]. \quad (18.94)$$

The real operator $\hat{\varphi}(t)$ behaves like the difference of a particle of frequency Ω and $-\Omega$, with an overall factor $1/2M\Omega$. It is then easy to find the retarded and advanced Green functions of the operators $\hat{\varphi}(t)$ and $\hat{\varphi}(t')$:

$$G^R(t, t') = \frac{\hbar}{2M\Omega} \left[G_\Omega^R(t, t') - G_{-\Omega}^R(t, t') \right] = -\frac{\hbar}{2M\Omega} \Theta(t - t') 2i \sin \Omega(t - t'), \quad (18.95)$$

$$G^A(t, t') = \frac{\hbar}{2M\Omega} \left[G_\Omega^A(t, t') - G_{-\Omega}^A(t, t') \right] = \frac{\hbar}{2M\Omega} \Theta(t - t') 2i \sin \Omega(t' - t). \quad (18.96)$$

From the spectral representation (18.53), we obtain for the “wrong commutator”

$$A(t, t') = \langle [\hat{\varphi}(t), \hat{\varphi}(t')]_{\mp} \rangle = \frac{\hbar}{2M\Omega} \coth^{\pm 1} \frac{\Omega}{2k_B T} 2 \cos \Omega(t - t'). \quad (18.97)$$

The relation with (18.93) is again a manifestation of the fluctuation-dissipation theorem (18.53).

The average of these two functions yields the time-dependent correlation function at finite temperature containing only the product of the operators

$$G^P(t, t') \equiv \langle \hat{\varphi}(t) \hat{\varphi}(t') \rangle = \frac{\hbar}{2M\Omega} [(1 \pm 2n_\Omega) \cos \Omega(t - t') - i \sin \Omega(t - t')], \quad (18.98)$$

with the average particle number n_Ω of (18.36). In the limit of zero temperature where $n_\Omega \equiv 0$, this reduces to

$$G^P(t, t') = \langle \hat{\varphi}(t) \hat{\varphi}(t') \rangle = \frac{\hbar}{2M\Omega} e^{-i\Omega(t-t')}. \quad (18.99)$$

The time-ordered Green function is obtained from this by the obvious relation

$$G(t, t') = \Theta(t - t') G^P(t, t') \pm \Theta(t' - t) G^P(t', t) = \frac{1}{2} [A(t, t') + \epsilon(t - t') C(t, t')], \quad (18.100)$$

where $\epsilon(t - t')$ is the step function of Eq. (1.316). Explicitly, the time-ordered Green function is

$$G(t, t') \equiv \langle \hat{T} \hat{\varphi}(t) \hat{\varphi}(t') \rangle = \frac{\hbar}{2M\Omega} [(1 \pm 2n_\Omega) \cos \Omega|t - t'| - i \sin \Omega|t - t'|], \quad (18.101)$$

which reduces for $T \rightarrow 0$ to

$$G(t, t') = \langle \hat{T} \hat{\varphi}(t) \hat{\varphi}(t') \rangle = \frac{\hbar}{2M\Omega} e^{-i\Omega|t-t'|}. \quad (18.102)$$

Thus, as a mnemonic rule, a finite temperature is introduced into a zero-temperature Green function by simply multiplying the real part of the exponential function by a factor $1 \pm 2n_\Omega$. This is another way of stating the *fluctuation-dissipation theorem*.

There is another way of writing the time-ordered Green function (18.101) in the bosonic case:

$$G(t, t') \equiv \langle \hat{T} \hat{\varphi}(t) \hat{\varphi}(t') \rangle = \frac{\hbar}{2M\Omega} \frac{\cosh \left[\frac{\Omega}{2} (\hbar\beta - i|t - t'|) \right]}{\sinh \frac{\hbar\Omega\beta}{2}}. \quad (18.103)$$

For $t - t' > 0$, this coincides precisely with the periodic Green function $G_e^p(\tau, \tau') = G_e^p(\tau - \tau')$ at imaginary-times $\tau > \tau'$ [see (3.251)], if τ and τ' are continued analytically to it and it' , respectively. Decomposing (18.101) into real and imaginary parts we see by comparison with (18.100) that anticommutator and commutator functions are the doubled real and imaginary parts of the time-ordered Green function:

$$A(t, t') = 2 \operatorname{Re} G(t, t'), \quad C(t, t') = 2i \operatorname{Im} G(t, t'). \quad (18.104)$$

In the fermionic case, the hyperbolic functions \cosh and \sinh in numerator and denominator are simply interchanged, and the result coincides with the analytically continued antiperiodic imaginary-time Green function (3.266).

The time-reversal properties (18.61)–(18.64) of the Green functions become for real fields $\hat{\varphi}(t)$:

$$G^A(t, t') = \mp G^R(t', t), \quad (18.105)$$

$$A(t, t') = \pm A(t', t), \quad (18.106)$$

$$C(t, t') = \mp C(t', t), \quad (18.107)$$

$$G(t, t') = \pm G(t', t). \quad (18.108)$$

18.6 Nonequilibrium Green Functions

Up to this point we have assumed the system to be in intimate contact with a heat reservoir which ensures a constant temperature throughout the volume. The disturbance in (18.3) was taken to be small, so that only a small fraction of the particles could be excited. If the disturbance grows larger, large clouds of excitations can be formed in a local region. Such a system leaves thermal equilibrium, and the response is necessarily nonlinear. The system must be studied in its full quantum-mechanical time evolution. In order to describe such a process theoretically, we shall assume an initial equilibrium characterized by some density operator [compare (2.367)]

$$\hat{\rho} = \sum_n \rho_n |n\rangle \langle n|, \quad (18.109)$$

with eigenvalues

$$\rho_n = e^{-E_n/T}. \quad (18.110)$$

The disturbance sets in at some time t_0 . If the initial state is out of equilibrium, the formalism to be described remains applicable, with only a few adaptations, if the initial state at t_0 is still characterized by a density operator of type (18.109), but has probabilities ρ_n different from (18.110). Of course, in the limit of very small deviations from thermal equilibrium, the formalism to be described reduces to the previously treated linear-response theory.

We first develop a perturbation theory for the time evolution of operators in a nonequilibrium situation. This serves to set up a path integral formalism for the description of the dynamical behavior of a single particle in contact with a thermal reservoir. This description can, in principle, be extended to ensembles of many particles by considering a similar path integral for a fluctuating field. After the discussion in Chapter 7, the necessary second quantization is straightforward and requires no detailed presentation.

The perturbation theory for nonequilibrium quantum-statistical mechanics to be developed now is known under the name of *closed-time path Green function formalism* (CTPGF). This formalism was developed by Schwinger [4] and Keldysh [5], and has been applied successfully to many nonequilibrium problems in statistical physics, in particular to superconductivity and plasma physics.

The fundamental problem of nonequilibrium statistical mechanics is finding the time evolution of thermodynamic averages of products of Heisenberg operators $\hat{\varphi}_H(t)$. For interesting applications it is useful to keep the formulation general and deal with relativistic *fields* of operators $\hat{\varphi}_H(\mathbf{x}, t)$. As in Section 7.6, an extra spatial argument \mathbf{x} allows for a different time-dependent operator $\hat{\varphi}(t)$ at each point \mathbf{x} in space. In order to prepare ourselves for the most interesting study of electromagnetic fields, we consider the simplest relativistically invariant classical action describing an observable field in D dimensions which has the form

$$\mathcal{A}_0 = \int dt d^D x \mathcal{L}_0(\mathbf{x}, t) \equiv \frac{1}{2} \int dt d^D x \left\{ [\dot{\varphi}(\mathbf{x}, t)]^2 - [\nabla \varphi(\mathbf{x}, t)]^2 - m^2 \varphi^2(\mathbf{x}, t) \right\}. \quad (18.111)$$

As in Section 7.6, we go over to a countable set of infinite points \mathbf{x} assuming that space is a fine lattice of spacing ϵ , with the continuum limit $\epsilon \rightarrow 0$ taken at the end. The associated Euler-Lagrange equation extremizing the action is the *Klein-Gordon equation*

$$\ddot{\varphi}(\mathbf{x}, t) + (-\partial_{\mathbf{x}}^2 + m^2)\varphi(\mathbf{x}, t) = 0. \quad (18.112)$$

This is solved by plane waves

$$f_{\mathbf{p}}(\mathbf{x}, t) = \frac{1}{\sqrt{2\omega_{\mathbf{p}}V}} e^{-i\omega_{\mathbf{p}}t + i\mathbf{p}\mathbf{x}}, \quad \bar{f}_{\mathbf{p}}(\mathbf{x}, t) = \frac{1}{\sqrt{\omega_{\mathbf{p}}V}} e^{i\omega_{\mathbf{p}}t + i\mathbf{p}\mathbf{x}} \quad (18.113)$$

of positive and negative energy. As in Section 7.6, we imagine the system to be confined to a finite cubic volume V . Then the momenta \mathbf{p} are discrete. The solutions (18.113) behave like an infinite set of harmonic oscillator solution, one for each momentum vector \mathbf{p} , with the \mathbf{p} -dependent frequencies

$$\omega_{\mathbf{p}} \equiv \sqrt{\mathbf{p}^2 + m^2}. \quad (18.114)$$

The general solution of (18.112) may be expanded as

$$\varphi(\mathbf{x}, t) = \sum_{\mathbf{p}} \frac{1}{2\omega_{\mathbf{p}}V} \left(a_{\mathbf{p}} e^{-i\omega_{\mathbf{p}}t + i\mathbf{p}\mathbf{x}} + a_{\mathbf{p}}^* e^{i\omega_{\mathbf{p}}t + i\mathbf{p}\mathbf{x}} \right). \quad (18.115)$$

The canonical momenta of the field variables $\varphi(\mathbf{x}, t)$ are the field velocities

$$\pi(\mathbf{x}, t) \equiv p_{\mathbf{x}}(t) \equiv \dot{\varphi}(\mathbf{x}, t). \quad (18.116)$$

The fields are quantized by the canonical commutation rules

$$[\hat{\pi}(\mathbf{x}, t), \varphi(\mathbf{x}', t)] = -i\delta_{\mathbf{x}\mathbf{x}'}. \quad (18.117)$$

The quantum field is now expanded as in (18.115), but in terms of operators $\hat{a}_{\mathbf{p}}$ and their Hermitian adjoint operators $\hat{a}_{\mathbf{p}}^\dagger$. These satisfy the usual canonical commutation rules of creation and annihilation operators of Eq. (7.294):

$$[\hat{a}_{\mathbf{p}}(t), \hat{a}_{\mathbf{p}'}^\dagger(t)] = \delta_{\mathbf{p}\mathbf{p}'}, \quad [\hat{a}_{\mathbf{p}}^\dagger(t), \hat{a}_{\mathbf{p}'}^\dagger(t)] = 0, \quad [\hat{a}_{\mathbf{p}}(t), \hat{a}_{\mathbf{p}'}(t)] = 0. \quad (18.118)$$

The simplest nonequilibrium quantities to be studied are the thermal averages of one or two such field operators. More generally, we may investigate the averages of one or two fields with respect to an arbitrary initial density operator $\hat{\rho}$, the so-called ρ -averages:

$$\begin{aligned}\langle \hat{\varphi}_H(x) \rangle_\rho &= \text{Tr} [(\hat{\rho} \hat{\varphi}_H(x))], \\ \langle \hat{\varphi}_H(x) \hat{\varphi}_H(y) \rangle_\rho &= \text{Tr} [\hat{\rho} \hat{\varphi}_H(x) \hat{\varphi}_H(y)].\end{aligned}\quad (18.119)$$

For brevity, we have gone over to a four-vector notation and use spacetime coordinates $x \equiv (\mathbf{x}, t)$ to write $\hat{\varphi}_H(\mathbf{x}, t)$ as $\hat{\varphi}_H(x)$.

In general, the fields $\varphi(\mathbf{x}, t)$ will interact with each other and with further fields, adding to (18.111) some interaction \mathcal{A}^{int} . The behavior of an interacting field system can then be studied in perturbation theory. This is done by techniques related to those in Section 1.7. First we identify a time-independent part of the Hamiltonian for which we can solve the Schrödinger equation exactly. This is called the free part of the Hamiltonian \hat{H}_0 . For the field $\varphi(\mathbf{x}, t)$ at hand this follows from the action (18.111) via the usual Legendre transformation (1.13). Its operator version is

$$\hat{H}_0 = \int d^D x \hat{\mathcal{H}}_0(\mathbf{x}, t) \equiv \frac{1}{2} \int d^D x \left\{ [\dot{\hat{\varphi}}(\mathbf{x}, t)]^2 + [\nabla \hat{\varphi}(\mathbf{x}, t)]^2 + m^2 \hat{\varphi}^2(\mathbf{x}, t) \right\}. \quad (18.120)$$

The interaction \mathcal{A}^{int} gives rise to an interaction Hamiltonian $\hat{H}^{\text{int}}(t)$. Then we introduce the field operators in Dirac's *interaction picture* $\hat{\varphi}(x)$. These are related to the Heisenberg operators via the free Hamiltonian \hat{H}_0 , by

$$\hat{\varphi}(x) \equiv e^{i\hat{H}_0(t-t_0)} \hat{\varphi}_H(x, t_0) e^{-i\hat{H}_0(t-t_0)}. \quad (18.121)$$

The operators in the two pictures are equal to each other at a time t_0 at which the density operator $\hat{\rho}$ is known. We also introduce the interaction picture for the interaction Hamiltonian³

$$\hat{H}_I^{\text{int}}(t) \equiv e^{i\hat{H}t} \hat{H}^{\text{int}}(t) e^{-i\hat{H}t}. \quad (18.122)$$

This operator is used to set up the time evolution operator in the interaction picture

$$\hat{U}(t, t_0) \equiv \hat{T} \exp \left[i \int_{t_0}^t dt' \hat{H}_I^{\text{int}}(t') \right]. \quad (18.123)$$

It allows us to express the time dependence of the field operators $\hat{\varphi}(x)$ as follows:

$$\hat{\varphi}_H(x) = \hat{U}(t_0, t) \hat{\varphi}(x) \hat{U}(t, t_0). \quad (18.124)$$

³For consistency, the field operator $\hat{\varphi}(x)$ should carry the same subscript I which is, however, omitted to shorten the notation.

The ρ -averages of the Heisenberg fields in the interaction representation are therefore

$$\langle \hat{\varphi}_H(x) \rangle_\rho = \text{Tr} \left[\hat{\rho} \hat{U}(t_0, t) \hat{\varphi}(x) \hat{U}(t, t_0) \right], \quad (18.125)$$

$$\langle \hat{\varphi}_H(x) \hat{\varphi}_H(x') \rangle_\rho = \begin{cases} \text{Tr} \left[\hat{\rho} \hat{U}(t_0, t) \hat{\varphi}(x) \hat{U}(t, t') \hat{\varphi}(x') \hat{U}(t', t_0) \right], & t > t', \\ \text{Tr} \left[\hat{\rho} \hat{U}(t_0, t') \hat{\varphi}(x') \hat{U}(t', t) \hat{\varphi}(x) \hat{U}(t, t_0) \right], & t' > t. \end{cases} \quad (18.126)$$

Now, suppose that the interaction has been active for a very long time, i.e., we let $t_0 \rightarrow -\infty$. In this limit, (18.125) can be rewritten in terms of the scattering operator $\hat{S} \equiv \hat{U}(\infty, -\infty)$ of the system.⁴ Using the time-ordering operator \hat{T} of Eq. (1.241), we may write

$$\langle \hat{\varphi}_H(x) \rangle_\rho = \text{Tr} \left[\hat{\rho} \hat{S}^\dagger \hat{T} \hat{S} \hat{\varphi}(x) \right], \quad (18.127)$$

$$\langle \hat{\varphi}_H(x) \hat{\varphi}_H(y) \rangle_\rho = \text{Tr} \left[\hat{\rho} \hat{S}^\dagger \hat{T} \hat{S} \hat{\varphi}(x) \hat{\varphi}(y) \right]. \quad (18.128)$$

These expressions are indeed the same as those in (18.125) and (18.125); for instance

$$\begin{aligned} \hat{S}^\dagger \hat{T} \left(\hat{S} \hat{\varphi}(x) \right) &= \hat{U}(-\infty, t) \hat{U}(t, \infty) \hat{T} \left(\hat{U}(\infty, t) \hat{\varphi}(x) \hat{U}(t, -\infty) \right) \\ &= \hat{U}(-\infty, t) \hat{\varphi}(x) \hat{U}(t, -\infty). \end{aligned} \quad (18.129)$$

For further development it is useful to realize that the operators in the expectations (18.127) and (18.128) can be reinterpreted time-ordered products of a new type, ordered along a *closed-time contour* which extends from $t = -\infty$ to $t = \infty$ and *back*. This contour is imagined to encircle the time axis in the complex t -plane as shown in Figure 18.1. The contour runs from $t = -\infty$ to $t = \infty$ above the real

Figure 18.1 Closed-time contour in forward–backward path integrals.

time axis and returns below it. Accordingly, we distinguish t values from the upper branch and the lower branch by writing them as t_+ and t_- , respectively. Similarly we define $x(t_+) \equiv x_+$ and $x(t_-) \equiv x_-$. When viewed as a function of the closed-time contour, the operator

$$\hat{S}^\dagger \hat{T} \left(\hat{S} \hat{\varphi}(x) \right) \quad (18.130)$$

⁴The matrix elements of \hat{S} between momentum eigenstates form the so-called S -matrix.

can be rewritten as

$$\hat{T}_{\text{P}} \left(\hat{S}^\dagger \hat{S} \hat{\varphi}(x_+) \right), \quad (18.131)$$

where \hat{T}_{P} performs a time ordering along the closed-time contour. The coordinate x lies on the positive branch of the contour, where it is denoted by x_+ . The operator \hat{T}_{P} is called *path-ordering operator*.

We can then write down immediately a generating functional for an arbitrary product of field operators ordered along the closed-time path:

$$\hat{T}_{\text{P}} \left\{ \hat{S}^\dagger \hat{S} \exp \left[i \int dx j(x_+) \hat{\varphi}(x_+) \right] \right\}, \quad (18.132)$$

where dx is short for $d^3x dt$. Functional differentiation with respect to $j(x_+)$ produces $\hat{\varphi}(x_+) \equiv \hat{\varphi}(x)$. For symmetry reasons it is also useful to introduce the source $j(x_-)$ coupled to the field on the lower time branch $\hat{\varphi}(x_-)$. Thus we shall work with the symmetric generating functional

$$Z[j_{\text{P}}] = \text{Tr} \left(\hat{\rho} \hat{T}_{\text{P}} \hat{S}^\dagger \hat{S} \exp \left\{ i \left[\int dx j(x_+) \hat{\varphi}(x_+) + \int dx j(x_-) \hat{\varphi}(x_-) \right] \right\} \right).$$

It can be written as

$$Z[j_{\text{P}}] = \text{Tr} \left\{ \hat{\rho} \hat{T}_{\text{P}} \hat{S}^\dagger \hat{S} \exp \left[i \int_{\text{P}} dx j_{\text{P}}(x) \hat{\varphi}_{\text{P}}(x) \right] \right\}, \quad (18.133)$$

with the subscript p distinguishing the time branches.

The path-ordering symbol serves to write down a useful formal expression for the interaction representation of the operator $\hat{S}^\dagger \hat{S}$.⁵

$$\hat{S}^\dagger \hat{S} = \hat{T}_{\text{P}} \exp \left[-i \int_{\text{P}} dt \hat{H}_I^{\text{int}}(t) \right]. \quad (18.134)$$

In terms of this, $Z[j_{\text{P}}]$ takes the suggestive form

$$Z[j_{\text{P}}] = \text{Tr} \left\{ \hat{\rho} \hat{T}_{\text{P}} \exp \left[-i \int_{\text{P}} dt \hat{H}_I^{\text{int}}(t) + i \int_{\text{P}} dx j_{\text{P}}(x) \hat{\varphi}_{\text{P}}(x) \right] \right\}. \quad (18.135)$$

To calculate the integrals along the closed-time contour p , it is advantageous to traverse the lower time branch in the same direction as the upper from $t = -\infty$ to ∞ (since we are used to integrating in this direction), and rewrite the closed-contour integral in the source term,

$$\int_{\text{P}} dx j_{\text{P}}(x) \hat{\varphi}_{\text{P}}(x) = \int d^3x \left[\int_{-\infty}^{\infty} dt j(\mathbf{x}, t_+) \hat{\varphi}(x_+) + \int_{\infty}^{-\infty} dt j(\mathbf{x}, t_-) \hat{\varphi}(x_-) \right], \quad (18.136)$$

⁵Note that the left-hand side is equal to 1 due to \hat{S} being unitary. However, this identity cannot be inserted into the path-ordered expressions (18.131)–(18.133), since the current terms require a factorization of \hat{S} or \hat{S}^\dagger at specific times and an insertion of field operators between the factors.

as

$$\int_{\mathbb{P}} dx j_{\mathbb{P}}(x) \hat{\varphi}_{\mathbb{P}}(x) = \int d^3x \int_{-\infty}^{\infty} dt [j(\mathbf{x}, t_+) \hat{\varphi}(x_+) - j(\mathbf{x}, t_-) \hat{\varphi}(x_-)]. \quad (18.137)$$

Obviously, the functional derivative with respect to $-j(\mathbf{x}, t_-)$ produces a factor $\hat{\varphi}(x_-)$. Correspondingly, we shall imagine the two fields $\hat{\varphi}(x_+)$, $\hat{\varphi}(x_-)$ as two components of a vector

$$\hat{\vec{\varphi}}(x) = \begin{pmatrix} \hat{\varphi}(x_+) \\ \hat{\varphi}(x_-) \end{pmatrix}, \quad (18.138)$$

with the associated current

$$\vec{j}(x) = \begin{pmatrix} j(x_+) \\ -j(x_-) \end{pmatrix}. \quad (18.139)$$

In this vector notation, the source term reads

$$\int dx \vec{j}(x) \hat{\vec{\varphi}}(x), \quad (18.140)$$

and all closed-time path formulas go directly over into vector or matrix formulas whose integrals run only once along the positive time axis, for example

$$\int_{\mathbb{P}} dx j_{\mathbb{P}}(x) G_{\mathbb{P}}(x, x') j_{\mathbb{P}}(x') = \int dx \vec{j}(x) G(x, x') \vec{j}(x'), \quad (18.141)$$

where $G(x, x')$ on the right-hand side denotes the 2×2 matrix

$$G(x, y) = \begin{pmatrix} G_{++}(x, y) & G_{+-}(x, y) \\ G_{-+}(x, y) & G_{--}(x, y) \end{pmatrix} \equiv \begin{pmatrix} G(x_+, y_+) & G(x_+, y_-) \\ G(x_-, y_+) & G(x_-, y_-) \end{pmatrix}. \quad (18.142)$$

Since all formulas for $j_{\mathbb{P}}$ and $\hat{\varphi}_{\mathbb{P}}$ hold also for \vec{j} and $\hat{\vec{\varphi}}$, we shall identify the closed-time path objects with the corresponding vectors and matrices.

Differentiating the generating functional with respect to $j_{\mathbb{P}}$ produces all Green functions of the theory. Forming two derivatives gives the two-point Green function

$$G_{\mathbb{P}}(x, y) = \frac{\delta}{i\delta j_{\mathbb{P}}(x)} \frac{\delta}{i\delta j_{\mathbb{P}}(y)} Z[j_{\mathbb{P}}] \Big|_{j_{\mathbb{P}}=0} = \text{Tr} \left[\hat{\rho} \hat{T}_{\mathbb{P}} \hat{S}^{\dagger} \hat{S} \hat{\varphi}_{\mathbb{P}}(x) \hat{\varphi}_{\mathbb{P}}(y) \right], \quad (18.143)$$

which we decompose according to the branches of the closed-time contour in the same way as the matrix (18.142):

$$G_{\mathbb{P}}(x, y) = \begin{pmatrix} G_{++}(x, y) & G_{+-}(x, y) \\ G_{-+}(x, y) & G_{--}(x, y) \end{pmatrix}. \quad (18.144)$$

The four matrix elements collect precisely the four physically relevant time-dependent Green functions discussed in the last section for the case of $\hat{\rho}$ being an

equilibrium density operator. Here they may be out of thermal equilibrium, formed with an arbitrary ρ -average rather than the thermal average at a given temperature. Going back from the interaction picture to the Heisenberg picture, the matrix $G_{\text{P}}(x, y)$ is the expectation

$$G_{\text{P}}(x, y) = \langle \hat{T}_{\text{P}} \hat{\varphi}_H(x_{\text{P}}) \hat{\varphi}_H(y_{\text{P}}) \rangle_{\rho}, \quad (18.145)$$

where x_{P} can be x_+ or x_- . Considering the different components we observe that the path order is trivial as soon as x and y lie on different branches of the time axis. Since y_+ lies always before x_- , the path-ordering operator can be omitted so that

$$G_{-+}(x, y) = \langle \hat{\varphi}_H(x) \hat{\varphi}_H(y) \rangle_{\rho}. \quad (18.146)$$

In the opposite configuration, the path order is opposite. When reestablishing the original order, a negative sign arises for fermion fields. Hence,

$$G_{+-}(x, y) = \langle \hat{\varphi}_H(y) \hat{\varphi}_H(x) \rangle_{\rho} = \pm \langle \hat{\varphi}_H(x) \hat{\varphi}_H(y) \rangle_{\rho}. \quad (18.147)$$

In either case, a distinction of the upper and lower time branches is superfluous after an explicit path ordering.

If both x and y lie on the upper branch, the path order coincides with the usual time order so that $G_{++}(x, y)$ is equal to the expectation

$$G_{++}(x, y) = \langle \hat{T} \hat{\varphi}_H(x) \hat{\varphi}_H(y) \rangle_{\rho} \equiv G(x, y), \quad (18.148)$$

i.e., the ρ -average of the usual time-ordered Green function. Similarly, if x and y both lie on the lower branch, the path order coincides with the usual anti-time order and

$$G_{--}(x, y) = \langle \hat{\bar{T}} \hat{\varphi}_H(x) \hat{\varphi}_H(y) \rangle_{\rho} \equiv \bar{G}(x, y). \quad (18.149)$$

From these relations it is easy to see that only three of the four matrix elements of $G_{\text{P}}(x, y)$ are linearly independent, since there exists the relation

$$G_{++} + G_{--} = G_{+-} + G_{-+}. \quad (18.150)$$

This can be verified by writing out explicitly the time order and antiorder on the left-hand side. In the linear-response theory of Sections 18.1 and 18.2, the most convenient independent Green functions are the retarded and the advanced ones, together with the expectation of the anticommutator (the commutator for fermions). By analogy, we also define here, in the nonequilibrium case,

$$G^R(x, y) = \Theta(x - y) \langle [\hat{\varphi}_H(x), \hat{\varphi}_H(y)]_{\mp} \rangle_{\rho}, \quad (18.151)$$

$$G^A(x, y) = -\Theta(y - x) \langle [\hat{\varphi}_H(x), \hat{\varphi}_H(y)]_{\mp} \rangle_{\rho}, \quad (18.152)$$

$$A(x, y) = \langle [\hat{\varphi}_H(x), \hat{\varphi}_H(y)]_{\pm} \rangle_{\rho}. \quad (18.153)$$

As in (18.53), the last expression coincides with the absorptive or dissipative part of the Green function. The expectation of the commutator (the anticommutator for fermions),

$$C(x, y) = \langle [\hat{\varphi}_H(x), \hat{\varphi}_H(y)]_{\mp} \rangle_{\rho}, \quad (18.154)$$

is not an independent quantity. It is related to the others by

$$C(x, y) = G^R(x, y) - G^A(x, y). \quad (18.155)$$

A comparison of the Fourier decomposition of the field (18.115) with (18.92) shows that the Green functions are simple plane-wave superpositions of harmonic oscillator of all momenta \mathbf{p} and frequency $\Omega = \omega_{\mathbf{p}}$. The normalization factor \hbar/M becomes $1/V$. For instance

$$G^R(x, x') = \sum_{\mathbf{p}} \frac{M}{\hbar V} e^{i\mathbf{p}(\mathbf{x}-\mathbf{x}')} G^R(t, t')|_{\Omega=\omega_{\mathbf{p}}}. \quad (18.156)$$

In the continuum limit, where the sum over momenta goes over into an integral with the rule (7.571), this becomes, from (18.95),

$$G^R(x, x') = -\Theta(x - x') \int \frac{d^D p}{2\omega_{\mathbf{p}}(2\pi)^D} e^{i\mathbf{k}(\mathbf{x}-\mathbf{x}')} 2i \sin \omega_{\mathbf{p}}(t - t'). \quad (18.157)$$

Similarly we find from (18.102)

$$A(x, x') = \int \frac{d^D p}{2\omega_{\mathbf{p}}(2\pi)^D} e^{i\mathbf{k}(\mathbf{x}-\mathbf{x}')} 2 \cos \omega_{\mathbf{p}}(t - t'). \quad (18.158)$$

These and the other Green functions satisfy identities analogous to those formed from the position operator $\hat{\varphi}(t)$ of a simple harmonic oscillator in (18.105)–(18.108):

$$G^A(x, x') = \mp G^R(x', x), \quad (18.159)$$

$$A(x, x') = \pm A(x', x), \quad (18.160)$$

$$C(x, x') = \mp C(x', x). \quad (18.161)$$

$$G(x, x') = \pm G(x', x)^*. \quad (18.162)$$

It is now easy to express the matrix elements of the 2×2 Green function $G_{\mathbf{p}}(x, y)$ in (18.144) in terms of the three independent quantities (18.153). Since

$$\begin{aligned} G^R &= G_{-+} - G_{--} = G_{++} - G_{+-}, \\ G^A &= G_{+-} - G_{--} = G_{++} - G_{-+}, \\ A &= G_{-+} + G_{+-} = G_{++} + G_{--}, \\ C &= G_{-+} - G_{+-} = G^R - G^A, \end{aligned} \quad (18.163)$$

we find

$$\begin{aligned} G_{-+} &= \frac{1}{2}(A + C) = \frac{1}{2}(A + G^R - G^A), \\ G_{+-} &= \frac{1}{2}(A - C) = \frac{1}{2}(A - G^R + G^A), \end{aligned} \quad (18.164)$$

and

$$\begin{aligned} G_{++} &= G^R + G_{+-} = \frac{1}{2}(A + G^R + G^A), \\ G_{--} &= G_{+-} + G_{-+} - G_{++} \\ &= A - G_{++} = \frac{1}{2}(A - G^R - G^A). \end{aligned} \quad (18.165)$$

The matrix $G_{\text{P}}(x, y)$ can therefore be written as follows:

$$G_{\text{P}} = \frac{1}{2} \begin{pmatrix} A + G^R + G^A & A - G^R + G^A \\ A + G^R - G^A & A - G^R - G^A \end{pmatrix}. \quad (18.166)$$

For actual calculations it is somewhat more convenient to use a transformation introduced by Keldysh [5]. It arises from the similarity transformation

$$\tilde{G} = Q G_{\text{P}} Q^{-1}, \quad \text{with} \quad Q = \frac{1}{\sqrt{2}} \begin{pmatrix} 1 & -1 \\ 1 & 1 \end{pmatrix} = (Q^T)^{-1}, \quad (18.167)$$

producing the simpler triangular Green function matrix

$$\begin{aligned} \tilde{G}(x, y) &= \frac{1}{\sqrt{2}} \begin{pmatrix} 1 & -1 \\ 1 & 1 \end{pmatrix} \frac{1}{2} \begin{pmatrix} A + G^R + G^A & A - G^R + G^A \\ A + G^R - G^A & A - G^R - G^A \end{pmatrix} \\ &\quad \times \frac{1}{\sqrt{2}} \begin{pmatrix} 1 & 1 \\ -1 & 1 \end{pmatrix} = \begin{pmatrix} 0 & G^A \\ G^R & A \end{pmatrix}. \end{aligned} \quad (18.168)$$

Due to the calculational advantages it is worth re-expressing all quantities in the new basis. The linear source term, for example, becomes

$$\begin{aligned} \int_{\text{P}} dx j_{\text{P}}(x) \hat{\varphi}_{\text{P}}(x) &= \int dx (j(x_+), -j(x_-)) \begin{pmatrix} \hat{\varphi}(x_+) \\ \hat{\varphi}(x_-) \end{pmatrix} \\ &= \int dx \tilde{j}(x) \hat{\tilde{\varphi}}(x), \end{aligned} \quad (18.169)$$

with the source vectors

$$\tilde{\varphi}(x) \equiv Q \begin{pmatrix} \hat{\varphi}(x_+) \\ \hat{\varphi}(x_-) \end{pmatrix} = \frac{1}{\sqrt{2}} \begin{pmatrix} \hat{\varphi}(x_+) - \hat{\varphi}(x_-) \\ \hat{\varphi}(x_+) + \hat{\varphi}(x_-) \end{pmatrix}, \quad (18.170)$$

and the field vectors

$$\tilde{j}(x) \equiv \begin{pmatrix} j_1(x) \\ j_2(x) \end{pmatrix} = Q \begin{pmatrix} j(x_+) \\ -j(x_-) \end{pmatrix} = \frac{1}{\sqrt{2}} \begin{pmatrix} j(x_+) + j(x_-) \\ j(x_+) - j(x_-) \end{pmatrix}. \quad (18.171)$$

The quadratic source term

$$\begin{aligned} & \int dx dx' j_{\mathbf{P}}(x) G_{\mathbf{P}}(x, x') j_{\mathbf{P}}(x') \\ &= \int dx dx' (j(x_+), -j(x_-)) \begin{pmatrix} G_{++} & G_{+-} \\ G_{-+} & G_{--} \end{pmatrix} (x, x') \begin{pmatrix} j(x'_+) \\ -j(x'_-) \end{pmatrix} \end{aligned} \quad (18.172)$$

becomes

$$\int dx dx' \tilde{j}^T(x) \tilde{G}(x, x') \tilde{j}(x'). \quad (18.173)$$

The product⁶ of two Green functions $\tilde{G}^{(1)}$ and $\tilde{G}^{(2)}$ has the same triangular form as each factor. The three nonzero entries are composed as follows:

$$\begin{aligned} \tilde{G}^{12} &= \tilde{G}^{(1)} \tilde{G}^{(2)} = Q G_{\mathbf{P}}^{(1)} Q^{-1} Q G_{\mathbf{P}}^{(2)} Q^{-1} \\ &= \begin{pmatrix} 0 & G_1^A G_2^A \\ G_1^R G_2^R & G_1^R A_2 + A_1 G_2^A \end{pmatrix}. \end{aligned} \quad (18.174)$$

More details on these Green functions can be found in the literature [6].

18.7 Perturbation Theory for Nonequilibrium Green Functions

The interaction picture can be used to develop a perturbation expansion for nonequilibrium Green functions. For this we go back to the generating functional (18.135) and assume that the interaction depends only on the field operators. Usually it will be a local interaction, i.e., a spacetime integral over an interaction density:

$$\exp \left[-i \int_{\mathbf{P}} dt \hat{H}_I^{\text{int}}(t) \right] = \exp \left[i \int_{\mathbf{P}} dt \int d^3x L^{\text{int}}(\hat{\varphi}_{\mathbf{P}}(\mathbf{x}, t)) \right]. \quad (18.175)$$

The subsequent formal development applies also to the case of a more general non-local interaction

$$\exp \left\{ i \mathcal{A}_{\mathbf{P}}^{\text{int}}[\hat{\varphi}_{\mathbf{P}}] \right\}. \quad (18.176)$$

To account for the interaction, we use the fact used in Section 3.18, that within the expectation (18.135) the field $\hat{\varphi}_{\mathbf{P}}$ can be written as a differential operator $\delta/i\delta j_{\mathbf{P}}(x)$ applied to the source term. In this form, the interaction term can be moved outside the thermal expectation. The result is the generating functional in the interaction picture

$$Z[j_{\mathbf{P}}] = \exp \left\{ i \mathcal{A}_{\mathbf{P}}^{\text{int}}[\delta/i\delta j_{\mathbf{P}}] \right\} Z_0[j_{\mathbf{P}}], \quad (18.177)$$

⁶The product is meant in the functional sense, i.e.,
 $(G^{(1)}G^{(2)})(x, y) = \int dz G^{(1)}(x, z)G^{(2)}(z, y)$.

where

$$Z_0[j_P] = \text{Tr} \left\{ \hat{\rho} \hat{T}_P \exp \left[i \int_{\mathcal{P}} dx \hat{\varphi}_P(x) j_P(x) \right] \right\} \quad (18.178)$$

is the free partition function.

To apply this formula, we have to find $Z_0[j_P]$ explicitly. By expanding the exponential in powers of $i\mathcal{A}_P^{\text{int}}[\delta/i\delta j_P]$ and performing the functional derivatives $\delta/i\delta j_P$, we obtain the desired perturbation expansion for $Z[j_P]$.

For a general density operator $\hat{\rho}$, the free partition function $Z_0[j_P]$ cannot be written down in closed form. Here we give $Z_0[j_P]$ explicitly only for a harmonic system in thermal equilibrium, where the ρ -averages $\langle \dots \rangle_\rho$ are the thermal averages $\langle \dots \rangle_T$ calculated in Sections 18.1 and 18.2. Since the fluctuation terms in the field $\varphi(t)$ are quadratic, $Z_0[j_P]$ must have an exponent quadratic in the sources j_P . To satisfy (18.143), the functional is necessarily given by

$$Z_0[j_P] = \exp \left[-\frac{1}{2} \int dx dy j_P(x) G_P(x, y) j_P(y) \right]. \quad (18.179)$$

Inserting the 4×4 -matrix (18.166), this becomes

$$\begin{aligned} Z_0[j_+, j_-] &= \exp \left[-\frac{1}{2} \int dx \int dx' (j_+, -j_-) Q^{-1} \begin{pmatrix} 0 & G^A \\ G^R & A \end{pmatrix} Q \begin{pmatrix} j_+ \\ -j_- \end{pmatrix} \right] \\ &= \exp \left\{ -\frac{1}{4} \int dx \int dx' \left[(j_+ + j_-)(x) G^A(x, x') (j_+ - j_-)(x') \right. \right. \\ &\quad \left. \left. + (j_+ - j_-)(x) G^R(x, x') (j_+ + j_-)(x') \right. \right. \\ &\quad \left. \left. + (j_+ - j_-)(x) A(x, x') (j_+ - j_-)(x') \right] \right\}, \quad (18.180) \end{aligned}$$

where

$$j_+(x) \equiv j(x_+), \quad j_-(x) \equiv j(x_-). \quad (18.181)$$

The advanced Green functions are different from zero only for $t < t'$. Using relation (18.159), the second term is seen to be the same as the first. For the real field at hand, these terms are purely imaginary [see (18.156)]. The anticommutation function $A(x, x')$ is symmetric by (18.160). We therefore rewrite (18.180) as

$$\begin{aligned} Z_0[j_+, j_-] &= \exp \left\{ -\frac{1}{2} \int dx \int dx' \Theta(x' - x) \right. \\ &\quad \left. \times \left[(j_+ - j_-)(x) G^R(x, x') (j_+ + j_-)(x') + (j_+ - j_-)(x) A(x, x') (j_+ - j_-)(x') \right] \right\}. \quad (18.182) \end{aligned}$$

For any given spectral function, the exponent can easily be written down explicitly using the spectral representations (18.44) and (18.53).

As an important example consider the simple case of a single harmonic oscillator of frequency Ω . Then the field $\hat{\varphi}(x)$ depends only on the time t , and the commutator

and “wrong” commutator functions are given by (18.93) and (18.102). Reintroducing all factors \hbar and k_B , we have

$$Z_0[j_+, j_-] = \exp \left\{ -\frac{1}{2\hbar^2} \int dt \int dt' \Theta(t-t') \right. \\ \left. \times [(j_+ - j_-)(t)C(t, t')(j_+ + j_-)(t') + (j_+ - j_-)(t)A(t, t')(j_+ - j_-)(t')] \right\} \quad (18.183)$$

or, more explicitly,

$$Z_0[j_+, j_-] = \exp \left\{ -\frac{1}{2M\Omega\hbar} \int dt \int dt' \Theta(t'-t) \right. \\ \times \left[-(j_+ - j_-)(t) \quad i \sin \Omega(t-t') \quad (j_+ + j_-)(t') \right. \\ \left. + (j_+ - j_-)(t) \coth \frac{\hbar\Omega}{2k_B T} \cos \Omega(t-t') \quad (j_+ - j_-)(t') \right] \left. \right\}. \quad (18.184)$$

We have taken advantage of the presence of the Heaviside function to express the retarded Green function for $t > t'$ as a commutator function $C(t, t')$ [recall (18.151), (18.154)]. Together with the anticommutator function $A(t, t')$, we obtain for $t > t'$

$$G(t, t') = \frac{1}{2} [A(t, t') + C(t, t')] = \frac{\hbar}{2M\Omega} \frac{\cosh \frac{\Omega}{2} [\hbar\beta - i(t-t')]}{\sinh \frac{\hbar\Omega\beta}{2}}, \quad (18.185)$$

which coincides with the time-ordered Green function (18.101) for $t > t'$, and thus with the analytically continued periodic imaginary-time Green function (3.251). The exponent in this generating functional is thus quite similar to the equilibrium source term (3.221).

The generating functional (18.180) can, of course, be derived without the previous operator discussion completely in terms of path integrals for the harmonic oscillator in thermal equilibrium. Using the notation $\hat{X}(t)$ for a purely time-dependent oscillator field $\hat{\varphi}(x)$, we can take the generating functional directly from Eq. (3.168):

$$(X_b t_b | X_a t_a)^j_{\Omega} = \int \mathcal{D}X(t) \exp \left\{ \frac{i}{\hbar} \int_{t_a}^{t_b} dt \left[\frac{M}{2} (\dot{X}^2 - \Omega^2 X^2) + jX \right] \right\} \\ = e^{(i/\hbar)\mathcal{A}_{\text{cl},j}} F_{\Omega,j}(t_b, t_a). \quad (18.186)$$

with a total classical action

$$\mathcal{A}_{\text{cl},j} = \frac{1}{2} \frac{M\Omega}{\sin \Omega(t_b - t_a)} [(X_b^2 + X_a^2) \cos \Omega(t_b - t_a) - 2X_b X_a] \\ + \frac{1}{\sin \Omega(t_b - t_a)} \int_{t_a}^{t_b} dt [X_a \sin \Omega(t_b - t) + X_b \sin \Omega(t - t_a)] j(t), \quad (18.187)$$

and the fluctuation factor (3.170), and express (18.187) as in (3.171) in terms of the two independent solutions $D_a(t)$ and $D_b(t)$ of the homogenous differential equations (3.48) introduced in Eqs. (2.228) and (2.229):

$$\mathcal{A}_{\text{cl},j} = \frac{M}{2D_a(t_b)} [X_b^2 \dot{D}_a(t_b) - X_a^2 \dot{D}_b(t_a) - 2X_b X_a]$$

$$+ \frac{1}{D_a(t_b)} \int_{t_a}^{t_b} dt [X_b D_a(t) + X_a D_b(t)] j(t). \quad (18.188)$$

The fluctuation factor is taken as in (3.172). Then we calculate the thermal average of the forward-backward path integral of the oscillator $X(t)$ via the Gaussian integral

$$Z_0[j_+, j_-] = \int dX_b dX_a (X_b \hbar\beta | X_a 0)_\Omega (X_b t_b | X_a t_a)_\Omega^{j_+} (X_b t_b | X_a t_a)_\Omega^{j_-*}. \quad (18.189)$$

Here $(X_b \hbar\beta | X_a 0)_\Omega$ is the imaginary-time amplitude (2.411):

$$(X_b \hbar\beta | X_a 0) = \frac{1}{\sqrt{2\pi\hbar/M}} \sqrt{\frac{\Omega}{\sinh \hbar\beta}} \\ \times \exp \left\{ -\frac{1}{2\hbar} \frac{M\Omega}{\sinh \hbar\beta\Omega} [(X_b^2 + X_a^2) \cosh \hbar\beta\Omega - 2X_b X_a] \right\}. \quad (18.190)$$

We have preferred deriving $Z_0[j_+, j_-]$ in the operator language since this illuminates better the physical meaning of the different terms in the result (18.185).

18.8 Path Integral Coupled to Thermal Reservoir

After these preparations, we can embark on a study of a simple but typical problem of nonequilibrium thermodynamics. We would like to understand the quantum-mechanical behavior of a particle coupled to a thermal reservoir of temperature T and moving in an arbitrary potential $V(x)$ [7]. Without the reservoir, the probability of going from x_a, t_a to x_b, t_b would be given by⁷

$$|(x_b t_b | x_a t_a)|^2 = \left| \int \mathcal{D}x(t) \exp \left\{ \frac{i}{\hbar} \int dt \left[\frac{M}{2} \dot{x}^2 - V(x) \right] \right\} \right|^2. \quad (18.191)$$

This may be written as a path integral over two independent orbits, to be called $x_+(t)$ and $x_-(t)$:

$$(x_b t_b | x_a t_a)(x_b t_b | x_a t_a)^* = \int \mathcal{D}x_+(t) \mathcal{D}x_-(t) \\ \times \exp \left\{ \frac{i}{\hbar} \int_{t_a}^{t_b} dt \left[\frac{M}{2} (\dot{x}_+^2 - \dot{x}_-^2) - (V(x_+) - V(x_-)) \right] \right\}. \quad (18.192)$$

In accordance with the development in Section 18.7, the two orbits are reinterpreted as two branches of a single closed-time orbit $x_P(t)$. The time coordinate t_P of the path runs from t_a to t_b slightly above the real time axis and returns slightly below it, just as in Fig. 18.1. The probability distribution (18.191) can then be written as a path integral over the closed-time contour encircling the interval (t_a, t_b) :

$$|(x_b t_b | x_a t_a)|^2 = \int \mathcal{D}x_P \exp \left\{ \frac{i}{\hbar} \int_P dt \left[\frac{M}{2} \dot{x}_P^2 - V(x_P) \right] \right\}. \quad (18.193)$$

⁷In the sequel, we display the constants \hbar and k_B explicitly.

We now introduce a coupling to a thermal reservoir for which we use, as in the equilibrium discussion in Section 3.13, a bath of independent harmonic oscillators $\hat{\varphi}_i(t)$ of masses M_i and frequencies Ω_i in thermal equilibrium at temperature T . For simplicity, the coupling is assumed to be linear in $\hat{\varphi}_i(t)$ and the position of the particle $x(t)$. The bath contributes to (18.193) a factor involving the thermal expectation of the linear interaction

$$|(x_b t_b | x_a t_a)|^2 = \int \mathcal{D}x_P \exp \left\{ \frac{i}{\hbar} \int_P dt \left[\frac{M}{2} \dot{x}_P^2 - V(x_P) \right] \right\} \\ \times \text{Tr} \left\{ \hat{\rho} \hat{T}_P \exp \left[\frac{i}{\hbar} \sum_i c_i \int_P dt \hat{\varphi}_P^i(t) x_P(t) \right] \right\}. \quad (18.194)$$

Here, $\hat{\varphi}_P^i(t)$ for $i = 1, 2, 3, \dots$ are the position operators of the auxiliary harmonic oscillators. Since the oscillators are independent, the trace of the exponentials factorizes into a product of single-oscillator expressions

$$\text{Tr} \left\{ \hat{\rho} \hat{T}_P \exp \left[\frac{i}{\hbar} \sum_i c_i \int_P dt \hat{\varphi}_P^i(t) x_P(t) \right] \right\} = \prod_i \text{Tr} \left\{ \hat{\rho} \hat{T}_P \exp \left[\frac{i}{\hbar} c_i \int_P dt \hat{\varphi}_P^i(t) x_P(t) \right] \right\}. \quad (18.195)$$

The density operator $\hat{\rho}$ has the eigenvalues (18.110).

Each factor on the right-hand side is of the form (18.178) with $\hat{\varphi}(t) = c_i \hat{\varphi}_P^i(t)/\hbar$ and $j_{+,-} = x_{+,-}(t)$, so that (18.195) leads to the partition function (18.183), which reads here

$$Z_0^b[x_+, x_-] = \exp \left\{ -\frac{1}{2\hbar^2} \int dt \int dt' \Theta(t-t') \right. \\ \left. \times \left[(x_+ - x_-)(t) C_b(t, t') (x_+ + x_-)(t') + (x_+ - x_-)(t) A_b(t, t') (x_+ - x_-)(t') \right] \right\}, \quad (18.196)$$

where $C_b(t, t')$ and $A_b(t, t')$ collect the commutator and anticommutator functions of the bath. They are sums of correlation functions (18.93) and (18.102) of the individual oscillators of mass M_i and frequency Ω_i , each contributing with a weight c_i^2 . Thus we may write

$$C_b(t, t') = \sum_i c_i^2 \langle [\hat{\varphi}_i(t), \hat{\varphi}_i(t')] \rangle_T = -\hbar \int_{-\infty}^{\infty} \frac{d\omega'}{2\pi} \rho_b(\omega') i \sin \omega'(t-t'), \quad (18.197)$$

$$A_b(t, t') = \sum_i c_i^2 \langle \{\hat{\varphi}_i(t), \hat{\varphi}_i(t')\} \rangle_T = \hbar \int_{-\infty}^{\infty} \frac{d\omega'}{2\pi} \rho_b(\omega') \coth \frac{\hbar\omega'}{2k_B T} \cos \omega'(t-t'), \quad (18.198)$$

where the ensemble averages at a fixed temperature T are now denoted by a subscript T , and

$$\rho_b(\omega') \equiv 2\pi \sum_i \frac{c_i^2}{2M_i\Omega_i} [\delta(\omega' - \Omega_i) - \delta(\omega' + \Omega_i)] \quad (18.199)$$

is the spectral function of the bath. It is the antisymmetric continuation of the spectral function (3.408) to negative ω' . Since the spectral function of the bath $\rho_b(\omega')$

of (18.199) is odd in ω' , we can replace both trigonometric functions $-i \sin \omega'(t-t')$ and $\cos \omega'(t-t')$ in (18.199) by the exponentials $e^{-i\omega'(t-t')}$.

The expression in the exponent of (18.196) may be considered as an effective action in the path integral, caused by the thermal bath. We shall therefore write

$$Z_0[x_+, x_-] = \exp \left\{ \frac{i}{\hbar} \mathcal{A}^{\text{FV}}[x_+, x_-] \right\} = \exp \left\{ \frac{i}{\hbar} \left(\mathcal{A}_D^{\text{FV}}[x_+, x_-] + \mathcal{A}_F^{\text{FV}}[x_+, x_-] \right) \right\}, \quad (18.200)$$

where the effective action $\mathcal{A}^{\text{FV}}[x_+, x_-]$ consists of a dissipative part $\mathcal{A}_D^{\text{FV}}[x_+, x_-]$ and a fluctuation part $\mathcal{A}_F^{\text{FV}}[x_+, x_-]$. The expression $Z_0[x_+, x_-]$ is the famous *influence functional* first introduced by Feynman and Vernon.

Inserting (18.200) into (18.194) and displaying explicitly the two branches of the path $x_P(t)$ with the proper limits of time integrations, we obtain from (18.194) the probability for the particle to move from $x_a t_a$ to $x_b t_b$ as the path integral

$$\begin{aligned} |(x_b t_b | x_a t_a)|^2 &= \int \mathcal{D}x_+(t) \int \mathcal{D}x_-(t) \times \\ &\times \exp \left\{ \frac{i}{\hbar} \int_{t_a}^{t_b} dt \left[\frac{M}{2} (\dot{x}_+^2 - \dot{x}_-^2) - (V(x_+) - V(x_-)) \right] + \frac{i}{\hbar} \mathcal{A}^{\text{FV}}[x_+, x_-] \right\}. \end{aligned} \quad (18.201)$$

For a better understanding of the influence functional, we introduce an auxiliary retarded function

$$\gamma(t-t') \equiv \Theta(t-t') \frac{1}{M} \int_{-\infty}^{\infty} \frac{d\omega}{2\pi} \frac{\sigma_b(\omega)}{\omega} e^{-i\omega(t-t')}. \quad (18.202)$$

Then we can write

$$\Theta(t-t') C_b(t, t') = i\hbar M \dot{\gamma}(t-t') + i\hbar M \Delta\omega^2 \delta(t-t'), \quad (18.203)$$

where the quantity

$$\Delta\omega^2 \equiv -\frac{1}{M} \int_{-\infty}^{\infty} \frac{d\omega'}{2\pi} \frac{\sigma_b(\omega')}{\omega'} = -\frac{1}{M} \sum_i \frac{c_i^2}{M_i \Omega_i^2} \quad (18.204)$$

was introduced before in Eq. (3.420). Inserting the first term of the decomposition (18.203) into (18.196), the dissipative part of the influence functional can be integrated by parts in t' and becomes

$$\begin{aligned} \mathcal{A}_D^{\text{FV}}[x_+, x_-] &= -\frac{M}{2} \int_{t_a}^{t_b} dt \int_{t_a}^{t_b} dt' (x_+ - x_-)(t) \gamma(t-t') (\dot{x}_+ + \dot{x}_-)(t') \\ &\quad + \frac{M}{2} \int_{t_a}^{t_b} dt (x_+ - x_-)(t) \gamma(t-t_b) (x_+ + x_-)(t_a). \end{aligned} \quad (18.205)$$

The δ -function in (18.203) contributes to $\mathcal{A}_D^{\text{FV}}[x_+, x_-]$ a term analogous to (3.421)

$$\Delta \mathcal{A}_{\text{loc}}[x_+, x_-] = \frac{M}{2} \int_{t_a}^{t_b} dt \Delta\omega^2 (x_+^2 - x_-^2)(t), \quad (18.206)$$

which may simply be absorbed into the potential terms of the path integral (18.201), renormalizing them to

$$-\frac{i}{\hbar} \int_{t_a}^{t_b} dt [V_{\text{ren}}(x_+) - V_{\text{ren}}(x_-)]. \quad (18.207)$$

This renormalization is completely analogous to that in the imaginary-time formula (3.423).

The odd bath function $\rho_b(\omega')$ can be expanded in a power series with only odd powers of ω' . The lowest approximation

$$\rho_b(\omega') \approx 2M\gamma\omega', \quad (18.208)$$

describes Ohmic dissipation with some friction constant γ [recall (3.427)]. For frequencies much larger than the atomic relaxation rates, the friction goes to zero. This behavior is modeled by the Drude form (3.428) of the spectral function

$$\rho_b(\omega') \approx 2M\gamma\omega' \frac{\omega_D^2}{\omega_D^2 + \omega'^2}. \quad (18.209)$$

Inserting this into Eq. (18.202), we obtain the Drude form of the function $\gamma(t)$:

$$\gamma_D^R(t) \equiv \Theta(t) \gamma \omega_D e^{-\omega_D t}. \quad (18.210)$$

The superscript emphasizes the retarded nature. This can also be written as a Fourier integral

$$\gamma_D^R(t) = \int_{-\infty}^{\infty} \frac{d\omega'}{2\pi} \gamma_D^R(\omega') e^{-i\omega' t}, \quad (18.211)$$

with the Fourier components

$$\gamma_D^R(\omega') = \gamma \frac{i\omega_D}{\omega' + i\omega_D}. \quad (18.212)$$

The position of the pole in the lower half-plane ensures the retarded nature of the friction term by producing the Heaviside function in (18.210) [recall (1.312)].

The imaginary-time expansion coefficients γ_m of Eq. (3.431) are related to these by

$$\gamma_m = \gamma(\omega')|_{\omega' = i|\omega_m|}, \quad (18.213)$$

by close analogy with the relation between the retarded and imaginary-time Green functions (18.30) and (18.31).

In the Ohmic limit (18.208), the dissipative part of the influence functional simplifies. Then $\gamma_D^R(t)$ becomes narrowly peaked at positive t , and may be approximated by a right-sided *retarded* δ -function as

$$\gamma_D^R(t) \rightarrow \gamma \delta^R(t), \quad (18.214)$$

whose superscript R indicates the retarded asymmetry of the δ -function. With this, (18.205) becomes a local action

$$\mathcal{A}_D^{\text{FV}}[x_+, x_-] = -\frac{M}{2}\gamma \int_{t_a}^{t_b} dt (x_+ - x_-)(\dot{x}_+ + \dot{x}_-)^R - \frac{M}{2}\gamma(x_+^2 - x_-^2)(t_a). \quad (18.215)$$

The right-sided nature of the function $\delta^R(t)$ causes an infinitesimal *negative* shift in the time argument of the velocities $(\dot{x}_+ + \dot{x}_-)(t)$ with respect to the factor $(x_+ - x_-)(t)$, indicated by the superscript R . It expresses the *causality* of the friction forces and will be seen to be crucial in producing a probability conserving time evolution of the probability distribution.

The second term changes only the curvature of the effective potential at the initial time, and can be ignored.

It is useful to incorporate the slope information (18.208) also into the bath correlation function $A_b(t, t')$ in (18.198), and factorize it as

$$A_b(t, t') = 2M\gamma k_B T K(t, t'), \quad (18.216)$$

where

$$K(t, t') = K(t - t') \equiv \frac{1}{2M\gamma k_B T} \sum_i c_i^2 \langle \{\hat{\varphi}_i(t), \hat{\varphi}_i(t')\} \rangle_T. \quad (18.217)$$

The prefactor in (18.216) is conveniently abbreviated by the constant

$$w \equiv 2M\gamma k_B T, \quad (18.218)$$

which is related to the so-called *diffusion constant*

$$D \equiv k_B T / M\gamma \quad (18.219)$$

by

$$w = 2\gamma^2 M^2 D. \quad (18.220)$$

The Fourier decomposition of (18.217) is

$$K(t, t') = \int_{-\infty}^{\infty} \frac{d\omega'}{2\pi} K(\omega') e^{-i\omega'(t-t')}, \quad (18.221)$$

with

$$K(\omega') \equiv \frac{1}{2M\gamma} \frac{\rho_b(\omega')}{\omega'} \frac{\hbar\omega'}{2k_B T} \coth \frac{\hbar\omega'}{2k_B T}. \quad (18.222)$$

In the limit of a purely Ohmic dissipation this simplifies to

$$K(\omega') \rightarrow K^{\text{Ohm}}(\omega') \equiv \frac{\hbar\omega'}{2k_B T} \coth \frac{\hbar\omega'}{2k_B T}. \quad (18.223)$$

The function $K(\omega')$ has the normalization $K(0) = 1$, giving $K(t-t')$ a unit temporal area:

$$\int_{-\infty}^{\infty} dt K(t-t') = 1. \quad (18.224)$$

In the classical limit $\hbar \rightarrow 0$, the Drude spectral function (18.209) leads to

$$K_D^{\text{cl}}(\omega') = \frac{\omega_D^2}{\omega'^2 + \omega_D^2}, \quad (18.225)$$

with the Fourier transform

$$K_D^{\text{cl}}(t-t') = \frac{1}{2\omega_D} e^{-\omega_D(t-t')}. \quad (18.226)$$

In the limit of Ohmic dissipation, this becomes a δ -function. Thus $K(t-t')$ may be viewed as a δ -function broadened by quantum fluctuations and relaxation effects.

With the function $K(t, t')$, the fluctuation part of the influence functional in (18.196), (18.200), (18.201) becomes

$$\mathcal{A}_F^{\text{FV}}[x_+, x_-] = i \frac{w}{2\hbar} \int_{t_a}^{t_b} dt \int_{t_a}^{t_b} dt' (x_+ - x_-)(t) K(t, t') (x_+ - x_-)(t'). \quad (18.227)$$

Here we have used the symmetry of the function $K(t, t')$ to remove the Heaviside function $\Theta(t-t')$ from the integrand, and to extend the range of t' -integration to the entire interval (t_a, t_b) .

In the Ohmic limit, the probability of the particle to move from $x_a t_a$ to $x_b t_b$ is given by the path integral

$$\begin{aligned} |(x_b t_b | x_a t_a)|^2 &= \int \mathcal{D}x_+(t) \int \mathcal{D}x_-(t) \\ &\times \exp \left\{ \frac{i}{\hbar} \int_{t_a}^{t_b} dt \left[\frac{M}{2} (\dot{x}_+^2 - \dot{x}_-^2) - (V(x_+) - V(x_-)) \right] \right\} \\ &\times \exp \left\{ -i \int_{t_a}^{t_b} dt \frac{M\gamma}{2\hbar} (x_+ - x_-)(t) (\dot{x}_+ + \dot{x}_-)^R(t) \right. \\ &\quad \left. - \frac{w}{2\hbar^2} \int_{t_a}^{t_b} dt \int_{t_a}^{t_b} dt' (x_+ - x_-)(t) K^{\text{Ohm}}(t, t') (x_+ - x_-)(t') \right\}. \quad (18.228) \end{aligned}$$

This is the *closed-time path integral* of a particle in contact with a thermal reservoir.

The paths $x_+(t), x_-(t)$ may also be associated with a forward and a backward movement of the particle in time. For this reason, (18.228) is also called a *forward-backward path integral*. The hyphen is pronounced as *minus*, to emphasize the opposite signs in the partial actions.

It is now convenient to change integration variables and go over to average and relative coordinates of the two paths x_+, x_- :

$$\begin{aligned} x &\equiv (x_+ + x_-)/2, \\ y &\equiv x_+ - x_-. \end{aligned} \quad (18.229)$$

Then (18.228) becomes

$$\begin{aligned}
|(x_b t_b | x_a t_a)|^2 &= \int \mathcal{D}x(t) \int \mathcal{D}y(t) \\
&\times \exp \left\{ -\frac{i}{\hbar} \int_{t_a}^{t_b} dt \left[M \left(-\dot{y}\dot{x} + \gamma y \dot{x}^R \right) + V \left(x + \frac{y}{2} \right) - V \left(x - \frac{y}{2} \right) \right] \right. \\
&\quad \left. - \frac{w}{2\hbar^2} \int_{t_a}^{t_b} dt \int_{t_a}^{t_b} dt' y(t) K^{\text{Ohm}}(t, t') y(t') \right\}. \quad (18.230)
\end{aligned}$$

18.9 Fokker-Planck Equation

At high temperatures, the Fourier transform of the Kernel $K(t, t')$ in Eq. (18.223) tends to unity such that $K(t, t')$ becomes a δ -function, so that the path integral (18.230) for the probability distribution of a particle coupled to a thermal bath simplifies to

$$\begin{aligned}
P(x_b t_b | x_a t_a) &\equiv |(x_b t_b | x_a t_a)|^2 = \int \mathcal{D}x(t) \int \mathcal{D}y(t) \\
&\times \exp \left\{ -\frac{i}{\hbar} \int_{t_a}^{t_b} dt y [M\ddot{x} + M\gamma\dot{x}^R + V'(x)] - \frac{w}{2\hbar^2} \int_{t_a}^{t_b} dt y^2 \right\}. \quad (18.231)
\end{aligned}$$

The superscript R records the infinitesimal backward shift of the time argument as in Eq. (18.215). The y -variable can be integrated out, and we obtain

$$P(x_b t_b | x_a t_a) = \mathcal{N} \int \mathcal{D}x(t) \exp \left\{ -\frac{1}{2w} \int_{t_a}^{t_b} dt [M\ddot{x} + M\gamma\dot{x}^R + V'(x)]^2 \right\}. \quad (18.232)$$

The proportionality constant \mathcal{N} can be fixed by the normalization integral

$$\int dx_b P(x_b t_b | x_a t_a) = 1. \quad (18.233)$$

Since the particle is initially concentrated around x_a , the normalization may also be fixed by the initial condition

$$\lim_{t_b \rightarrow t_a} P(x_b t_b | x_a t_a) = \delta(x_b - x_a). \quad (18.234)$$

The right-hand side of (18.232) looks like a Euclidean path integral associated with the Lagrangian [8]

$$L_e = \frac{1}{2w} [M\ddot{x} + M\gamma\dot{x} + V'(x)]^2. \quad (18.235)$$

The result will, however, be different, due to time-ordering of the \dot{x}^R -term.

Apart from this, the Lagrangian is not of the conventional type since it involves a second time derivative. The action principle $\delta\mathcal{A} = 0$ now yields the Euler-Lagrange equation

$$\frac{\partial L}{\partial x} - \frac{d}{dt} \frac{\partial L}{\partial \dot{x}} + \frac{d^2}{dt^2} \frac{\partial L}{\partial \ddot{x}} = 0. \quad (18.236)$$

This equation can also be derived via the usual Lagrange formalism by considering x and \dot{x} as independent generalized coordinates x, v .

18.9.1 Canonical Path Integral for Probability Distribution

In Section 2.1 we have constructed path integrals for time evolution amplitudes to solve the Schrödinger equation. By analogy, we expect the path integral (18.232) for the probability distribution to satisfy a differential equation of the Schrödinger type. This equation is known as a *Fokker-Planck equation*. As in Section 2.1, the relation is established by rewriting the path integral in canonical form. Treating $v = \dot{x}$ as an independent dynamical variable, the canonical momenta of x and v are [9]

$$\begin{aligned} p &= i \frac{\partial L}{\partial \dot{x}} = i \frac{M\gamma}{w} [M\ddot{x} + M\gamma\dot{x} + V'(x)] = i \frac{M\gamma}{w} [M\dot{v} + M\gamma v + V'(x)], \\ p_v &= i \frac{\partial L}{\partial \dot{v}} = \frac{1}{\gamma} p. \end{aligned} \quad (18.237)$$

The Hamiltonian is given by the Legendre transform

$$H(p, p_v, x, v) = L_e(\dot{x}, \ddot{x}) - \sum_{i=1}^2 \frac{\partial L_e}{\partial \dot{x}_i} \dot{x}_i = L_e(v, \dot{v}) + ipv + ip_v \dot{v}, \quad (18.238)$$

where \dot{v} has to be eliminated in favor of p_v using (18.237). This leads to

$$H(p, p_v, x, v) = \frac{w}{2M^2} p_v^2 - ip_v \left[\gamma v + \frac{1}{M} V'(x) \right] + ipv. \quad (18.239)$$

The canonical path integral representation for the probability distribution reads therefore

$$\begin{aligned} P(x_b t_b | x_a t_a) &= \int \mathcal{D}x \int \frac{\mathcal{D}p}{2\pi} \int \mathcal{D}v \int \frac{\mathcal{D}p_v}{2\pi} \\ &\times \exp \left\{ \int_{t_a}^{t_b} dt [i(p\dot{x} + p_v \dot{v}) - H(p, p_v, x, v)] \right\}. \end{aligned} \quad (18.240)$$

It is easy to verify that the path integral over p enforces $v \equiv \dot{x}$, after which the path integral over p_v leads back to the initial expression (18.232). We may keep the auxiliary variable $v(t)$ as an independent fluctuating quantity in all formulas and decompose the probability distribution $P(x_b t_b | x_a t_a)$ with respect to the content of v as an integral

$$P(x_b t_b | x_a t_a) = \int_{-\infty}^{\infty} dv_b \int_{-\infty}^{\infty} dv_a P(x_b v_b t_b | x_a v_a t_a). \quad (18.241)$$

The more detailed probability distribution on the right-hand side has the path integral representation

$$\begin{aligned} P(x_b v_b t_b | x_a v_a t_a) &= |(x_b v_b t_b | x_a v_a t_a)|^2 = \int \mathcal{D}x \int \frac{\mathcal{D}p}{2\pi} \int \mathcal{D}v \int \frac{\mathcal{D}p_v}{2\pi} \\ &\times \exp \left\{ \int_{t_a}^{t_b} dt [i(p\dot{x} + p_v \dot{v}) - H(p, p_v, x, v)] \right\}, \end{aligned} \quad (18.242)$$

where the endpoints of v are now kept fixed at $v_b = v(t_b)$, $v_a = v(t_a)$.

We now use the relation between a canonical path integral and the Schrödinger equation discussed in Section 2.1 to conclude that the probability distribution (18.242) satisfies the Schrödinger-like differential equation [10]:

$$H(\hat{p}, \hat{p}_v, x, v)P(x v t_b | x_a v_a t_a) = -\partial_t P(x v t | x_a v_a t_a). \quad (18.243)$$

It is called the *Klein-Kramers equation* for the motion of an inert point particle with dissipation. It is a special case of a two-variable *Fokker-Planck equation* whose general version deals with N variables $\mathbf{x}x_1, \dots, x_N$ collected in a vector \mathbf{x} , and has the form

$$\partial_t P(\mathbf{x} t | \mathbf{x}_a v_a t_a) = \left[-\partial_i D_i(\mathbf{x}) + \partial_i \partial_j D_{ij}^{(2)}(\mathbf{x}) \right] P(\mathbf{x} t | \mathbf{x}_a v_a t_a). \quad (18.244)$$

The above equation (18.243) is a special case of this for $N = 2$;

$$\partial_t P(\mathbf{x} t | t_a \mathbf{x}_a) = (-\kappa_{ij} \partial_i x_j + D_{ij} \partial_i \partial_j) P(\mathbf{x} t | t_a \mathbf{x}_a). \quad (18.245)$$

with the *diffusion matrix*

$$\mathbf{D} = \begin{pmatrix} 0 & 0 \\ 0 & w/2M^2 \end{pmatrix} = \begin{pmatrix} 0 & 0 \\ 0 & \gamma k_B T / M \end{pmatrix} = \begin{pmatrix} 0 & 0 \\ 0 & \gamma^2 D \end{pmatrix}, \quad (18.246)$$

and

$$\boldsymbol{\kappa} = \begin{pmatrix} 0 & -1 \\ V'(x)/M & \gamma \end{pmatrix}. \quad (18.247)$$

It must be realized that when going over from the classical Hamiltonian (18.239) to the Hamiltonian operator in the differential equation (18.243), there is an operator ordering problem. Such a problem was encountered in Section 10.5 and discussed further at the end of Section 11.3. In this respect the analogy with the simple path integrals in Section 2.1 is not perfect. When writing down Eq. (18.243) we do not know in which order the momentum operator \hat{p}_v must stand with respect to v . If we were dealing with an ordinary functional integral in (18.232) we would know the order. It would be found as in the case of the electromagnetic interaction in Eq. (11.89) to have the symmetric order $-(\hat{p}_v v + v \hat{p}_v)/2$.

On physical grounds, it is easy to guess the correct order. The differential equation (18.243) has to conserve the total probability

$$\int dx dv P(x v t_b | x_a v_a t_a) = 1 \quad (18.248)$$

for all times t . This is guaranteed if all momentum operators stand to the left of all coordinates in the Hamiltonian operator. Indeed, integrating the Fokker-Planck equation (18.243) over x and v , only a left-hand position of the momentum operators leads to a vanishing integral, and thus to a time independent total probability. We suspect that this order must be derivable from the retarded nature of the velocity in the term $y\dot{x}^R$ in (18.231). This will be shown in the next section.

18.9.2 Solving the Operator Ordering Problem

The ordering problem in the Hamiltonian operator associated with (18.239) does not involve the potential $V(x)$. We may therefore study this problem most simply by considering the classical free Hamiltonian

$$\tilde{H}_0(p, p_v, x, v) = \frac{w}{2M^2} p_v^2 - i\gamma p_v v + ipv, \quad (18.249)$$

associated with the Lagrangian path integral

$$P_0(x_b t_b | x_a t_a) = \mathcal{N} \int \mathcal{D}x(t) \exp \left\{ -\frac{1}{2w} \int_{t_a}^{t_b} dt [M\ddot{x} + M\gamma\dot{x}^R]^2 \right\}, \quad (18.250)$$

if we ignore the operator ordering problem. We may further concentrate our attention upon the probability distribution with $x_b = x_a = 0$, and assume $t_b - t_a$ to be very large. Then the frequencies of all Fourier decompositions are continuous.

In spite of the restrictions to large $t_b - t_a$, the result to be derived will be valid for any time interval. The reason is that operator order is a property of extremely short time intervals, so that it does not matter, how long the time interval is on which we solve the problem.

Forgetting for a moment the retarded nature of the velocity \dot{x} , the Gaussian path integral can immediately be done and yields

$$\begin{aligned} P_0(0 t_b | 0 t_a) &\propto \text{Det}^{-1}(-\partial_t^2 - \gamma\partial_t) \\ &\propto \exp \left[-(t_b - t_a) \int_{-\infty}^{\infty} \frac{d\omega'}{2\pi} \log(\omega'^2 - i\gamma\omega') \right], \end{aligned} \quad (18.251)$$

where γ is *positive*. The integral on the right-hand side diverges. This is a consequence of the fact that we have not used Feynman's time slicing procedure for defining the path integral. As for an ordinary harmonic oscillator discussed in detail in Sections 2.3 and 2.14), this would lead to a finite integral in which ω' is replaced by $\tilde{\omega}' \equiv (2 - 2 \cos a\omega')/a^2$:

$$\frac{1}{2} \int_{-\infty}^{\infty} \frac{d\omega'}{2\pi} \log[\tilde{\omega}'^4 + \gamma^2 \tilde{\omega}'^2] = \frac{1}{2} \int_{-\infty}^{\infty} \frac{d\omega'}{2\pi} \log \tilde{\omega}'^2 + \frac{1}{2} \int_{-\infty}^{\infty} \frac{d\omega'}{2\pi} \log[\tilde{\omega}'^2 + \gamma^2] = 0 + \frac{\gamma}{2}. \quad (18.252)$$

For a derivation see Section 2.14, in particular the first term in Eq. (2.485). The same result can equally well be obtained without time slicing by regularizing the divergent integral in (18.251) analytically, as shown in (2.504). Recall the discussion in Section 10.6 where analytic regularization was seen to be the only method that allows to define path integrals without time slicing in such a way that they are invariant under coordinate transformations [11]. It is therefore suggestive to apply the same procedure also to the present path integrals with dissipation and to use the dimensionally regularized formula (2.541):

$$\int_{-\infty}^{\infty} \frac{d\omega'}{2\pi} \log(\omega' \pm i\gamma) = \frac{\gamma}{2}, \quad \gamma > 0. \quad (18.253)$$

Applying this to the functional determinant in (18.251) yields

$$\begin{aligned} \text{Det}(-\partial_t^2 - \gamma\partial_t) &= \text{Det}(i\partial_t)\text{Det}(i\partial_t + i\gamma) = \exp[\text{Tr} \log(i\partial_t) + \text{Tr} \log(i\partial_t + i\gamma)] \\ &= \exp\left[(t_b - t_a)\frac{\gamma}{2}\right], \end{aligned} \quad (18.254)$$

and thus

$$P_0(0 t_b | 0 t_a) \propto \exp\left[-(t_b - t_a)\frac{\gamma}{2}\right]. \quad (18.255)$$

This corresponds to an energy $\gamma/2$, and an ordering $-i\gamma(\hat{p}_v v + v\hat{p}_v)/2$ in the Hamiltonian operator.

We now take the retardation of the time argument of \dot{x}^R into account. Specifically, we replace the term $\gamma y \dot{x}^R$ in (18.230) by the Drude form on the left-hand side (18.214) before going to the limit $\omega_D \rightarrow \infty$:

$$\gamma y \dot{x}^R(t) \rightarrow \int dt' y(t) \gamma_D^R(t-t') x(t'), \quad (18.256)$$

containing now explicitly the retarded Drude function (18.210) of the friction. Then the frequency integral in (18.251) becomes

$$\int_{-\infty}^{\infty} \frac{d\omega'}{2\pi} \log\left(\omega'^2 - \gamma \frac{\omega' \omega_D}{\omega' + i\omega_D}\right) = \int_{-\infty}^{\infty} \frac{d\omega}{2\pi} \left[-\log(\omega' + i\omega_D) + \log(\omega'^2 + i\omega' \omega_D - \gamma \omega_D)\right], \quad (18.257)$$

where we have omitted a vanishing integral over $\log \omega'$ on account of (18.253). We now decompose

$$\log(\omega'^2 + i\omega' \omega_D - \gamma \omega_D) = \log(\omega' + i\omega_1) + \log(\omega' + i\omega_2), \quad (18.258)$$

with

$$\omega_{1,2} = \frac{\omega_D}{2} \left(1 \pm \sqrt{1 - \frac{4\gamma}{\omega_D}}\right), \quad (18.259)$$

and use formula (2.541) to find

$$\int_{-\infty}^{\infty} \frac{d\omega}{2\pi} \left[-\log(\omega' + i\omega_D) + \log(\omega'^2 + i\omega' \omega_D - \gamma \omega_D)\right] = -\frac{\omega_D}{2} + \frac{\omega_1}{2} + \frac{\omega_2}{2} = 0. \quad (18.260)$$

The vanishing frequency integral implies that the retarded functional determinant is trivial:

$$\text{Det}(-\partial_t^2 - \gamma\partial_t^R) = \exp\left[\text{Tr} \log(-\partial_t^2 - \gamma\partial_t^R)\right] = 1, \quad (18.261)$$

instead of (18.254) obtained from the frequency integral without the Drude modification. With the determinant (18.261), the probability becomes a constant

$$P_0(0 t_b | 0 t_a) = \text{const.} \quad (18.262)$$

This shows that the retarded nature of the friction force has *subtracted* an energy $\gamma/2$ from the energy in (18.255). Since the ordinary path integral corresponds to a Hamiltonian operator with a symmetrized term $-i(\hat{p}_v v + v \hat{p}_v)/2$, the subtraction of $\gamma/2$ changes this term to $-i\gamma\hat{p}_v v$.

Note that the opposite case of an *advanced* velocity term \dot{x}^A in (18.250) would be approximated by a Drude function $\gamma_D^A(t)$ which looks just like $\gamma_D^R(t)$ in (18.212), but with *negative* ω_D . The right-hand side of (18.260) would then become 2γ rather than zero. The corresponding formula for the functional determinant is

$$\text{Det}(-\partial_t^2 - \gamma\partial_t^A) = \exp \left[\text{Tr} \log(-\partial_t^2 - \gamma\partial_t^A) \right] = \exp [(t_b - t_a)\gamma], \quad (18.263)$$

where $\gamma\partial_t^A$ stands for the advanced version of the functional matrix (18.256) in which ω_D is replaced by $-\omega_D$. Thus we would find

$$P_0(0 t_b | 0 t_a) \propto \exp [-(t_b - t_a)\gamma], \quad (18.264)$$

with an *additional* energy $\gamma/2$ with respect to the ordinary formula (18.255). This corresponds to the opposite (unphysical) operator order $-i\gamma v \hat{p}_v$ in \hat{H}_0 , which would violate the probability conservation of time evolution twice as much as the symmetric order.

The above formulas for the functional determinants can easily be extended to the slightly more general case where $V(x)$ is the potential of a harmonic oscillator $V(x) = M\omega_0^2 x^2/2$. Then the path integral (18.232) for the probability distribution becomes

$$P_0(x_b t_b | x_a t_a) = \mathcal{N} \int \mathcal{D}x(t) \exp \left\{ -\frac{1}{2w} \int_{t_a}^{t_b} dt [M\ddot{x} + M\gamma\dot{x}^R + \omega_0^2 x]^2 \right\}, \quad (18.265)$$

which we evaluate at $x_b = x_a = 0$, where it is given by the properly retarded expression

$$\begin{aligned} P_0(0 t_b | 0 t_a) &\propto \text{Det}^{-1}(-\partial_t^2 - \gamma\partial_t + \omega_0^2) \\ &\propto \exp \left[-(t_b - t_a) \int_{-\infty}^{\infty} \frac{d\omega'}{2\pi} \log(\omega'^2 - i\gamma\omega' - \omega_0^2) \right]. \end{aligned} \quad (18.266)$$

The logarithm can be decomposed into a sum $\log(\omega' + i\omega_1) + \log(\omega' + i\omega_2)$ with

$$\omega_{1,2} = \frac{\gamma}{2} \left(1 \pm \sqrt{1 - \frac{4\omega_0^2}{\gamma^2}} \right). \quad (18.267)$$

We now apply the analytically regularized formula (2.541) to obtain

$$\int_{-\infty}^{\infty} \frac{d\omega'}{2\pi} [\log(\omega' + i\omega_1) + \log(\omega' + i\omega_2)] = \frac{\omega_1}{2} + \frac{\omega_2}{2} = \gamma. \quad (18.268)$$

Both under- and overdamped motion yield the same result. This is one of the situations where our remarks after Eqs. (2.544) and (2.543) concerning the cancellation of oscillatory parts apply. For the functional determinant (18.266), the result is

$$\text{Det}(-\partial_t^2 - \gamma\partial_t - \omega_0^2) = \exp \left[\text{Tr} \log(-\partial_t^2 - \gamma\partial_t - \omega_0^2) \right] = \exp \left[(t_b - t_a) \frac{\gamma}{2} \right]. \quad (18.269)$$

Note that the result is independent of ω_0 . This can simply be understood by forming the derivative of the logarithm of the functional determinant in (18.254) with respect to ω_0^2 . Since $\log \text{Det} M = \text{Tr} \log M$, this yields the trace of the associated Green function:

$$\frac{\partial}{\partial \omega_0^2} \text{Tr} \log(-\partial_t^2 - \gamma \partial_t - \omega_0^2) = - \int dt (-\partial_t^2 - \gamma \partial_t - \omega_0^2)^{-1}(t, t). \quad (18.270)$$

In Fourier space, the right-hand side turns into the frequency integral

$$- \int \frac{d\omega'}{2\pi} \frac{1}{(\omega' + i\omega_1)(\omega' + i\omega_1)}. \quad (18.271)$$

Since the two poles lie below the contour of integration, we may close it in the upper half-plane and obtain zero. Closing it in the lower half plane would initially lead to two nonzero contributions from the residues of the two poles which, however, cancel each other.

The Green function (18.270) is causal, in contrast to the oscillator Green function in Section 3.3 whose left-hand pole lies in the upper half-plane (recall Fig. 3.3). Thus it carries a Heaviside function as a prefactor [recall Eq. (1.305) and the discussion of causality there]. The vanishing of the integral (18.270) may be interpreted as being caused by the Heaviside function (1.304).

The γ -dependence of (18.269) can be calculated likewise:

$$\frac{\partial}{\partial \gamma} \log \text{Det} \partial_t (-\partial_t^2 - \gamma \partial_t - \omega_0^2) = - \int dt [\partial_t (-\partial_t^2 - \gamma \partial_t - \omega_0^2)^{-1}](t, t). \quad (18.272)$$

We perform the trace in frequency space:

$$i \int \frac{d\omega'}{2\pi} \frac{\omega'}{(\omega' + i\omega_1)(\omega' + i\omega_1)}. \quad (18.273)$$

If we now close the contour of integration with an infinite semicircle in the upper half plane to obtain a vanishing integral from the residue theorem, we must subtract the integral over the semicircle $i \int d\omega'/2\pi\omega'$ and obtain $1/2$, in agreement with (18.269).

Formula (18.269) can be generalized further to time-dependent coefficients

$$\text{Det} [-\partial_t^2 - \gamma(t)\partial_t - \Omega^2(t)] = \exp \left\{ \text{Tr} \log [-\partial_t^2 - \gamma(t)\partial_t - \Omega^2(t)] \right\} = \exp \left[\int_{t_a}^{t_b} dt \frac{\gamma(t)}{2} \right]. \quad (18.274)$$

This follows from the factorization

$$\text{Det} [-\partial_t^2 - \gamma(t)\partial_t - \Omega^2(t)] = \text{Det} [\partial_t + \Omega_1(t)] \text{Det} [\partial_t + \Omega_2(t)], \quad (18.275)$$

with

$$\Omega_1(t) + \Omega_2(t) = \gamma(t), \quad \partial_t \Omega_2(t) + \Omega_1(t)\Omega_2(t) = \Omega^2(t), \quad (18.276)$$

and applying formula (3.134).

The probability obtained from the general path integral (18.232) without retardation of the velocity term is therefore

$$P_0(0 t_b | 0 t_a) \propto \exp \left[-(t_b - t_a) \frac{\gamma}{2} \right], \quad (18.277)$$

as in (18.255).

Let us now introduce retardation of the velocity term by using the ω' -dependent Drude expression (18.212) for the friction coefficient. First we consider again the harmonic path integral (18.265), for which (18.266) becomes

$$P_0(0 t_b | 0 t_a) \propto \exp \left\{ -(t_b - t_a) \int_{-\infty}^{\infty} \frac{d\omega'}{2\pi} \log \left[\omega'^2 - i\gamma_D^R(\omega')\omega' - \omega_0^2 \right] \right\}. \quad (18.278)$$

Rewriting the logarithm as $-\log(\omega' + i\omega_D) + \sum_{k=1}^3 \log(\omega' + i\omega_k)$ with

$$\omega_{1,2} = \frac{\gamma}{2} \left(1 \pm \sqrt{1 - \frac{4\omega_0^2}{\gamma^2}} \right), \quad \omega_3 = \omega_D - \gamma \quad (18.279)$$

[recall Eq. (3.454) in the equilibrium discussion of Section 3.15], we use again formula (2.541) to find

$$\int_{-\infty}^{\infty} \frac{d\omega'}{2\pi} \left[-\log(\omega' + i\omega_D) + \sum_{k=1}^3 \log(\omega' + i\omega_k) \right] = -\omega_D + \sum_{k=1}^3 \frac{\omega_k}{2} = 0. \quad (18.280)$$

Thus γ and ω_0 disappear from the functional determinant, and we remain with

$$P_0(0 t_b | 0 t_a) = \text{const.} \quad (18.281)$$

This implies a unit functional determinant [12]

$$\text{Det}(\partial_t^2 + i\gamma\partial_t^R + \omega_0^2) = 1, \quad (18.282)$$

in contrast to the unretarded determinant (18.269). The γ -independence of this can also be seen heuristically as in (18.270) by forming the derivative with respect to γ :

$$\frac{\partial}{\partial \gamma} \text{Det}(-\partial_t^2 - \gamma\partial_t^R - \omega_0^2) = - \int dt [\partial_t^R(\partial_t^2 - \gamma\partial_t - \omega_0^2)^{-1}(t, t)]. \quad (18.283)$$

Since the retarded derivative carries a Heaviside factor $\Theta(t - t')$ of (1.304), we find zero for $t = t'$.

The result 1/2 of the unretarded derivative in (18.272) can similarly be understood as a consequence of the average Heaviside function (1.313) at $t = t'$.

An advanced time derivative in the determinant (18.282) would, of course, have produced the result

$$\text{Det}(\partial_t^2 + i\gamma\partial_t^A + \omega_0^2) = \gamma. \quad (18.284)$$

By analogy with (18.275), the general retarded determinant is also independent of $\gamma(t)$ and $\Omega(t)$.

$$\text{Det} \left[-\partial_t^2 - \gamma(t) \partial_t^R - \Omega^2(t) \right] = 1. \quad (18.285)$$

In the advanced case, we would find similarly

$$\text{Det} \left[-\partial_t^2 - \gamma(t) \partial_t^A - \Omega^2(t) \right] = \exp \left[\int dt \gamma(t) \right]. \quad (18.286)$$

By comparing the functional determinants (18.269) and (18.282) we see that the retardation prescription can be avoided by a trivial additive change of the Lagrangian (18.235) to

$$L_e(x, \dot{x}) = \frac{1}{2w} [\ddot{x} + M\gamma\dot{x} + V'(x)]^2 - \frac{\gamma}{2}. \quad (18.287)$$

From this, the path integral can be calculated with the usual time slicing, and the result can be deduced directly from Ref. [8].

The Hamiltonian associated with this Lagrangian is only slightly modified with respect to the naive form (18.249):

$$H_0(p, p_v, x, v) = \frac{w}{2M^2} p_v^2 - i\gamma p_v v + ipv - \frac{\gamma}{2}. \quad (18.288)$$

The extra $\gamma/2$ ensures that the operator version of the Hamiltonian (18.239) has \hat{p}_v to the left of v .

18.9.3 Strong Damping

For $\gamma \gg V''(x)/M$, the dynamics is dominated by dissipation, and the Lagrangian (18.235) takes a more conventional form in which only x and \dot{x} appear:

$$L_e(x, \dot{x}) = \frac{1}{2w} [M\gamma\dot{x}^R + V'(x)]^2 = \frac{1}{4D} \left[\dot{x}^R + \frac{1}{M\gamma} V'(x) \right]^2, \quad (18.289)$$

where \dot{x}^R lies slightly *earlier* $V'(x(t))$. The probability distribution

$$P(x_b t_b | x_a t_a) = \mathcal{N} \int \mathcal{D}x \exp \left[- \int_{t_a}^{t_b} dt L_e(x, \dot{x}^R) \right] \quad (18.290)$$

looks like an ordinary Euclidean path integral for the density matrix of a particle of mass $M = 1/2D$. As such it obeys a differential equation of the Schrödinger type. Forgetting for a moment the subtleties of the retardation, we introduce an auxiliary momentum integration and go over to the canonical representation of (18.290):

$$P(x_b t_b | x_a t_a) = \int \mathcal{D}x \int \frac{\mathcal{D}p}{2\pi} \exp \left\{ \int_{t_a}^{t_b} dt \left[ip\dot{x} - 2D \frac{p^2}{2} + ip \frac{1}{M\gamma} V'(x) \right] \right\}. \quad (18.291)$$

This probability distribution satisfies therefore the Schrödinger type of equation

$$H(\hat{p}_b, x_b)P(x_b t_b | x_a t_a) = -\partial_{t_b} P(x_b t_b | x_a t_a), \quad (18.292)$$

with the Hamiltonian operator

$$H(\hat{p}, x) \equiv 2D \frac{\hat{p}^2}{2} - i\hat{p} \frac{1}{M\gamma} V'(x) = -D \partial_x \left[\partial_x + \frac{1}{DM\gamma} V'(x) \right]. \quad (18.293)$$

In order to conserve probability, the momentum operator has to stand to the left of the potential term. Only then does the integral over x_b of Eq. (18.292) vanish. Equation (18.292) is the overdamped Klein-Kramers equation, also called the *Smoluchowski equation*. It is a special case of ordinary Fokker-Planck equation.

Without the retardation on \dot{x} in (18.290), the path integral would give a symmetrized operator $-i[\hat{p}V'(x) + V'(x)\hat{p}]/2$ in \hat{H} . This follows from the fact that the coupling $(1/2DM\gamma)\dot{x}V'(x)$ looks precisely like the coupling of a particle to a magnetic field with a “vector potential” $A(x) = (1/2DM\gamma)V'(x)$ [see (10.171)].

Realizing this it is not difficult to account quite explicitly for the effect of retardation of the velocity in the path integral (18.289). Let us assume, for a moment, that w is very small. Then the path integral (18.290) without the retardation,

$$P_0(x_b t_b | x_a t_a) = \mathcal{N} \int \mathcal{D}x \exp \left\{ -\frac{1}{2w} \int_{t_a}^{t_b} dt [M\gamma \dot{x} + V'(x)]^2 \right\}, \quad (18.294)$$

can be performed in the Gaussian approximation resulting for $x_b = x_a = 0$ in the inverse functional determinant

$$P_0(0 t_b | 0 t_a) = \text{Det}^{-1} [\partial_t + V''(x)/M\gamma], \quad (18.295)$$

whose value is according to formula (3.134)

$$\text{Det} [\partial_t + V''(x)/M\gamma] = \exp \left[\int dt V''(x)/2M\gamma \right]. \quad (18.296)$$

The retarded version of this determinant is trivial:

$$\text{Det} [\partial_t^R + V''(x)/M\gamma] = 1, \quad (18.297)$$

as we learned from Eq. (18.285). The advanced version would be [compare (18.286)]

$$\text{Det} [\partial_t^A + V''(x)/M\gamma] = \exp \left[\int dt V''(x)/M\gamma \right]. \quad (18.298)$$

Although the determinants (18.296), (18.297), and (18.298) were discussed here only for a large time interval $t_b - t_a$, the formulas remain true for all time intervals, due to the trivial first-order nature of the differential operator. In a short time interval, however, the second derivative is approximately time-independent. For this reason the difference between ordinary and retarded path integrals (18.290) is

given by the difference between the functional determinants (18.296) and (18.297) not only if w is very small but for all w . Thus we can avoid the retardation of the velocity as in Eq. (18.287) by adding to the Lagrangian (18.289) a term containing the second derivative of the potential:

$$L_e(x, \dot{x}) = \frac{1}{4D} \left[\dot{x} + \frac{1}{M\gamma} V'(x) \right]^2 - \frac{1}{2M\gamma} V''(x). \quad (18.299)$$

From this, the path integral can be calculated with the same slicing as for the gauge-invariant coupling in Section 10.5:

$$P_0(x_b t_b | x_a t_a) = \mathcal{N} \int \mathcal{D}x(t) \exp \left[- \int_{t_a}^{t_b} dt \left\{ \frac{1}{4D} \left[\dot{x} + \frac{V'(x)}{M\gamma} \right]^2 - \frac{V''(x)}{2M\gamma} \right\} \right]. \quad (18.300)$$

As an example consider a harmonic potential $V(x) = M\omega_0^2 x^2/2$, where the Lagrangian (18.299) becomes

$$L_e(x, \dot{x}) = \frac{1}{4D} (\dot{x} + \kappa x)^2 - \frac{\kappa}{2}, \quad (18.301)$$

with the abbreviation $\kappa \equiv \omega_0^2/\gamma$. The equation of motion reads

$$-\ddot{x} + \kappa^2 x = 0, \quad (18.302)$$

and its solution connecting x_a, t_a with x_b, t_b is

$$x(t) = \frac{1}{e^{2\kappa t_a} - e^{2\kappa t_b}} \left[e^{\kappa(t+t_a)} x_a - e^{\kappa(-t+t_a+2\kappa t_b)} x_a - e^{\kappa(t+t_b)} x_b + e^{\kappa(-t+2t_a+t_b)} x_b \right]. \quad (18.303)$$

This has the total Euclidean action

$$\mathcal{A}_e = \frac{\kappa (e^{\kappa t_b} x_b - e^{\kappa t_a} x_a)^2}{2D (e^{2\kappa t_b} - e^{2\kappa t_a})} - \frac{\kappa}{2}. \quad (18.304)$$

The fluctuation determinant is from Eq. (2.171), after an appropriate substitution of variables,

$$F_\kappa(t_b - t_a) = \frac{1}{\sqrt{2\pi \sinh \kappa(t_b - t_a)}}. \quad (18.305)$$

The probability distribution is then given by

$$P(x_b t_b | x_a t_a) = F_\kappa(t_b - t_a) e^{-\mathcal{A}_e} = \frac{1}{\sqrt{2\pi \sigma^2(t_b - t_a)}} \exp \left\{ - \frac{[x_b - \bar{x}(t_b - t_a)]^2}{2\sigma^2(t_b - t_a)} \right\}, \quad (18.306)$$

where $\bar{x}(t)$, $\sigma^2(t)$ are the averages

$$\bar{x}(t) \equiv \langle x(t) \rangle = x_a e^{-\kappa t}, \quad \sigma^2(t) \equiv \langle [x(t) - \bar{x}(t)]^2 \rangle = \frac{D}{\kappa} (1 - e^{-2\kappa t}), \quad (18.307)$$

obtained from the integrals⁸

$$\bar{x}(t_b - t_a) \equiv \langle x(t_b - t_a) \rangle \equiv \int_{-\infty}^{\infty} x_b P(x_b t_b | x_a t_a), \quad (18.308)$$

$$\langle [x(t_b - t_a) - \bar{x}(t_b - t_a)]^2 \rangle \equiv \int_{-\infty}^{\infty} [x_b - \bar{x}(t_b - t_a)]^2 P(x_b t_b | x_a t_a). \quad (18.309)$$

The canonical momentum associated with the Lagrangian (18.301) is $p = (\dot{x} + \kappa x)/2D$ so that the Hamiltonian operator becomes, via the Euclidean Legendre transformation (2.340), and with the operator ordering fixed as discussed after Eq. (18.247):

$$\hat{H}(p, x) = D\hat{p}^2 + i\kappa\hat{p}x, \quad p \equiv -i\partial_x. \quad (18.310)$$

This is the same operator as in Eq. (18.293), and the Fokker-Planck equation (18.292) reads, for the harmonic potential:

$$(-D\partial_{x_b}^2 + \kappa\partial_{x_b}x_b) P(x_b t_b | x_a t_a) = -\partial_{t_b} P(x_b t_b | x_a t_a). \quad (18.311)$$

For $t_b \rightarrow t_a$, the probability distribution (18.306) starts out as a δ -function around the initial position x_a . In the limit of large $t_b - t_a$, it converges against the limiting distribution

$$\lim_{t_b \rightarrow \infty} P(x_b t_b | x_a t_a) = \sqrt{\frac{\kappa}{2\pi D}} \exp\left\{-\kappa \frac{x_b^2}{2D}\right\}. \quad (18.312)$$

Replacing κ again by $\omega_0^2/\gamma = V''(0)/M\gamma$, and D from (18.219), this becomes

$$\lim_{t_b \rightarrow \infty} P(x_b t_b | x_a t_a) = \sqrt{\frac{V''(0)}{2\pi k_B T}} \exp\left\{-\frac{1}{k_B T} V(x_b)\right\}. \quad (18.313)$$

Thus, the limiting distribution of (18.290) depends only on x_b . It is given by the Boltzmann factor associated with the potential $V(x)$, in which the particle moves. This result can be generalized to a large class of potentials.

An interesting related result can be derived by introducing an external source term $j_b x(t_b)$ into the Lagrangian (18.299). By repeated functional differentiation with respect to j_b we find that the expectation values

$$\langle x^n \rangle = \lim_{t_b \rightarrow \infty} \langle x^n(t_b) \rangle = \lim_{t_b \rightarrow \infty} \frac{\int \mathcal{D}x x^n(t_b) e^{-\int_{t_a}^{t_b} dt L_e(x, \dot{x}^R)}}{\int \mathcal{D}x e^{-\int_{t_a}^{t_b} dt L_e(x, \dot{x}^R)}} \quad (18.314)$$

have the large-time limit

$$\lim_{t_b \rightarrow \infty} \langle x^n(t_b) \rangle = \langle x^n \rangle = \frac{\int dx x^n e^{-V(x)/k_B T}}{\int dx e^{-V(x)/k_B T}}. \quad (18.315)$$

The generalization of this relation to quantum field theory forms the basis of *stochastic quantization* in Section 18.12.

⁸An alternative method for calculating such expectation values will be presented in Section 18.15.

18.10 Langevin Equations

Consider the forward–backward path integral (18.230) for high γT . Then the second exponent limits the fluctuations of y to satisfy $|y| \ll |x|$, and $K(t, t')$ will be assumed to take the Drude form (18.226), which becomes a δ -function for $\omega_D \rightarrow \infty$. Then we can expand

$$V\left(x + \frac{y}{2}\right) - V\left(x - \frac{y}{2}\right) \sim yV'(x) + \frac{y^3}{24}V'''(x) + \dots, \quad (18.316)$$

keeping only the first term. We further introduce an auxiliary quantity $\eta(t)$ by

$$\eta(t) \equiv M\ddot{x}(t) + M\gamma\dot{x}^R(t) + V'(x(t)). \quad (18.317)$$

With this, the exponential function in (18.230) becomes after a partial integration of the first term using the endpoint properties $y(t_b) = y(t_a) = 0$:

$$\exp\left\{-\frac{i}{\hbar}\int_{t_a}^{t_b} dt y\eta - \frac{w}{2\hbar^2}\int_{t_a}^{t_b} dt \int_{t_a}^{t_b} dt' y(t)K(t, t')y(t')\right\}. \quad (18.318)$$

The variable y can obviously be integrated out and we find a probability distribution

$$P[\eta] \propto \exp\left\{-\frac{1}{2w}\int_{t_a}^{t_b} dt \int_{t_a}^{t_b} dt' \eta(t)K^{-1}(t, t')\eta(t')\right\}, \quad (18.319)$$

where the fluctuation width w was given in (18.218), and $K^{-1}(t, t')$ denotes the inverse functional matrix of $K(t, t')$.

The defining equation (18.317) for $\eta(t)$ may be viewed as a *stochastic differential equation* to be solved for arbitrary initial positions $x(t_a) = x_a$ and velocities $\dot{x}(t_a) = v_a$. The differential equation is driven by a Gaussian random *noise* variable $\eta(t)$ with a correlation function

$$\langle \eta(t) \rangle_\eta = 0, \quad \langle \eta(t)\eta(t') \rangle_\eta = wK(t - t'), \quad (18.320)$$

where the expectation value of an arbitrary functional of $F[x]$ is defined by the path integral

$$\langle F[x] \rangle_\eta \equiv \mathcal{N} \int_{x(t_a)=x_a} \mathcal{D}x P[\eta] F[x]. \quad (18.321)$$

The normalization factor \mathcal{N} is fixed by the condition $\mathcal{N} \int \mathcal{D}\eta P[\eta] = 1$, so that $\langle 1 \rangle_\eta = 1$. In the sequel, this factor will always be absorbed in the measure $\mathcal{D}\eta$.

For each noise function $\eta(t)$, the solution of the differential equation yields a path $x_\eta(x_a, x_b, t_a)$ with a final position $x_b = x_\eta(x_a, x_b, t_b)$ and velocity $v_b = \dot{x}_\eta(x_a, x_b, t_b)$, all being functionals of $\eta(t)$. From this we can calculate the distribution $P(x_b v_b t_b | x_a v_a t_a)$ of the final x_b and v_b by summing over all paths resulting from the noise functions $\eta(t)$ with the probability distribution (18.319). The result is of course the same as the distribution (18.242) obtained previously from the canonical path integral.

It is useful to exhibit clearly the dependence on initial and final velocities by separating the stochastic differential equation (18.317) into two first-order equations

$$M\dot{v}(t) + M\gamma v^R(t) + V'(x(t)) = \eta(t), \quad (18.322)$$

$$\dot{x}(t) = v(t), \quad (18.323)$$

to be solved for initial values $x(t_a) = x_a$ and $\dot{x}(t_a) = v_a$. For a given noise function $\eta(t)$, the final positions and velocities have the probability distribution

$$P_\eta(x_b v_b t_b | x_a v_a t_a) = \delta(x_\eta(t) - x_b) \delta(\dot{x}_\eta(t) - v_b). \quad (18.324)$$

Given these distributions for all possible noise functions $\eta(t)$, we find the final probability distribution $P(x_b v_b t_b | x_a v_a t_a)$ from the path integral over all $\eta(t)$ calculated with the noise distribution (18.319). We shall write this in the form

$$P(x_b v_b t_b | x_a v_a t_a) = \langle P_\eta(x_b v_b t_b | x_a v_a t_a) \rangle_\eta. \quad (18.325)$$

Let us change of integration variable from $x(t)$ to $\eta(t)$. This produces a Jacobian

$$J[x] \equiv \text{Det}[\delta\eta(t)/\delta x(t')] = \det[M\partial_t^2 + M\gamma\partial_t^R + V''(x(t))]. \quad (18.326)$$

In Eq. (18.285) we have seen that due to the retardation of ∂_t^R , this Jacobian is unity. Hence we can rewrite the expectation value (18.321) as a functional integral

$$\langle F[x] \rangle_\eta \equiv \int \mathcal{D}\eta P[\eta] F[x] \Big|_{x(t_a)=x_a}. \quad (18.327)$$

From the probability distribution $P(x_b v_b t_b | x_a v_a t_a)$ we find the pure position probability $P(x_b t_b | x_a t_a)$ by integrating over all initial and final velocities as in Eq. (18.241). Thus we have shown that a solution of the forward-backward path integral at high temperature (18.232) can be obtained from a solution of the stochastic differential equations (18.317), or more specifically, from the pair of stochastic differential equations (18.322) and (18.323).

The stochastic differential equation (18.317) together with the correlation function (18.320) is called *semiclassical Langevin equation*. The fluctuation width w in (18.320) was given in (18.218). The attribute *semiclassical* emphasizes the truncation of the expansion (18.316) after the first term, which can be justified only for nearly harmonic potentials. For a discussion of the range of applicability of the truncation see the literature [14]. The untruncated path integral is equivalent to an operator form of the Langevin equation, the so-called *quantum Langevin equation* [15]. This equivalence will be discussed further in Subsection 18.19.

The physical interpretation of Eq. (18.320) goes as follows. For $T \rightarrow 0$ and $\hbar \rightarrow 0$ at $\hbar/T = \text{const}$, the random variable $\eta(t)$ does not fluctuate at all and (18.317) reduces to the classical equation of motion of a particle in a potential $V(x)$, with an additional friction term proportional to γ . For T and \hbar both finite, the

particle is shaken around its classical path by thermal and quantum fluctuations. At high temperatures (at fixed \hbar), $K(\omega')$ reduces to

$$\lim_{T \rightarrow \infty} K(\omega') \equiv 1. \quad (18.328)$$

Then $\eta(t)$ is an instantaneous random variable with zero average and a nonzero pair correlation function:

$$\langle \eta(t) \rangle_\eta = 0, \quad \langle \eta(t)\eta(t') \rangle_\eta = w \delta(t - t'), \quad (18.329)$$

All higher correlation functions vanish. A random variable with these characteristics is referred to as *white noise*. The stochastic differential equation (18.317) with the white noise (18.329) reduces to the *classical Langevin equation with inertia* [16].

In the opposite limit of small temperatures, $K(\omega')$ diverges like

$$K(\omega') \xrightarrow{T \rightarrow 0} \frac{\hbar|\omega'|}{2k_B T}, \quad (18.330)$$

so that $wK(\omega')$ has the finite limit

$$\lim_{T \rightarrow 0} wK(\omega') = M\gamma\hbar|\omega'|. \quad (18.331)$$

To find the Fourier transformation of this, we use the Fourier decomposition of the Heaviside function (1.306)

$$\Theta(\omega') = \frac{1}{2\pi} \int_{-\infty}^{\infty} dt e^{-i\omega't} \frac{i}{t + i\eta} \quad (18.332)$$

to form the antisymmetric combination

$$\begin{aligned} \Theta(\omega') - \Theta(-\omega') &= \frac{1}{2\pi} \int_{-\infty}^{\infty} dt e^{-i\omega't} \left(\frac{i}{t + i\eta} + \frac{i}{t - i\eta} \right) \\ &\equiv \frac{i}{\pi} \int_{-\infty}^{\infty} dt e^{-i\omega't} \frac{\mathcal{P}}{t}. \end{aligned} \quad (18.333)$$

A multiplication by ω' yields

$$\begin{aligned} |\omega'| = \omega'[\Theta(\omega') - \Theta(-\omega')] &= -\frac{1}{\pi} \int_{-\infty}^{\infty} dt \partial_t e^{-i\omega't} \frac{\mathcal{P}}{t} = \frac{1}{\pi} \int_{-\infty}^{\infty} dt e^{-i\omega't} \partial_t \frac{\mathcal{P}}{t} \\ &= -\frac{1}{\pi} \int_{-\infty}^{\infty} dt e^{-i\omega't} \frac{\mathcal{P}}{t^2}. \end{aligned} \quad (18.334)$$

By comparison with (18.331) we see that the pure quantum limit of $K(t - t')$ can be written as

$$wK(t - t') \stackrel{T=0}{=} -\frac{M\gamma\hbar}{\pi} \frac{\mathcal{P}}{(t - t')^2}. \quad (18.335)$$

Hence the quantum-mechanical motion in contact with a thermal reservoir looks just like a classical motion, but disturbed by a random source with temporally long-range correlations

$$\langle \eta(t)\eta(t') \rangle_\eta = -\frac{M\gamma\hbar}{\pi} \frac{\mathcal{P}}{(t-t')^2}. \quad (18.336)$$

The temporal range is found from the temporal average

$$\langle (\Delta t)^2 \rangle_t \equiv \int_{-\infty}^{\infty} d\Delta t (\Delta t)^2 K(\Delta t) = -\frac{\partial^2}{\partial \omega'^2} K(\omega') \Big|_{\omega'=0} = -\frac{1}{6} \left(\frac{\hbar}{k_B T} \right)^2. \quad (18.337)$$

Apart from the negative sign (which would be positive for Euclidean times), the random variable acquires more and more memory as the temperature decreases and the system moves deeper into the quantum regime. Note that no extra normalization factor is required to form the temporal average (18.337), due to the unit normalization of $K(t-t')$ in (18.224).

In the overdamped limit, the classical Langevin equation with inertia (18.317) reduced to the *overdamped Langevin equation*:

$$\dot{x}(t) = -V'(x(t))/M\gamma + \eta(t)/M\gamma. \quad (18.338)$$

At high temperature, the noise variable $\eta(t)$ has the correlation functions (18.329). Then the stochastic differential equation (18.338) is said to describe a *Wiener process*. The first term on the right-hand side $r_x(x(t)) \equiv -V'(x(t))/M\gamma$ is called the *drift* of the process.

The probability distribution of $x(t)$ resulting from this process is calculated as in Eqs. (18.325), (18.321) from the path integral

$$P(x_b t_b | x_a t_a) = \int \mathcal{D}\eta P[\eta] \delta(x_\eta(t) - x_b), \quad (18.339)$$

and $\mathcal{D}\eta$ is normalized so that $\int \mathcal{D}\eta P[\eta] = 1$.

A path integral representation closely related to this is obtained by using the identity

$$\int_{x(t_a)=x_a}^{x(t_b)=x_b} \mathcal{D}x \delta[\dot{x} - \eta] = \delta(x_\eta(t_b) - x_b), \quad (18.340)$$

which can easily be proved by time-slicing the Fourier representation of the δ -functional

$$\delta[\dot{x} - \eta] = \int \mathcal{D}p e^{i \int dt p(\dot{x} - \eta)} \quad (18.341)$$

and performing all the momentum integrals. This brings the path integral (18.339) to the form

$$P(x_b t_b | x_a t_a) = \int_{x(t_a)=x_a}^{x(t_b)=x_b} \mathcal{D}x \int \mathcal{D}\eta P[\eta] \delta[\dot{x} - \eta]. \quad (18.342)$$

For a harmonic potential $V(x) = M\omega_0^2 x^2/2$, where the overdamped Langevin equation reads

$$\dot{x}(t) = -\omega_0^2 x(t)/M\gamma + \eta(t)/M\gamma = -\kappa x(t)/M\gamma + \bar{\eta}(t), \quad (18.343)$$

where the noise variable $\bar{\eta}(t) \equiv \eta(t)/M\gamma$ has the correlation functions

$$\langle \bar{\eta}(t) \rangle = 0, \quad \langle \bar{\eta}(t)\bar{\eta}(t') \rangle_\eta = \frac{w}{M^2\gamma^2} \delta(t-t') = 2D\delta(t-t'), \quad (18.344)$$

the calculation of the stochastic path integral yields, of course, once more the probability (18.306).

18.11 Path Integral Solution of Klein-Kramers Equation

For a free particle at finite temperature, there exists another way of representing the solution (18.440). Consider the original path integral for the probability in Eq. (18.240) with the Hamiltonian (18.288). Let us introduce the thermal velocity $v_T \equiv \sqrt{k_B T/M}$ and write the action as [compare (2.340)]

$$\mathcal{A}_e = \int_{t_a}^{t_b} dt [-i(px + p_v \dot{v}) + H(p, p_v, v, x)], \quad (18.345)$$

with

$$H(p, p_v, v, x) = \gamma v_T^2 \left(p_v - i \frac{v}{2v_T^2} \right)^2 + \frac{\gamma}{4v_T^2} \left(v + 2i \frac{v_T^2}{\gamma} p \right)^2 + \frac{v_T^2}{\gamma} p^2 + \frac{\gamma}{2}. \quad (18.346)$$

In the path integral (18.240), we may integrate out $x(t)$, which converts the path integral over $p(t)$ into an ordinary integral, so that we obtain the integral representation

$$P(x_b v_b t_b | x_a v_a t_a) = \int \frac{dp}{2\pi} P(v_b t_b | v_a p_a)_p e^{ip(x_b - x_a) - v_T^2 p^2 (t_b - t_a)/\gamma}, \quad (18.347)$$

where

$$P_p(v_b t_b | v_a t_a) = \int \mathcal{D}v \int \frac{\mathcal{D}p_v}{2\pi} \exp \left\{ \int_{t_a}^{t_b} dt [ip_v \dot{v} - H_p(p_v, v)] \right\}, \quad (18.348)$$

with the p -dependent Hamiltonian governing p_v and v :

$$H_p(p_v, v) \equiv \gamma v_T^2 \left(p_v - i \frac{v}{2v_T^2} \right)^2 + \frac{\gamma}{4v_T^2} \left(v + 2i \frac{v_T^2}{\gamma} p \right)^2 - \frac{\gamma}{2}. \quad (18.349)$$

In the associated Hamiltonian operator, the shift of p_v by $-iv/2v_T^2$ can be removed by a similarity transformation to

$$\tilde{H}_p(p_v, v) \equiv e^{v^2/4v_T^2} \hat{H}_p e^{-v^2/4v_T^2} = \gamma v_T^2 p_v^2 + \frac{\gamma}{4v_T^2} \left(v + 2i \frac{v_T^2}{\gamma} p \right)^2 - \frac{\gamma}{2}. \quad (18.350)$$

Thus we can rewrite $P_p(v_b t_b | v_a t_a)$ as

$$P_p(v_b t_b | v_a t_a) = e^{-v_b^2/4v_T^2} \tilde{P}_p(v_b t_b | v_a t_a) e^{v_a^2/4v_T^2} \quad (18.351)$$

where $\tilde{P}_p(v_b t_b | v_a t_a)$ is the probability associated with the Hamiltonian $\tilde{H}_p(p_v, v)$. This describes a harmonic oscillator with frequency γ around the p -dependent center at $v_p = -2iv_T^2 p/\gamma$. If we denote the mass of this oscillator by $m = 1/2\gamma v_T^2$, we can immediately write down the wave eigenfunctions as $\psi_n(v - v_p)$ with $\psi(x)$ of Eq. (2.302). The energies are $n\gamma$. Thus we may express the probability distribution of x and v as a spectral representation

$$P(x_b v_b t_b | x_a v_a t_a) = e^{-(v_b^2 - v_a^2)/4v_T^2} \int \frac{dp}{2\pi} \sum_{n=0}^{\infty} \psi_n(v_b - v_p) \psi_n(v_a - v_p) e^{-n\gamma(t_b - t_a)} \\ \times e^{ip(x_b - x_a) - v_T^2 p^2 (t_b - t_a)/\gamma}, \quad (18.352)$$

where

$$\psi_n(v) = \frac{1}{(2^n n! \sqrt{\pi})^{1/2} (\sqrt{2} v_T)^{1/2}} e^{-v^2/4v_T^2} H_n(v/\sqrt{2} v_T). \quad (18.353)$$

In the limit of strong damping, only $n = 0$ contributes to the sum, and we find

$$P(x_b v_b t_b | x_a v_a t_a) = \frac{e^{-(v_b^2 - v_a^2)/4v_T^2}}{\sqrt{2\pi} v_T} \int \frac{dp}{2\pi} e^{-[(v_b - v_p)^2 + (v_a - v_p)^2]/4v_T^2} e^{ip(x_b - x_a) - v_T^2 p^2 (t_b - t_a)/\gamma}.$$

Integrating this over v_b leads to

$$P(x_b t_b | x_a v_a t_a) = \int \frac{dp}{2\pi} e^{ip(x_b - x_a - v_a/\gamma) - v_T^2 p^2 (t_b - t_a)/\gamma} = \frac{1}{\sqrt{4\pi v_T^2/\gamma}} e^{-\frac{\gamma(x_b - x_a - v_a/\gamma)^2}{4v_T^2(t_b - t_a)}}, \quad (18.354)$$

where we have neglected terms of order γ^{-2} in the exponent. A compact expression for the general solution will be derived in (18.440) by stochastic calculus.

18.12 Stochastic Quantization

In Eq. (18.314) we observed that the expectation value of powers of a classical variable x in a potential $V(x)$ can be recovered as a result of a path integral associated with the Lagrangian (18.299). From Eq. (18.339) we know that the path integral (18.314) can be replaced by the stochastic path integral:

$$\langle x^n \rangle = \lim_{s \rightarrow \infty} \langle x^n(s) \rangle = \lim_{s \rightarrow \infty} \int \mathcal{D}\eta x_\eta^n(s) P[\eta], \quad (18.355)$$

where

$$P[\eta] \equiv \int \mathcal{D}\eta e^{-(1/4k_B T) \int_{s_a}^s ds' \eta^2(s')}, \quad (18.356)$$

To simplify the equations, we have replaced the physical time by a rescaled parameter $s = t/M\gamma$.

Equivalently we may say that we obtain the expectation values (18.355) by solving the stochastic differential equation of the Wiener process

$$x'(s) = -V'(x) + \eta(s), \quad (18.357)$$

where $\eta(s)$ is a white noise with the pair correlation functions

$$\langle \eta(s) \rangle_T = 0, \quad \langle \eta(s)\eta(s') \rangle_T = 2k_B T \delta(s - s'), \quad (18.358)$$

and going to the large- s limit of the expectation values $\langle x^n(s) \rangle$.

This can easily be generalized to Euclidean quantum mechanics. Suppose we want to calculate the correlation functions (3.298)

$$\langle x(\tau_1)x(\tau_2)\cdots x(\tau_n) \rangle \equiv Z^{-1} \int \mathcal{D}x x(\tau_1)x(\tau_2)\cdots x(\tau_n) \exp\left(-\frac{1}{\hbar}\mathcal{A}_e\right). \quad (18.359)$$

We introduce an additional auxiliary time variable s and set up a stochastic differential equation

$$\partial_s x(\tau; s) = -\frac{\delta \mathcal{A}_e}{\delta x(\tau; s)} + \eta(\tau; s), \quad (18.360)$$

where $\eta(\tau; s)$ has correlation functions

$$\langle \eta(\tau; s) \rangle = 0, \quad \langle \eta(\tau; s)\eta(\tau'; s') \rangle = 2\hbar\delta(\tau - \tau')\delta(s - s'). \quad (18.361)$$

The role of the thermal fluctuation width $2k_B T$ in (18.358) is now played by $2\hbar$. The correlation functions (18.359) can now be calculated from the auxiliary correlation functions of $x(\tau, s)$ in the large- s limit:

$$\langle x(\tau_1)x(\tau_2)\cdots x(\tau_n) \rangle = \lim_{s \rightarrow \infty} \langle x(\tau_1, s)x(\tau_2, s)\cdots x(\tau_n, s) \rangle. \quad (18.362)$$

Due to the extra time variable of stochastic variable $x(\tau; s)$ with respect to (18.357), the probability distribution associated with the stochastic differential equation (18.379) is a functional $P[x_b(\tau), s_b; x_a(\tau), s_a]$ given by the functional generalization of the path integral (18.300):

$$P[x_b(\tau_b), s; x_a(\tau), s_a] = \mathcal{N} \int \mathcal{D}x(\tau; s) \times e^{-\int_{s_a}^{s_b} ds \left\{ \frac{1}{4\hbar} \int_{-\infty}^{\infty} d\tau [\partial_s x(\tau; s) + \frac{\delta}{\delta x(\tau; s)} \mathcal{A}_e] - \frac{1}{2\hbar} \frac{\delta^2}{\delta x(\tau; s)^2} \mathcal{A}_e \right\}}. \quad (18.363)$$

This satisfies the functional generalization of the Fokker-Planck equation (18.292):

$$H[\hat{p}(\tau), x(\tau)]P(x(\tau)s|x_a(\tau); s_a) = -\partial_s P(x(\tau)s|x_a(\tau); s_a), \quad (18.364)$$

with the Hamiltonian

$$H[\hat{p}(\tau), x(\tau)] = \int_{-\infty}^{\infty} d\tau \left[\hbar \hat{p}^2(\tau) - i\hat{p}(\tau) \frac{\delta}{\delta x(\tau)} \mathcal{A}_e \right], \quad (18.365)$$

where $\hat{p}(\tau) \equiv \delta/\delta x(\tau)$. We have dropped the subscript b of the final state, for brevity. Explicitly, the Fokker-Planck equation (18.364) reads

$$-\int_{-\infty}^{\infty} d\tau \frac{\hbar \delta}{\delta x(\tau)} \left[\frac{\hbar \delta}{\delta x(\tau)} + \frac{\delta \mathcal{A}_e}{\delta x(\tau)} \right] P[x(\tau), s; x_a(\tau), s_a] = -\hbar \partial_s P[x(\tau), s; x_a(\tau), s_a]. \quad (18.366)$$

For $s \rightarrow \infty$, the distribution becomes independent of the initial path $x_a(\tau)$, and has the limit [compare (18.314)]

$$\lim_{s \rightarrow \infty} P[x(\tau), s; x_a(\tau), s_a] = \frac{e^{-\mathcal{A}_e[x]/\hbar}}{\int \mathcal{D}x(\tau) e^{-\mathcal{A}_e[x]/\hbar}}, \quad (18.367)$$

and the correlation functions (18.378) are given by the usual path integral, apart from the normalization which is here such that $\langle 1 \rangle = 1$.

As an example, consider a harmonic oscillator where Eq. (18.360) reads

$$\partial_s x(\tau; s) = -M(-\partial_\tau^2 + \omega^2)x(\tau; s) + \eta(\tau; s). \quad (18.368)$$

This is solved by

$$x(\tau; s) = \int_0^s ds' e^{-M(-\partial_\tau^2 + \omega^2)(s'-s)} \eta(\tau; s'). \quad (18.369)$$

The correlation function reads, therefore,

$$\langle x(\tau_1; s_1)x(\tau_2; s_2) \rangle = \int_0^{s_1} ds'_1 \int_0^{s_2} ds'_2 e^{M(-\partial_\tau^2 + \omega^2)(s'_1 + s'_2 - s_1 - s_2)} \langle \eta(\tau_1; s'_1) \eta(\tau_2; s'_2) \rangle. \quad (18.370)$$

Inserting (18.361), this becomes

$$\langle x(\tau_1; s_1)x(\tau_2; s_2) \rangle = \hbar \int_0^\infty ds \left[e^{-M(-\partial_\tau^2 + \omega^2)(s + |s_1 - s_2|)} - e^{-M(-\partial_\tau^2 + \omega^2)(s + s_1 + s_2)} \right], \quad (18.371)$$

or

$$\langle x(\tau_1; s_1)x(\tau_2; s_2) \rangle = \frac{\hbar}{M} \frac{1}{-\partial_\tau^2 + \omega^2} \left[e^{-M(-\partial_\tau^2 + \omega^2)|s_1 - s_2|} - e^{-M(-\partial_\tau^2 + \omega^2)(s_1 + s_2)} \right]. \quad (18.372)$$

For Dirichlet boundary conditions ($x_b = x_a = 0$) where operator $(-\partial_\tau^2 + \omega^2)$ has the sinusoidal eigenfunctions of the form (3.63) with eigenfrequencies (3.64), this has the spectral representation

$$\begin{aligned} \langle x(\tau_1; s_1)x(\tau_2; s_2) \rangle &= \frac{\hbar}{M} \frac{2}{t_b - t_a} \sum_{n=1}^{\infty} \frac{1}{\nu_n^2 + \omega^2} \sin \nu_n(\tau_1 - \tau_a) \sin \nu_n(\tau_2 - \tau_a) \\ &\times \left[e^{-M(\nu_n^2 + \omega^2)|s_1 - s_2|} - e^{-M(-\nu_n^2 + \omega^2)(s_1 + s_2)} \right]. \end{aligned} \quad (18.373)$$

For large s_1, s_2 , the second term can be omitted. If, in addition, $s_1 = s_2$, we obtain the imaginary-time correlation function [compare (3.69), (3.304), and (3.36)]:

$$\begin{aligned} \lim_{s_1=s_2 \rightarrow \infty} \langle x(\tau_1; s)x(\tau_2; s) \rangle &= \langle x(\tau_1)x(\tau_2) \rangle = \frac{\hbar}{M} \frac{1}{-\partial_\tau^2 + \omega^2}(\tau_1, \tau_2) \\ &= \frac{\hbar}{M} \frac{\sinh \omega(\tau_b - \tau_>) \sinh \omega(\tau_< - \tau_a)}{\omega \sinh \omega(\tau_b - \tau_a)}. \end{aligned} \quad (18.374)$$

We can use these results to calculate the time evolution amplitude according to an imaginary-time version of Eq. (3.318):

$$(\mathbf{x}_b \tau_b | \mathbf{x}_a \tau_a) = C(\mathbf{x}_b, \mathbf{x}_a) e^{-A_e(\mathbf{x}_b, \mathbf{x}_a; \tau_b - \tau_a)/\hbar} e^{-\int_{\tau_a}^{\tau_b} \frac{M}{2} d\tau' \langle L_{e,\text{fl}}(\mathbf{x}_b, \dot{\mathbf{x}}_b) \rangle / \hbar}, \quad (18.375)$$

where $A_e(\mathbf{x}_b, \mathbf{x}_a; \tau_b - \tau_a)$ is the Euclidean version of the classical action (4.87). If the Lagrangian has the standard form, then

$$\langle L_{e,\text{fl}}(\mathbf{x}_b, \dot{\mathbf{x}}_b) \rangle = \frac{M}{2} \langle \delta \dot{\mathbf{x}}_b^2 \rangle, \quad (18.376)$$

and we obtain the imaginary-time evolution amplitude in an expression like (3.318). The constant of integration is determined by solving the differential equation (3.319), and a similar equation for \mathbf{x}_a . From this we find as before that $C(\mathbf{x}_b, \mathbf{x}_a)$ is independent of \mathbf{x}_b and \mathbf{x}_a .

For the harmonic oscillator with Dirichlet boundary conditions we calculate from this

$$\frac{M}{2} \langle \delta \dot{\mathbf{x}}_b^2 \rangle = \frac{\hbar \omega}{2} D \coth \omega(\tau_b - \tau_a). \quad (18.377)$$

Integrating this over τ_b yields $\hbar(D/2) \log[2 \sinh \omega(\tau_b - \tau_a)]$, so that the second exponential in (18.375) reduces to the correct fluctuation factor in the D -dimensional imaginary-time amplitude [compare (2.411)].

The formalism can easily be carried over to real-time quantum mechanics. We replace $t \rightarrow -i\tau$ and $\mathcal{A}_e \rightarrow -i\mathcal{A}$, and find that the real-time correlation functions are obtained from the large- s limit

$$\langle x(t_1)x(t_2) \cdots x(t_n) \rangle = \lim_{s \rightarrow \infty} \langle x(t_1, s)x(t_2, s) \cdots x(t_n, s) \rangle, \quad (18.378)$$

where $x(t; s)$ satisfies the stochastic differential equation

$$\hbar \partial_s x(t; s) = i \frac{\delta \mathcal{A}}{\partial x(t; s)} + \eta(t; s), \quad (18.379)$$

where the noise $\eta(t; s)$ has the same correlation functions as in (18.361), if we replace τ by t . This procedure of calculating quantum-mechanical correlation functions is called *stochastic quantization* [17].

18.13 Stochastic Calculus

The relation between Langevin and Fokker-Planck equations is a major subject of the so-called *stochastic calculus*. Given a Langevin equation, the time order of the potential $V(x)$ with respect to \dot{x} and \ddot{x} is a matter of choice. Different choices form the basis of the *Itô* or the *Stratonovich calculus*. The retarded position which appears naturally in the derivation from the forward-backward path integral favors the use of the Itô calculus. A midpoint ordering as in the gauge-invariant path integrals in Section 10.5 corresponds to the Stratonovich calculus.

18.13.1 Kubo's stochastic Liouville equation

It is worthwhile to trace how the retarded operator order of the friction term enters the framework of stochastic calculus. Thus we assume that the stochastic differential equations (18.322) and (18.323) have been solved for a specific noise function $\eta(t)$ such that we know the probability distribution $P_\eta(x v t | x_a v_a t_a)$ in (18.324). Now we observe that the time dependence of this distribution is governed by a simple differential equation known as *Kubo's stochastic Liouville equation* [18], which is derived as follows [19]. A time derivative of (18.324) yields

$$\partial_t P_\eta(x v t | x_a v_a t_a) = \dot{x}_\eta(t) \delta'(x_\eta(t) - x) \delta(\dot{x}_\eta(t) - v) + \ddot{x}_\eta(t) \delta(x_\eta(t) - x) \delta'(\dot{x}_\eta(t) - v). \quad (18.380)$$

The derivatives of the δ -functions are initially with respect to the arguments $x_\eta(t)$ and $\dot{x}_\eta(t)$. These can, however, be expressed in terms of derivatives with respect to $-x$ and $-v$. However, since $\ddot{x}_\eta(t)$ depends on $\dot{x}_\eta(t)$ we have to be careful where to put the derivative $-\partial_v$. The general formula for such an operation may be expressed as follows: Given an arbitrary dynamical variable $z(t)$ which may be any local function (local in the temporal sense) of $x(t)$ and $\dot{x}(t)$, and whose derivative is some function of $z(t)$, i.e., $\dot{z}(t) = F(z(t))$, then

$$\frac{d}{dt} \delta(z(t) - z) = \dot{z}(t) \frac{\partial}{\partial z(t)} \delta(z(t) - z) = -\frac{\partial}{\partial z} [\dot{z}(t) \delta(z(t) - z)] = -\frac{\partial}{\partial z} [F(z) \delta(z(t) - z)]. \quad (18.381)$$

To prove this formula, we multiply each expression by an arbitrary smooth test function $g(z)$ and integrate over z . Each integral yields indeed the same result $\dot{g}(z(t)) = \dot{z}(t) g'(z(t)) = F(z) g'(z(t))$. Applying the identity (18.381) to (18.380), we obtain an equation for $P_\eta(x v t | x_a v_a t_a)$:

$$\partial_t P_\eta(x v t | x_a v_a t_a) = -[\partial_x \dot{x}_\eta(t) + \partial_v \ddot{x}_\eta(t)] P_\eta(x v t | x_a v_a t_a). \quad (18.382)$$

We now express $\ddot{x}_\eta(t)$ with the help of the Langevin equation (18.317) in terms of the friction force $-M\gamma\dot{x}_\eta(t)$, the force $-V'(x_\eta(t))$, and the noise $\eta(t)$. In the presence of the δ -function $\delta(\dot{x}_\eta(t) - v)$, the velocity $\dot{x}_\eta(t)$ can everywhere be replaced by v , and Eq. (18.382) becomes

$$\partial_t P_\eta(x v t | x_a v_a t_a) = -\left\{ v \partial_x + \frac{1}{M} [\eta(t) + f(x, v)] \right\} P_\eta(x v t | x_a v_a t_a), \quad (18.383)$$

where

$$f(x, v) \equiv -M\gamma v - V'(x) \quad (18.384)$$

is the sum of potential and friction forces. This is Kubo's stochastic Liouville equation which, together with the correlation function (18.218) of the noise variable and the prescription (18.325) of forming expectation values, determines the temporal behavior of the probability distribution $P(x v t | x_a v_a t_a)$.

18.13.2 From Kubo's to Fokker-Planck Equations

Let us calculate the expectation value of $P_\eta(x v t | x_a v_a t_a)$ with respect to noise fluctuations and show that $P(x v t | x_a v_a t_a)$ of Eq. (18.325) satisfies the Fokker-Planck equation with inertia (18.243). First we observe that in a Gaussian expectation value (18.321), the multiplication of a functional $F[\eta]$ by η produces the same result as the functional differentiation with respect to η with a subsequent functional multiplication by the correlation function $\langle \eta(t)\eta(t') \rangle$:

$$\langle \eta(t)F[\eta] \rangle_\eta = \int dt' \langle \eta(t)\eta(t') \rangle_\eta \left\langle \frac{\delta \eta(t)}{\delta \eta(t')} F[\eta] \right\rangle_\eta. \quad (18.385)$$

This follows from the fact that $\eta(t)$ can be obtained from a functional derivative of the Gaussian distribution in (18.321) as:

$$\eta(t) e^{-\frac{1}{2w} \int dt dt' \eta(t) K^{-1}(t, t') \eta(t')} = -w \int dt' K(t, t') \frac{\delta}{\delta \eta(t')} e^{-\frac{1}{2w} \int dt dt' \eta(t) K^{-1}(t, t') \eta(t')}. \quad (18.386)$$

Inside the functional integral (18.321) over $\eta(t)$, an integration by parts moves the functional derivative $-\delta/\delta\eta(t')$ in front of $F[\eta]$ with a sign change. The surface terms can be discarded since the integrand decrease exponentially fast for large noises $\eta(t)$. Thus we obtain indeed the useful formula (18.385).

With the goal of a Gaussian average (18.321) in mind, we can therefore replace Eq. (18.383) by

$$\partial_t P_\eta(x v t | x_a v_a t_a) = - \left\{ v \partial_x + \frac{1}{M} \partial_v \left[w \int dt' K(t, t') \frac{\delta}{\delta \eta(t')} + f(x, v) \right] \right\} P_\eta(x v t | x_a v_a t_a). \quad (18.387)$$

After this, we observe that

$$\frac{\delta}{\delta \eta(t')} \delta(x_\eta(t) - x) \delta(\dot{x}_\eta(t) - v) = - \left[\frac{\delta x_\eta(t)}{\delta \eta(t')} \partial_x + \frac{\delta \dot{x}_\eta(t)}{\delta \eta(t')} \partial_v \right] \delta(x_\eta(t) - x) \delta(\dot{x}_\eta(t) - v). \quad (18.388)$$

From the stochastic differential equation (18.317) we deduce the following behavior of the functional derivatives:

$$\frac{\delta \dot{x}_\eta(t)}{\delta \eta(t')} = \frac{1}{M} \delta(t-t') - \gamma \Theta(t-t') + \text{smooth function of } t-t', \quad (18.389)$$

$$\frac{\delta \dot{x}_\eta(t)}{\delta \eta(t')} = \frac{1}{M} \Theta(t-t') + \mathcal{O}(t-t'), \quad (18.390)$$

$$\frac{\delta x_\eta(t)}{\delta \eta(t')} = \mathcal{O}((t-t')^2). \quad (18.391)$$

Inserting (18.380) with (18.390) and (18.391) into (18.387), the functional derivatives (18.390) and (18.391) are multiplied by $K(t, t')$ and integrated over t' .

Consider now the regime of large temperatures. There the function $K(t, t')$ is narrowly peaked around $t = t'$, forming almost a δ -function [recall the unit normalization (18.328)]. We shall emphasize this by writing $K(t, t') \equiv \delta_\epsilon(t-t')$, with the subscript indicating the width ϵ of $K(t, t')$ which goes to zero like $\hbar/k_B T$ for large T [recall (18.337)]. In this limit, the contribution of the derivative (18.391) vanishes, whereas (18.390) contributes to (18.387) a term

$$\begin{aligned} & \int dt' K(t, t') \frac{\delta}{\delta \eta(t')} \delta(x_\eta(t) - x) \delta(\dot{x}_\eta(t) - v) \quad (18.392) \\ &= - \int dt' \delta_\epsilon(t-t') \frac{\delta \dot{x}_\eta(t)}{\delta \eta(t')} \partial_v \delta(x_\eta(t) - x) \delta(\dot{x}_\eta(t) - v) = - \frac{1}{2M} \partial_v \delta(x_\eta(t) - x) \delta(\dot{x}_\eta(t) - v). \end{aligned}$$

The factor $1/2$ on the right-hand side arises from the fact that the would-be δ -function $\delta_\epsilon(t-t')$ is symmetric in $t-t'$, so that its convolution with the Heaviside function $\Theta(t-t')$ is nonzero only over half the peak. Taking the noise average (18.325), we obtain from (18.387) the Fokker-Planck equation with inertia (18.243):

$$\partial_t P(x v t | x_a v_a t_a) = \left\{ -v \partial_x + \frac{1}{M} \partial_v \left[\frac{w}{2M} \partial_v - f(x, v) \right] \right\} P(x v t | x_a v_a t_a). \quad (18.393)$$

Note that the differential operators have precisely the same order as in Eq. (18.239) as a consequence of formula, here (18.381).

In the overdamped limit, the derivation of the Fokker-Planck equation becomes simple. Then we have to consider only the pure x -space distribution

$$P_\eta(x t | x_a t_a) = \int dv P_\eta(x v t | x_a v_a t_a) = \delta(x_\eta(t) - x), \quad (18.394)$$

whose time derivative is given by

$$\begin{aligned} \partial_t P_\eta(x t | x_a v_a t_a) &= -\partial_x \dot{x}_\eta(t) P_\eta(x t | x_a v_a t_a) \\ &= -\frac{1}{M\gamma} \partial_x [\eta(t) - V'(x)] P_\eta(x t | x_a v_a t_a). \end{aligned} \quad (18.395)$$

After treating the noise term $\eta(t)$ according to the rule (18.385),

$$\eta(t) \rightarrow w \int dt' \delta_\epsilon(t-t') \frac{\delta}{\delta \eta(t')}, \quad (18.396)$$

we use

$$\frac{\delta}{\delta\eta(t')} \delta(x_\eta(t) - x) = -\frac{\delta x_\eta(t)}{\delta\eta(t')} \delta(x_\eta(t) - x) \quad (18.397)$$

and

$$\begin{aligned} \frac{\delta \dot{x}_\eta(t)}{\delta\eta(t')} &= \frac{1}{M\gamma} \delta(t - t') + \text{smooth function of } t - t', \\ \frac{\delta x_\eta(t)}{\delta\eta(t')} &= \frac{1}{M\gamma} \Theta(t - t') + \mathcal{O}(t - t'), \end{aligned} \quad (18.398)$$

to find the overdamped Fokker-Planck equation (18.292):

$$\partial_t P(x t | x_a t_a) = \left[D \partial^2 + \frac{1}{M\gamma} V'(x) \right] P(x t | x_a t_a). \quad (18.399)$$

The distributions $P(x t | x_a t_a)$ and $P(x v t | x_a v_a t_a)$ develop from initial δ -function distributions $P(x t_a | x_a t_a) = \delta(x - x_a)$ and $P(x v t_a | x_a t_a) = \delta(x - x_a) \delta(v - v_a)$.

Let us multiply these δ -functions with arbitrary initial probabilities $P(x, t_a)$ and $P(x v, t_a)$ and integrate over x and v . Then we obtain the stochastic path integrals

$$P(x, t) = \int \mathcal{D}\eta e^{-(1/2w) \int dt dt' \eta(t) K^{-1}(t, t') \eta(t')} P(x_{a\eta}(t), t_a), \quad (18.400)$$

$$P(x v, t) = \int \mathcal{D}\eta e^{-(1/2w) \int dt dt' \eta(t) K^{-1}(t, t') \eta(t')} P(x_{a\eta}(t), v_{a\eta}(t), t), \quad (18.401)$$

where $x_{a\eta}$ and $v_{a\eta}$ are initial positions and velocities of paths which arrive at the final x and v following the equation of motion with a fixed noise $\eta(t)$:

$$x_{a\eta}(t) = x - \int_{t_a}^t dt' \dot{x}(t'), \quad v_{a\eta}(t) = v - \int_{t_a}^t dt' \dot{v}(t'). \quad (18.402)$$

At high temperatures, the overdamped equation can be written with (18.338) as

$$P(x, t) = \int \mathcal{D}\eta e^{-(1/2w) \int dt \eta^2(t)} P \left(x - \frac{1}{M\gamma} \int_{t_a}^t dt' [\eta(t') - V'(x(t'))], t \right). \quad (18.403)$$

The time evolution equation (18.399) follows from this by calculating for a short time increment ϵ :

$$\begin{aligned} P(x, t + \epsilon) &= \int \mathcal{D}\eta e^{-(1/2w) \int dt \eta^2(t)} \left\{ -\frac{\epsilon}{M\gamma} \int_t^{t+\epsilon} dt' [\eta(t') - V'(x(t'))] \partial_x \right. \\ &\quad \left. + \frac{1}{2M^2\gamma^2} \int_t^{t+\epsilon} dt' \int_t^{t+\epsilon} dt'' [\eta(t') - V'(x(t'))] [\eta(t'') - V'(x(t''))] \partial_x^2 + \dots \right\} \\ &\quad \times P \left(x - \frac{1}{M\gamma} \int_{t_a}^t dt' [\eta(t') - V'(x(t'))], t \right). \end{aligned} \quad (18.404)$$

We now use the correlation functions (18.329), ignore all powers higher than linear in ϵ , and find in the limit $\epsilon \rightarrow 0$ directly the equation (18.399).

18.13.3 Itô's Lemma

An important tool for dealing with stochastic variables is supplied by *Itô's lemma*. Let $x(t)$ be a stochastic variable following a Wiener process with a drift $r_x(x(t), t)$ which is supposed to be a smooth function of $x(t)$ and t [compare (18.338)], i.e., $\dot{x}(t)$ fluctuates harmonically with a white noise around its average $\langle \dot{x}(t) \rangle = r_x(x(t), t)$ according to a stochastic differential equation

$$\dot{x}(t) = \langle \dot{x}(t) \rangle + \eta(t) = r_x + \eta(t). \quad (18.405)$$

We shall omit the smooth dependence of r_x on its arguments since this will be irrelevant for the subsequent arguments. The white noise has zero average $\langle \eta(t) \rangle = 0$, and its only nonzero correlation function is

$$\langle \eta(t)\eta(t') \rangle = \sigma^2 \delta(t - t'). \quad (18.406)$$

The value of $x(t)$ at a slightly later time $t + \epsilon$ is $x(t + \epsilon) = x(t) + \Delta x(t)$, where

$$\Delta x(t) \equiv \int_t^{t+\epsilon} dt' \dot{x}(t') = \epsilon r_x + \int_t^{t+\epsilon} dt' \eta(t'). \quad (18.407)$$

Consider now an arbitrary function $f(x(t))$. Its value at the time $t + \epsilon$ has the Taylor expansion

$$\begin{aligned} f(x(t + \epsilon)) &= f(x(t)) + f'(x(t))\Delta x(t) \\ &\quad + \frac{1}{2}f''(x(t))[\Delta x(t)]^2 + \frac{1}{3!}f^{(3)}[\Delta x(t)]^3 + \dots \end{aligned} \quad (18.408)$$

The linear term in $\Delta x(t)$ on the right-hand side of (18.408) has the average

$$\langle \Delta x(t) \rangle = \int_t^{t+\epsilon} dt' \langle \dot{x}(t') + \eta(t') \rangle = \int_t^{t+\epsilon} dt' \langle \dot{x}(t') \rangle \approx \epsilon r_x, \quad (18.409)$$

where we have omitted the arguments $x(t)$ and t of $r_x(x(t), t)$, since the variation of $r_x(x(t), t)$ in the small interval $(t, t + \epsilon)$ can be neglected to lowest order in ϵ .

The average of the quadratic term $\langle [\Delta x(t)]^2 \rangle$ is

$$\begin{aligned} \langle [\Delta x(t)]^2 \rangle &= \int_t^{t+\epsilon} dt_1 \int_t^{t+\epsilon} dt_2 \langle [\langle \dot{x}(t_1) \rangle + \eta(t_1)] [\langle \dot{x}(t_2) \rangle + \eta(t_2)] \rangle \\ &\approx \epsilon^2 r_x^2 + \langle \eta(t_1)\eta(t_2) \rangle. \end{aligned}$$

The second term is of the order ϵ due to the δ -function in the correlation function (18.406). Thus we find

$$\langle [\Delta x(t)]^2 \rangle = \epsilon \sigma^2 + \mathcal{O}(\epsilon^2). \quad (18.410)$$

The average of the cubic term $\langle [\Delta x(t)]^3 \rangle$ is given by the integral

$$\begin{aligned} &\int_t^{t+\epsilon} dt_1 \int_t^{t+\epsilon} dt_2 \int_t^{t+\epsilon} dt_3 \langle [\langle \dot{x}(t_1) \rangle + \eta(t_1)] [\langle \dot{x}(t_2) \rangle + \eta(t_2)] [\langle \dot{x}(t_3) \rangle + \eta(t_3)] \rangle \\ &= \int_t^{t+\epsilon} dt_1 \int_t^{t+\epsilon} dt_2 \int_t^{t+\epsilon} dt_3 \left[\langle \dot{x}(t_1) \rangle \langle \dot{x}(t_2) \rangle \langle \dot{x}(t_3) \rangle + \langle \dot{x}(t_1) \rangle \langle \eta(t_2) \eta(t_3) \rangle \right. \\ &\quad \left. + \langle \dot{x}(t_2) \rangle \langle \eta(t_1) \eta(t_3) \rangle + \langle \dot{x}(t_3) \rangle \langle \eta(t_1) \eta(t_2) \rangle \right] \\ &= \epsilon^3 r_x^3 + 3\epsilon^2 r_x \sigma^2 = \mathcal{O}(\epsilon^2). \end{aligned} \quad (18.411)$$

The averages of the higher powers $[\Delta x(t)]^n$ are obviously at least of order $\epsilon^{n/2}$. Thus we find in the limit $\epsilon \rightarrow 0$ the simple formula

$$\langle \dot{f}(x(t)) \rangle = \langle f'(x(t)) \rangle \langle \dot{x}(t) \rangle + \frac{\sigma^2}{2} \langle f''(x(t)) \rangle. \quad (18.412)$$

Note that in a time-sliced formulation, $f(x(t))\dot{x}(t)$ has the form $f(x_n)(x_{n+1} - x_n)/\epsilon$, with independently fluctuating x_n and x_{n+1} , so that we may treat x_n and $(x_{n+1} - x_n)/\epsilon$ as independent fluctuating variables. In the continuum limit $x(t)$ and $\dot{x}(t)$ become independent.

The important point noted by Itô is now that this result is not only true for the averages but also for the derivative $\dot{f}(x(t))$ itself, i.e., $f(x(t))$ obeys the stochastic differential equation

$$\dot{f}(x(t)) = f'(x(t)) \dot{x}(t) + \frac{\sigma^2}{2} f''(x(t)), \quad (18.413)$$

which is known as Itô's lemma.

In order to prove this we must show that the omitted fluctuations in the higher powers $[\Delta x(t)]^n$ for $n \geq 2$ are of higher order in ϵ than the leading fluctuation of $\Delta x(t)$ which is of order ϵ . Indeed, let us denote the fluctuating part of $[\Delta x(t)]^n$ by $z_n(t)$. For $n = 1, 2$, these are

$$z_1(t) = \int_t^{t+\epsilon} dt \eta(t), \quad z_2(t) \equiv [z_{2,1}(t) + z_{2,2}(t)], \quad (18.414)$$

where the two parts of $z_2(t)$ are

$$z_{2,1}(t) = 2 \int_t^{t+\epsilon} dt_1 \langle \dot{x}(t_1) \rangle z_1(t) \approx 2\epsilon r_x z_1(t), \quad z_{2,2}(t) = [z_1(t)]^2. \quad (18.415)$$

The fluctuations of $z_{2,1}(t)$ are smaller than the leading ones of $z_1(t)$ by a factor ϵ . They can therefore be ignored in the limit $\epsilon \rightarrow 0$.

The size of the fluctuations $z_{2,2}(t)$ are estimated by calculating its variance $\langle [z_{2,2}(t)]^2 \rangle - \langle z_{2,2}(t) \rangle^2$. The first of the two expectation values is

$$\langle [z_{2,2}(t)]^2 \rangle = \int_t^{t+\epsilon} dt_1 \int_t^{t+\epsilon} dt_2 \int_t^{t+\epsilon} dt_3 \int_t^{t+\epsilon} dt_4 \langle \eta(t_1)\eta(t_2)\eta(t_3)\eta(t_4) \rangle. \quad (18.416)$$

According to Wick's rule (3.305) for harmonic fluctuations, the expectation value on the right-hand side is equal to the sum of three pair contractions

$$\langle \eta(t_1)\eta(t_2) \rangle \langle \eta(t_3)\eta(t_4) \rangle + \langle \eta(t_1)\eta(t_3) \rangle \langle \eta(t_2)\eta(t_4) \rangle + \langle \eta(t_1)\eta(t_4) \rangle \langle \eta(t_2)\eta(t_3) \rangle. \quad (18.417)$$

Inserting (18.406) and performing the integrals yields

$$\langle [z_{2,2}(t)]^2 \rangle = 3\epsilon^2 \sigma^4. \quad (18.418)$$

The second term in the variance of $z_{2,2}(t)$ is

$$\langle z_{2,2}(t) \rangle^2 = \langle z_1^2(t) \rangle^2 = \left[\int_t^{t+\epsilon} dt_1 \int_t^{t+\epsilon} dt_2 \langle \eta(t_1) \eta(t_2) \rangle \right]^2 = \epsilon^2 \sigma^4. \quad (18.419)$$

Hence we obtain for the variance of $z_{2,2}(t)$:

$$\langle [z_{2,2}(t)]^2 \rangle - \langle z_{2,2}(t) \rangle^2 = 2\sigma^4 \epsilon^2. \quad (18.420)$$

This must be compared with the variance of the leading fluctuations $z_1(t)$ in (18.413):

$$\langle [z_1(t)]^2 \rangle - \langle z_1(t) \rangle^2 = \int_t^{t+\epsilon} dt_1 \int_t^{t+\epsilon} dt_2 \langle \eta(t_1) \eta(t_2) \rangle = \epsilon \sigma^2, \quad (18.421)$$

which implies that $z_1(t)$ is of the order of $\sigma\sqrt{\epsilon}$. Thus the fluctuating part of $[\Delta x(t)]^2$ is by a factor $\sqrt{\epsilon}$ smaller than that of $\Delta x(t)$, so that it can be ignored in the continuum limit $\epsilon \rightarrow 0$.

Thus we have proved that not only the expectation value $\langle [\Delta x(t)]^2 \rangle$ becomes equal to $\epsilon \sigma^2$ as stated in Eq. (18.410), but also the fluctuating quantity $[\Delta x(t)]^2$ itself:

$$[\Delta x(t)]^2 = \epsilon \sigma^2 + \mathcal{O}(\epsilon^2). \quad (18.422)$$

In a similar way we can derive the estimates $[\Delta x(t)]^n = \mathcal{O}((\sigma\sqrt{\epsilon})^n)$ for all higher fluctuations $z_n(t)$ in the Taylor expansion (18.408). These can all be neglected compared to $z_1(t)$, thus proving Itô's lemma (18.413).

For an exponential function, Itô's lemma yields

$$\frac{d}{dt} e^{Px} = \left(P\dot{x} + \frac{\sigma^2 P^2}{2} \right) e^{Px}. \quad (18.423)$$

This can be integrated to

$$e^{Px} = e^{\int_0^t dt' P\dot{x}} e^{P^2 \sigma^2 t/2}. \quad (18.424)$$

The expectation value of this can also be formulated as a rule for calculating the expectation value of an exponential of an integral over a Gaussian noise variable with zero average:

$$\left\langle e^{P \int_0^t dt' \eta(t')} \right\rangle = e^{P^2 \int_0^t dt' \int_0^t dt'' \langle \eta(t') \eta(t'') \rangle} = e^{P^2 \sigma^2 t/2}. \quad (18.425)$$

This rule can also be derived directly from Wick's rule (3.310). The right-hand side corresponds to the *Debye-Waller factor* introduced in solid-state physics to describe the reduction of the intensities of Bragg peaks by thermal fluctuations of the atomic positions [see Eq. (3.311)].

There is a simple mnemonic way of formalizing this derivation of Eq. (18.413) in a sloppy differential notation. We expand

$$f(x(t+dt)) = f(x(t) + \dot{x}dt) = f(x(t)) + f'(x(t))\dot{x}(t)dt + \frac{1}{2}f''(x(t))\dot{x}^2(t)dt^2 + \dots, \quad (18.426)$$

and insert in the higher-order expansion terms $\dot{x} = \langle \dot{x} \rangle + \eta(t)$ where $\langle \eta(t) \rangle = 0$ and the expectation

$$\langle \eta^2(t) \rangle dt = \sigma^2, \quad (18.427)$$

which expresses infinitesimally the correct equation

$$\int_t^{t+\epsilon} dt' \langle \eta(t')\eta(t) \rangle = \int_t^{t+\epsilon} dt' \sigma^2 \delta(t' - t) = \sigma^2. \quad (18.428)$$

The variable $\dot{x}^2(t)dt^2$ has an expectation value $\sigma^2 dt$ and a variance $\langle [\dot{x}^2(t)dt^2]^2 - \langle \dot{x}^2(t)dt^2 \rangle^2 \rangle = 2\sigma^2 dt^2$, so that $\dot{x}^2(t)dt^2$ in (18.426) can be replaced as follows:

$$\dot{x}^2(t)dt^2 \rightarrow \sigma^2 dt/2. \quad (18.429)$$

A corresponding estimate holds for all higher powers:

$$z_n \approx \mathcal{O}((\sigma\sqrt{\epsilon})^n). \quad (18.430)$$

or

$$\dot{x}^n(t)dt^n \approx \mathcal{O}((\sigma\sqrt{dt})^n). \quad (18.431)$$

These can all be omitted in the expansion (18.426), thus leading back to Itô's rule (18.412).

It must be realized that Itô's lemma is valid only in the limit $\epsilon \rightarrow 0$. For a discrete time axis with small but finite time intervals $\Delta t = \epsilon$, the fluctuations of $z_n(t)$ cannot strictly be ignored but are only suppressed by a small factor $\sigma\sqrt{\Delta T}$. The discrete version of Itô's lemma expands the fluctuating difference $\Delta f(x(t_n)) \equiv f(x(t_{n+1})) - f(x(t_n))$ as follows:

$$\frac{\Delta f(x(t_n))}{\Delta t} = f'(x(t_n))\frac{\Delta x(t_n)}{\Delta t} + \frac{\sigma^2}{2}f''(x(t_n)) + \mathcal{O}(\sigma\sqrt{\Delta t}). \quad (18.432)$$

18.14 Solving the Langevin Equation

In Eq. (18.306) we have found the probability distribution for the motion of a particle with large dissipation by solving the path integral (18.300) for the harmonic oscillator potential $V(x) = \omega_0^2 x^2/2$. For completeness, let us calculate the same result within stochastic calculus. The stochastic differential equation associated with the Lagrangian (18.301) is

$$\dot{x}(t) = -\kappa x(t) + \bar{\eta}(t), \quad (18.433)$$

where

$$\langle \bar{\eta}(t) \rangle_{\eta}, \quad \langle \bar{\eta}(t) \bar{\eta}(t') \rangle_{\eta} = 2D \delta(t - t'). \quad (18.434)$$

This equation is solved by

$$x(t) = x_0 e^{-\kappa t} + \int_0^t dt_1 e^{-\kappa(t-t_1)} \bar{\eta}(t_1), \quad (18.435)$$

so that we obtain $\langle x(t) \rangle_{\eta} = x_0 e^{-\gamma t}$ and

$$\begin{aligned} \langle x(t)x(t') \rangle_{\eta} &= x_0^2 e^{-\kappa(t+t')} + 2D \int_0^t dt_1 e^{-\kappa(t-t_1)} \int_0^{t'} dt_2 e^{-(t'-t_2)} \delta(t_1 - t_2) \\ &= x_0^2 e^{-\kappa(t+t')} + \kappa^{-1} D \left(e^{-\kappa|t-t'|} - e^{-\kappa(t+t')} \right), \end{aligned} \quad (18.436)$$

and the mean-square deviation

$$\langle [x(t) - \langle x(t) \rangle]_{\eta}^2 \rangle_{\eta} = \kappa^{-1} D \left(1 - e^{-2\kappa t} \right). \quad (18.437)$$

From these expectation values we recover immediately the previous distribution function (18.306).

This result can easily be generalized to a D -component Langevin equation

$$\dot{\mathbf{x}}(t) = -\boldsymbol{\kappa} \mathbf{x}(t) + \bar{\boldsymbol{\eta}}(t), \quad (18.438)$$

where $\boldsymbol{\kappa}$ is a matrix, and $\bar{\boldsymbol{\eta}}(t)$ a noise vector. Its correlation functions may be expressed in terms of a diffusion matrix \mathbf{D} as

$$\langle \bar{\boldsymbol{\eta}}(t) \rangle = 0, \quad \langle \bar{\boldsymbol{\eta}}(t) \bar{\boldsymbol{\eta}}^T(t') \rangle_{\eta} = 2\mathbf{D} \delta(t - t'), \quad (18.439)$$

to be compared with the one-dimensional expressions (18.329).

Then the probability (18.306) becomes

$$\begin{aligned} P(\mathbf{x}_b t_b | \mathbf{x}_a t_a) &= \frac{1}{\sqrt{2\pi}^D} \frac{1}{\sqrt{\det [\sigma^2(t_b - t_a)]}^D} \\ &\times \exp \left\{ -\frac{1}{2} [x_b - \bar{x}(t_b - t_a)]^i [\sigma_{ij}^2(t_b - t_a)]^{-1} [x_b - \bar{x}(t_b - t_a)]^j \right\}, \end{aligned} \quad (18.440)$$

where

$$\bar{\mathbf{x}}(t) = e^{-\boldsymbol{\kappa} t} \mathbf{x}_a, \quad (18.441)$$

and

$$\sigma_{ij}^2(t) \equiv \langle [x(t) - \bar{x}(t)]^i [x(t) - \bar{x}(t)]^j \rangle_{\eta}. \quad (18.442)$$

The probability (18.440) solves the Fokker-Planck equation (18.245)

$$\partial_t P(\mathbf{x} t | t_a \mathbf{x}_a) = (-\kappa_{ij} \partial_i x_j + D_{ij} \partial_i \partial_j) P(\mathbf{x} t | t_a \mathbf{x}_a). \quad (18.443)$$

The D -component result (18.440) allows us to solve the Langevin equation with inertia in Eq. (18.317). We simply rewrite the equivalent pair of equations (18.322) and (18.323) in the matrix form (18.438) with $x_1 = x$ and $x_2 = v$, and identify

$$\boldsymbol{\kappa} = \begin{pmatrix} 0 & -1 \\ \omega_0^2 & \gamma \end{pmatrix}, \quad \bar{\boldsymbol{\eta}}(t) = \frac{1}{M} \begin{pmatrix} 0 \\ \eta(t) \end{pmatrix}, \quad (18.444)$$

so that the diffusion matrix takes the form (18.246).

The eigenvalues of the nonhermitian matrix $\boldsymbol{\kappa}$ in (18.441) are $\kappa_{1,2} = \frac{1}{2}(\gamma \pm \sqrt{\gamma^2 - 4\omega_0^2})$. The associated eigenvectors $\mathbf{u}^{(1,2)}$ satisfying $\boldsymbol{\kappa}\mathbf{u}^{(1,2)} = \kappa_{1,2}\mathbf{u}^{(1,2)}$ are $(-1, \kappa_1)$ and $(1, -\kappa_2)$, respectively, while those to the left satisfying $\mathbf{v}^{(1,2)}\boldsymbol{\kappa} = \kappa_{(1,2)}\mathbf{v}^{(1,2)}$ are $(\kappa_2, 1)/(\kappa_1 - \kappa_2)$ and $(\kappa_1, 1)/(\kappa_1 - \kappa_2)$, respectively. The two sets of eigenvectors are mutually orthonormal and complete: $\mathbf{u}^{(i)} \cdot \mathbf{v}^{(j)} = \delta^{ij}$, $\sum_k v_i^{(k)} u_j^{(k)} = \delta_{ij}$. The matrix $\boldsymbol{\kappa}$ has then the spectral representation $\kappa_{ij} = \sum_k \kappa_k u_i^{(k)} v_j^{(k)}$, and an exponential $(e^{-\boldsymbol{\kappa}t})_{ij} = \sum_k e^{-\kappa_k t} u_i^{(k)} v_j^{(k)}$, which reads explicitly

$$e^{-\boldsymbol{\kappa}t} = \frac{1}{\kappa_1 - \kappa_2} \begin{pmatrix} \kappa_1 e^{-\kappa_2 t} - \kappa_2 e^{-\kappa_1 t} & e^{-\kappa_2 t} - e^{-\kappa_1 t} \\ \omega_0^2 (e^{-\kappa_1 t} - e^{-\kappa_2 t}) & \kappa_1 e^{-\kappa_1 t} - \kappa_2 e^{-\kappa_2 t} \end{pmatrix}. \quad (18.445)$$

The inverse matrix $[\sigma_{ij}^2(t_b - t_a)]^{-1}$ is given by

$$[\sigma_{ij}^2(t)]^{-1} = [\det \sigma_{ij}^2(t)]^{-1} \begin{pmatrix} \sigma_{vv}^2(t) & -\sigma_{xv}^2(t) \\ -\sigma_{xv}^2(t) & \sigma_{xx}^2(t) \end{pmatrix} \quad (18.446)$$

where the matrix elements $\sigma_{ij}^2(t_b - t_a)$ are calculated from the expectation values (18.442). This is done by expressing the solution of (18.438) as in (18.435) in the form

$$\mathbf{x}(t) = e^{-\boldsymbol{\kappa}t} \mathbf{x}_a + \int_{t_a}^t dt \bar{\boldsymbol{\eta}}(t), \quad (18.447)$$

and using the correlation functions (18.439) to find

$$\begin{aligned} \sigma_{xx}^2(t) &= \frac{\gamma^2 D}{(\kappa_1 - \kappa_2)^2} \left[\frac{1}{\kappa_1} (1 - e^{-2\kappa_1 t}) + \frac{1}{\kappa_2} (1 - e^{-2\kappa_2 t}) - \frac{4}{\kappa_1 + \kappa_2} (1 - e^{-\kappa_1 + \kappa_2} t) \right], \\ \sigma_{xv}^2(t) &= \frac{\gamma^2 D}{(\kappa_1 - \kappa_2)^2} (e^{-\kappa_1 t} - e^{-\kappa_2 t})^2, \\ \sigma_{vv}^2(t) &= \frac{\gamma^2 D}{(\kappa_1 - \kappa_2)^2} \left[\kappa_1 (1 - e^{-2\kappa_1 t}) + \kappa_2 (1 - e^{-2\kappa_2 t}) - \frac{4}{\kappa_1^{-1} + \kappa_2^{-1}} (1 - e^{-\kappa_1 + \kappa_2} t) \right]. \end{aligned} \quad (18.448)$$

After a long time, these converge to

$$\sigma_{xx}^2(t) \rightarrow \frac{\gamma D}{\kappa_1 \kappa_2} = \frac{\gamma D}{\omega_0^2}, \quad \sigma_{xv}^2(t) \rightarrow 0, \quad \sigma_{vv}^2(t) \rightarrow \gamma D, \quad (18.449)$$

so that the determinant $\det \sigma_{ij}^2(t)$ becomes $\gamma^2 D^2 / \omega_0^2$, and the distribution (18.440) turns into the Boltzmann distribution

$$\lim_{t_b \rightarrow \infty} P(x_b v_b t_b | x_a v_a t_a) = \frac{\omega_0}{2\pi\gamma D} e^{-(v_b^2 + \omega_0^2 x_b^2)/2\gamma D} = \frac{M\omega_0}{2\pi k_B T} e^{-M(v_b^2 + \omega_0^2 x_b^2)/2k_B T}. \quad (18.450)$$

The velocity shows the well-known *Maxwell distribution*:

$$P(v_b) = \frac{1}{\sqrt{2\pi\gamma D}} e^{-v_b^2/2\gamma D} = \frac{1}{\sqrt{2\pi k_B T/M}} e^{-Mv_b^2/2k_B T} = \frac{1}{\sqrt{2\pi}v_T} e^{-v_b^2/2v_T^2}, \quad (18.451)$$

which exhibits an average thermal velocity

$$v_T \equiv \sqrt{k_B T/M}. \quad (18.452)$$

If we integrate the two-dimensional result $P(x_b v_b t_b | x_a v_a t_a)$ over all final velocities, we obtain

$$P(x_b t_b | x_a v_a t_a) = \int dv_b P(x_b v_b t_b | x_a v_a t_a) = \frac{1}{\sqrt{2\pi\sigma_{xx}^2(t_b-t_a)}} \exp \left\{ -\frac{1}{2} \frac{[x_b - \bar{x}(t_b-t_a)]^2}{\sigma_{xx}^2(t_b-t_a)} \right\}. \quad (18.453)$$

Note that this depends on v_a via $\bar{x}(t_b-t_a) = x_a + \gamma^{-1}(1 - e^{-\gamma(t_b-t_a)})v_a$.

In the absence of an external potential, i.e. for $\omega_0 = 0$, the eigenvalues $\kappa_{1,2}$ are γ and 0, respectively, and the matrix $e^{-\kappa t}$ reduces to

$$e^{-\kappa t} = \begin{pmatrix} 1 & \gamma^{-1}(1 - e^{-\gamma t}) \\ 0 & e^{-\gamma t} \end{pmatrix}. \quad (18.454)$$

The matrix elements $\sigma_{ij}^2(t)$ are simply⁹

$$\sigma_{xx}^2(t) = \gamma^{-1} D (2\gamma t - 3 + 4e^{-\gamma t} - e^{-2\gamma t}), \quad \sigma_{xv}^2(t) = D(1 - e^{-\gamma t})^2, \quad \sigma_{vv}^2(t) = \gamma D(1 - e^{-2\gamma t}), \quad (18.455)$$

whose determinant is

$$\det \sigma_{ij}^2(t) = D^2 \left[2\gamma t(1 - e^{-2\gamma t}) + (1 - e^{-\gamma t})^2(-4 - 2e^{-\gamma t} + e^{-3\gamma t}) \right]. \quad (18.456)$$

In the large-time limit, these become

$$\sigma_{xx}^2(t) \rightarrow 2Dt, \quad \sigma_{xv}^2(t) \rightarrow D, \quad \sigma_{vv}^2(t) \rightarrow \gamma D, \quad \det \sigma_{ij}^2(t) \rightarrow 2\gamma t D^2. \quad (18.457)$$

The last result can, of course, be derived by integrating the pair of Langevin equations with inertia (18.322) and (18.323) for zero potential $V(x)$ successively. First the equation for $v(t)$ which reads $v(t) = v_0 e^{-\gamma t} + \int_0^t dt_1 e^{-\gamma(t-t_1)} \eta(t_1)/M$, and yields $\langle v(t)v(t') \rangle_\eta = v_0^2 e^{-\gamma(t+t')} + \gamma D (e^{-\gamma|t-t'|} - e^{-\gamma(t+t')})$, using the white noise correlation functions (18.329). The equations for $x(t)$ are obtained from these by integration over t .

⁹See Section 18.15 for an alternative method of calculating the expectation values (18.442).

18.15 Heisenberg Picture for Probability Evolution

It is possible to develop a Heisenberg operator description of the time dependence of thermal expectations. This goes by complete analogy with the development in Section 2.23 for the quantum-mechanical time evolution amplitude. Consider the thermal expectations of x and x^2 for a particle which sits at the initial time $t = t_a$ at x_a . They are given by the integrals

$$\langle x \rangle \equiv \int_{-\infty}^{\infty} dx_b x_b P(x_b t_b | x_a t_a), \quad (18.458)$$

$$\langle x^2 \rangle \equiv \int_{-\infty}^{\infty} dx_b x_b^2 P(x_b t_b | x_a t_a). \quad (18.459)$$

For simplicity, let us first look at the case of a dominant friction term. As in quantum mechanics, it is useful to introduce a bra-ket notation, but for the *probabilities* rather than the amplitudes,

$$\langle x_b t_b | x_a t_a \rangle \equiv |(x_b t_b | x_a t_a)|^2. \quad (18.460)$$

The fact that this probability satisfies the Fokker-Planck equation implies that we can write it as

$$\langle x_b t_b | x_a t_a \rangle = e^{-(t_b - t_a)H(\hat{p}_b, x_b)} \delta(x_b - x_a). \quad (18.461)$$

Thus we may introduce time-independent basis vectors $|x_a\rangle$ satisfying

$$\langle x_b | x_a \rangle = \delta(x_b - x_a). \quad (18.462)$$

On this basis, the operators \hat{p} , \hat{x} are defined in the usual way. They satisfy

$$\langle x_b | \hat{x} = x_b \langle x_b |, \quad \langle x_b | \hat{p} = -i \frac{\partial}{\partial x_b} \langle x_b |. \quad (18.463)$$

Then we may rewrite (18.461) in bra-ket notation as

$$\langle x_b t_b | x_a t_a \rangle = \langle x_b | e^{-H(\hat{p}, \hat{x})(t_b - t_a)} | x_a \rangle. \quad (18.464)$$

The expectation value of any function $f(x)$ is calculated as follows

$$\begin{aligned} \langle f(x) \rangle &= \int_{-\infty}^{\infty} dx_b f(x_b) \langle x_b | e^{-(t_b - t_a)H(\hat{p}, \hat{x})} | x_a \rangle \\ &= \int_{-\infty}^{\infty} dx_b \langle x_b | f(\hat{x}) e^{-(t_b - t_a)H(\hat{p}, \hat{x})} | x_a \rangle \\ &= \int_{-\infty}^{\infty} dx_b \int_{-\infty}^{\infty} dx \langle x_b | e^{-(t_b - t_a)H(\hat{p}, \hat{x})} | x \rangle \langle x | f(\hat{x}(t_b - t_a)) | x_a \rangle. \end{aligned} \quad (18.465)$$

In the last term we have introduced the time-dependent Heisenberg type of operator

$$\hat{x}(t) \equiv e^{tH(\hat{p}, \hat{x})} \hat{x} e^{-tH(\hat{p}, \hat{x})}. \quad (18.466)$$

The probability $P(x_b t_b | x_a t_a)$ satisfies the normalization condition

$$\begin{aligned} \int_{-\infty}^{\infty} dx_b P(x_b t_b | x_a t_a) &= \int_{-\infty}^{\infty} dx_b \langle x_b t_b | x_a t_a \rangle \\ &= \int_{-\infty}^{\infty} dx_b \langle x_b | e^{-(t_b - t_a)H(\hat{p}, \hat{x})} | x_a \rangle = 1. \end{aligned} \quad (18.467)$$

Applying this to the last line of (18.465), we arrive at the simple formula

$$\langle f(x) \rangle = \int_{-\infty}^{\infty} dx_b \langle x_b | f(\hat{x}(t_b - t_a)) | x_a \rangle. \quad (18.468)$$

For the Brownian motion of a point particle where

$$L_e = \frac{\dot{x}^2}{4D}, \quad H = Dp^2, \quad (18.469)$$

the Heisenberg operators are

$$\hat{p}(t) = \hat{p}, \quad \hat{x}(t) = e^{\hat{H}t} \hat{x} e^{-\hat{H}t} = \hat{x} - i2D\hat{p}t, \quad (18.470)$$

and

$$\begin{aligned} \hat{x}^2(t) &= \hat{x}^2 - i2D \cdot (\hat{p}\hat{x} + \hat{x}\hat{p})t - 4D^2\hat{p}^2t^2, \\ &= \hat{x}^2 + 2Dt - i2D \cdot 2\hat{x}\hat{p} - 4D^2\hat{p}^2t. \end{aligned} \quad (18.471)$$

It is easy to calculate the following matrix elements:

$$\begin{aligned} \int_{-\infty}^{\infty} dx_b \langle x_b | \hat{x} | x_a \rangle &= x_a, \\ \int_{-\infty}^{\infty} dx_b \langle x_b | \hat{p} | x_a \rangle &= -i \int_{-\infty}^{\infty} dx_b \frac{\partial}{\partial x_b} \delta(x_b - x_a) = 0, \\ \int_{-\infty}^{\infty} dx_b \langle x_b | \hat{x}^2 | x_a \rangle &= \int_{-\infty}^{\infty} dx_b x_b^2 \delta(x_b - x_a) = x_a^2, \\ \int_{-\infty}^{\infty} dx_b \langle x_b | \hat{p}^2 | x_a \rangle &= - \int_{-\infty}^{\infty} dx_b \frac{\partial^2}{\partial x_b^2} \delta(x_b - x_a) = 0, \\ \int_{-\infty}^{\infty} dx_b \langle x_b | \hat{p}\hat{x} | x_a \rangle &= -i \int_{-\infty}^{\infty} dx_b \frac{\partial}{\partial x_b} \delta(x_b - x_a) x_a = 0. \end{aligned} \quad (18.472)$$

The vanishing integrals reflect the translational invariance of the integrated bra state $\int_{-\infty}^{\infty} dx_b \langle x_b |$, which is therefore annihilated by a translational operator \hat{p}_b on its right:

$$\int_{-\infty}^{\infty} dx_b \langle x_b | \hat{p} = 0. \quad (18.473)$$

With the help of Eqs. (18.472), we obtain

$$\langle x \rangle = x_a, \quad \langle x^2 \rangle = x_a^2 + 2D(t_b - t_a), \quad (18.474)$$

and

$$\langle (x - x_a)^2 \rangle = 2D(t_b - t_a). \quad (18.475)$$

Clearly, a similar formalism can be developed for the general case with the Lagrangian containing \ddot{x} -terms. All we have to do is define time-dependent Heisenberg operators for both sets of canonical coordinates x, p, v, p_v . For instance, consider the case of a free particle, where $V(x) = 0$ and the Hamiltonian (18.239) reduces to

$$H = \frac{w}{2M^2} p_v^2 - i\gamma p_v v + ipv. \quad (18.476)$$

If we want to calculate expectations $\langle f(x, v) \rangle$ for a particle initially at x_a with an initial velocity $\dot{x}_a = v_a$, we now have to evaluate integrals of the form

$$\begin{aligned} \langle f(x, v) \rangle &= \int_{-\infty}^{\infty} dx_b \int_{-\infty}^{\infty} dv_b f(x_b, v_b) P(x_b v_b t_b | x_a v_a t_a) \\ &= \int_{-\infty}^{\infty} dx_b \int_{-\infty}^{\infty} dv_b \langle x_b v_b | f(\hat{x}(t_b - t_a), \hat{v}(t_b - t_a)) | x_a v_a \rangle. \end{aligned} \quad (18.477)$$

Here we introduce basis vectors $|xv\rangle$ which diagonalize the operators \hat{x} , \hat{v} . The momentum operators satisfy

$$\langle xv|\hat{p} = -\frac{\partial}{\partial x}\langle xv|, \quad \langle xv|\hat{p}_v = -\frac{\partial}{\partial v}\langle xv|. \quad (18.478)$$

Then we can write

$$\langle x^2 \rangle = \int_{-\infty}^{\infty} dx_b \int_{-\infty}^{\infty} dv_b \langle x_b v_b | \hat{x}^2(t_b - t_a) | x_a v_a \rangle, \quad (18.479)$$

where $\hat{x}(t)$ is the Heisenberg operator defined by

$$\hat{x}(t) = e^{tH(\hat{p}, \hat{p}_v, \hat{x}, \hat{v})} \hat{x} e^{-tH(\hat{p}, \hat{p}_v, \hat{x}, \hat{v})}. \quad (18.480)$$

The Heisenberg equations of motions are

$$\begin{aligned} \dot{\hat{p}}(t) &= [\hat{H}, \hat{p}(t)] = 0, \\ \dot{\hat{p}}_v(t) &= [\hat{H}, \hat{p}_v(t)] = \gamma \hat{p}_v(t) - \hat{p}(t), \\ \dot{\hat{x}}(t) &= [\hat{H}, \hat{x}(t)] = \hat{v}(t), \\ \dot{\hat{v}}(t) &= [\hat{H}, \hat{v}(t)] = -i \frac{w}{M^2} \hat{p}_v(t) - \gamma \hat{v}(t). \end{aligned} \quad (18.481)$$

According to the first equation, $\hat{p}(t)$ is a constant operator:

$$\hat{p}(t) \equiv \hat{p} = \text{const.}$$

The second equation is solved by

$$\hat{p}_v(t) = \hat{p}_v e^{\gamma t} - \frac{1}{\gamma} \hat{p} (e^{\gamma t} - 1), \quad (18.482)$$

where \hat{p}_v is the initial value of $\hat{p}_v(t)$ at $t = 0$. With this, the fourth equation in (18.481) can be integrated to give

$$\begin{aligned} \hat{v}(t) &= \hat{v} e^{-\gamma t} - i \frac{w}{M^2} \int_0^t dt' e^{-\gamma(t-t')} \hat{p}_v(t') \\ &= \hat{v} e^{-\gamma t} - i \frac{w}{\gamma M^2} \left[\hat{p}_v \sinh \gamma t - \frac{1}{\gamma} \hat{p} (\cosh \gamma t - 1) \right]. \end{aligned} \quad (18.483)$$

Inserting this into the third equation in (18.481) we obtain immediately

$$\hat{x}(t) = \hat{x} + \hat{v} \frac{1}{\gamma} (1 - e^{-\gamma t}) - i \frac{w}{\gamma M^2} \left[p_v \cosh \gamma t - \frac{1}{\gamma} p (\sinh \gamma t - \gamma t) \right]. \quad (18.484)$$

Using now the relations extending (18.473):

$$\int_{-\infty}^{\infty} dx_b \int_{-\infty}^{\infty} dx_{2b} \langle x_b x_{2b} | \left\{ \begin{array}{c} \hat{p} \\ \hat{p}_v \end{array} \right\} = 0 \quad (18.485)$$

to express the translational invariance of the integrated bra state, we find directly

$$\langle x \rangle = x_a + \dot{x}_a \frac{1}{\gamma} \left(1 - e^{-\gamma(t_b - t_a)} \right), \quad \langle v \rangle = v_a e^{-\gamma(t_b - t_a)}, \quad (18.486)$$

in agreement with (18.441) and (18.454). The expectations values of the quadratic cumulants $\langle (x - \langle x \rangle)^2 \rangle$, $\langle (x - \langle x \rangle)(v - \langle v \rangle) \rangle$, $\langle (v - \langle v \rangle)^2 \rangle$ are found to be the same as in (18.457).

18.16 Supersymmetry

An interesting new symmetry can be derived from the functional determinant (18.296) which causes the extra last term in the exponent of the path integral (18.300). Let us rewriting this implicitly as

$$P_0(x_b t_b | x_a t_a) \propto \int \mathcal{D}x(t) \text{Det} \left[\partial_t + \frac{V''(x)}{M\gamma} \right] \exp \left\{ - \int_{t_a}^{t_b} dt \frac{1}{4D} \left[\dot{x} + \frac{V'(x)}{M\gamma} \right]^2 \right\}. \quad (18.487)$$

In this expression, the time ordering of the velocity \dot{x} with respect to $V'(x)/M\gamma$ is arbitrary. It may be quantum-mechanical (Stratonovich-like), but equally well retarded (Itô-like), or advanced, as long as the same ordering is used in both the Lagrangian and the determinant.

The new symmetry arises if one generates the determinant with the help of an auxiliary fermion field $c(t)$ from a path integral over $c(t)$:

$$\det [\partial_t + V''(x(t))/M\gamma] \propto \int \mathcal{D}c \mathcal{D}\bar{c} e^{-\int dt \bar{c}(t) [M\gamma \partial_t + V''(x(t))] c(t)}. \quad (18.488)$$

In quantum field theory, such auxiliary fermionic fields are referred to as *ghost fields*. With these we can rewrite the path integral (18.290) for the probability distribution as an ordinary path integral

$$P(x_b t_b | x_a t_a) = \int \mathcal{D}x \int \mathcal{D}c \mathcal{D}\bar{c} \exp \{ -\mathcal{A}_{\text{PS}}[x, c, \bar{c}] \}, \quad (18.489)$$

where \mathcal{A}_{PS} is the Euclidean action

$$\mathcal{A}_{\text{PS}} = \frac{1}{2DM^2\gamma^2} \int_{t_a}^{t_b} dt \left\{ \frac{1}{2} [M\gamma \dot{x} + V'(x)]^2 + \bar{c}(t) [M\gamma \partial_t + V''(x(t))] c(t) \right\}, \quad (18.490)$$

first written down by Parisi and Sourlas [20] and by McKane [21]. This action has a particular property. If we denote the expression in the first brackets by

$$U_x \equiv M\gamma \partial_t x + V'(x), \quad (18.491)$$

the operator between the Grassmann variables in (18.490) is simply the functional derivative of U_x :

$$U_{xy} \equiv \frac{\delta U_x}{\delta y} = M\gamma \partial_t + V''(x). \quad (18.492)$$

Thus we may write

$$\mathcal{A}_{\text{PS}} = \frac{1}{2D} \int_{t_a}^{t_b} dt \left[\frac{1}{2} U_x^2 + \bar{c}(t) U_{xy} c(t) \right], \quad (18.493)$$

where $U_{xy}c(t)$ is the usual short notation for the functional matrix multiplication $\int dt' U_{xy}(t, t')c(t')$. The relation between the two terms makes this action *supersymmetric*. It is invariant under transformations which mix the Fermi and Bose degrees of freedom. Denoting by ε and $\bar{\varepsilon}$ a small anticommuting Grassmann variable and its conjugate (see Section 7.10), the action is invariant under the field transformations

$$\delta x(t) = \bar{\varepsilon} c(t) + \bar{c}(t) \varepsilon, \quad (18.494)$$

$$\delta \bar{c}(t) = -\bar{\varepsilon} U_x, \quad (18.495)$$

$$\delta c(t) = U_x \varepsilon. \quad (18.496)$$

The invariance follows immediately after observing that

$$\delta U_x = \bar{\varepsilon} U_{xy} c(t) + \bar{c}(t) U_{xy} \varepsilon. \quad (18.497)$$

Formally, a similar construction is also possible for a particle with inertia in the path integral (18.232), which is an ordinary path integral involving the Lagrangian (18.287). Here we can write

$$P(x_b t_b | x_a t_a) = \mathcal{N} \int \mathcal{D}x J[x] \exp \left\{ -\frac{1}{2w} \int_{t_a}^{t_b} dt [M\ddot{x} + M\gamma\dot{x} + V'(x)]^2 \right\}, \quad (18.498)$$

where $J[x]$ abbreviates the determinant

$$J[x] = \det [M\partial_t^2 + M\gamma\partial_t + V''(x(t))], \quad (18.499)$$

which is known from formula (18.274). The path integral (18.498) is valid for *any* ordering of the velocity term, as long as it is the same in the exponent and the functional determinant.

We may now express the functional determinant as a path integral over fermionic ghost fields

$$J[x] = \det [M\partial_t^2 + M\gamma\partial_t + V''(x(t))] \propto \int \mathcal{D}c\mathcal{D}\bar{c} e^{-\int dt \bar{c}(t) [M\partial_t^2 + M\gamma\partial_t + V''(x(t))] c(t)}, \quad (18.500)$$

and rewrite the probability distribution $P(x_b t_b | x_a t_a)$ as an ordinary path integral

$$P(x_b t_b | x_a t_a) \propto \int \mathcal{D}x \int \mathcal{D}c\mathcal{D}\bar{c} \exp \{-\mathcal{A}^{\text{KS}}[x, \bar{c}]\}, \quad (18.501)$$

where $\mathcal{A}[x, \bar{c}]$ is the Euclidean action

$$\mathcal{A}^{\text{KS}}[x, \bar{c}] \equiv \int_{t_a}^{t_b} dt \left\{ \frac{1}{2w} [M\ddot{x} + M\gamma\dot{x} + V'(x)]^2 + \bar{c}(t) [M\partial_t^2 + M\gamma\partial_t + V''(x(t))] c(t) \right\}. \quad (18.502)$$

This formal expression contains subtleties arising from the boundary conditions when calculating the Jacobian (18.500) from the functional integral on the right-hand side. It is necessary to factorize the second-order operator in the functional determinant and express the determinant of each first-order factor as a functional integral over Grassmann variables as in (18.488). At the end, the action is again supersymmetric, but there are twice as many auxiliary Fermi fields [22].

As a check of this formula, we may let the coupling to the thermal reservoir go to zero, $\gamma \rightarrow 0$. Then the first factor in (18.501),

$$\exp \left(-\int_{t_a}^{t_b} dt \left\{ \frac{1}{2w} [M\ddot{x} + M\gamma\dot{x} + V'(x)]^2 \right\} \right)$$

becomes proportional to a δ -functional $\delta[M\ddot{x} + V'(x)]$. The argument is simply the functional derivative of the original action of the quantum system in (18.191), so that we obtain in the limit $\delta[\delta\mathcal{A}/\delta x]$. The functional matrix between the Grassmann fields in (18.501), on the other hand, reduces to $\delta^2\mathcal{A}/\delta x(t)\delta x(t')$, and we arrive at the path integral

$$P(x_b t_b | x_a t_a) \underset{\gamma \rightarrow 0}{\propto} \int \mathcal{D}x \delta[\delta\mathcal{A}/\delta x] \times \int \mathcal{D}c\mathcal{D}\bar{c} \exp \left\{ -\int_{t_a}^{t_b} dt \int_{t_a}^{t_b} dt' \bar{c}(t) \delta^2\mathcal{A}/\partial x(t)\partial x(t') c(t') \right\}. \quad (18.503)$$

Performing the integral over the Grassmann variables yields

$$P(x_b t_b | x_a t_a) \underset{\gamma \rightarrow 0}{\propto} \int \mathcal{D}x \delta[\delta\mathcal{A}/\delta x] \text{Det} [\delta^2\mathcal{A}/\partial x(t)\partial x(t')]. \quad (18.504)$$

The δ -functional selects from all paths only those which obey the Euler-Lagrange equations of motion. With the help of the functional identity

$$\delta[M\ddot{x} + V'(x)] = \delta[x - x_c] \times \text{Det}^{-1}[M\ddot{x} + V''(x)], \quad (18.505)$$

which generalizes identity $\delta(f(x)) = \delta(x)/f'(x)$ if $f(0) = 0$, the above path integral becomes simply

$$P(x_b t_b | x_a t_a) \underset{\gamma \rightarrow 0}{\propto} \int \mathcal{D}x \delta[x - x_{cl}], \quad (18.506)$$

which is the correct probability distribution of classical physics. Note the important difference with respect to the classical amplitude in Eq. (4.96), where the concentration of the path integral on the classical path is enforced by a strongly oscillating complex expression requiring the semiclassical fluctuation factor in Eq. (4.97) for proper normalization. In the probability (18.506) this is achieved by a real δ -functional.

Note that by a Fourier decomposition of the δ -functional (18.503) we obtain the alternative path integral representation of classical physics

$$P(x_b t_b | x_a t_a) \underset{\gamma \rightarrow 0}{\propto} \int \mathcal{D}x \mathcal{D}\lambda \mathcal{D}c \mathcal{D}\bar{c} e^{-\int_{t_a}^{t_b} dt \delta \mathcal{A} / \delta x(t) \lambda(t) - \int_{t_a}^{t_b} dt \int_{t_a}^{t_b} dt' \bar{c}(t) \delta^2 \mathcal{A} / \delta x(t) \delta x(t') c(t')}. \quad (18.507)$$

This is supersymmetric under the transformations

$$\delta x = \bar{\epsilon} c, \quad \delta c = 0, \quad \delta \bar{c} = -\bar{\epsilon} \lambda, \quad \delta \lambda = 0, \quad (18.508)$$

as observed by Gozzi [23].

There exists a compact way of rewriting the action using *superfields*. We define a three-dimensional *superspace* consisting of time and two auxiliary Grassmann variables θ and $\bar{\theta}$. Then we define a superfield

$$X(t) \equiv x(t) + i\bar{\theta}c(t) - i\bar{\theta}c(t) - \bar{\theta}\lambda(t). \quad (18.509)$$

We now consider the superaction

$$\mathcal{A}^{\text{super}} \equiv \int d\bar{\theta} d\theta \mathcal{A}[X] \equiv \int d\bar{\theta} d\theta \mathcal{A}[x + i\bar{\theta}c - i\theta\bar{c} - \bar{\theta}\theta\lambda] \quad (18.510)$$

and expand the action into a functional Taylor series:

$$\int d\bar{\theta} d\theta \left\{ \mathcal{A}[x] + \frac{\delta \mathcal{A}}{\delta x} (i\bar{\theta}c - i\theta\bar{c} - \bar{\theta}\theta\lambda) + \frac{1}{2} (i\bar{\theta}c - i\theta\bar{c} - \bar{\theta}\theta\lambda) \frac{\partial^2 \mathcal{A}}{\delta x \delta x} (i\bar{\theta}c - i\theta\bar{c} - \bar{\theta}\theta\lambda) \right\}.$$

Due to the nilpotency (7.375) of the Grassmann variables, the expansion stops after the second term. Recalling now the integration rules (7.378) and (7.379), this becomes

$$\frac{\delta \mathcal{A}}{\delta x} \lambda + \frac{1}{2} \bar{c} \frac{\partial^2 \mathcal{A}}{\delta x \delta x} c,$$

which is precisely the short-hand functional notation for the negative exponent in the path integral (18.507).

18.17 Stochastic Quantum Liouville Equation

At lower temperatures, where quantum fluctuations become important, the forward-backward path integral (18.230) does not allow us to derive a Schrödinger-like differential equation for the probability distribution $P(x v t | x_a v_a t_a)$. To see the obstacle, we go over to the canonical representation of (18.230):

$$|(x_b t_b | x_a t_a)|^2 = \int \mathcal{D}x \mathcal{D}y \int \frac{\mathcal{D}p}{2\pi} \frac{\mathcal{D}p_y}{2\pi} \exp \left\{ \frac{i}{\hbar} \int_{t_a}^{t_b} dt [p\dot{x} + p_y \dot{y} - H_T] \right\}, \quad (18.511)$$

where

$$H_T = \frac{1}{M} p_y p_x + \gamma p_y y + V(x + y/2) - V(x - y/2) - i \frac{w}{2\hbar} y \hat{K}^{\text{Ohm}} y \tag{18.512}$$

plays the role of a temperature-dependent quasi-Hamiltonian for an Ohmic system associated with the Lagrangian of the forward-backward path integral (18.230). The notation $\hat{K}^{\text{Ohm}} y(t)$ abbreviates the product of the functional matrix $K^{\text{Ohm}}(t, t')$ with the functional vector $y(t')$ defined by $\hat{K}^{\text{Ohm}} y(t) \equiv \int dt' K^{\text{Ohm}}(t, t') y(t')$. Hence is H_T a nonlocal object (in the temporal sense), and this is the reason for calling it quasi-Hamiltonian.

It is useful to omit y -integrations at the endpoints in the path integral (18.511), and set up a path integral representation for the product of amplitudes

$$U(x_b y_b t_b | x_a y_a t_a) \equiv (x_b + y_b/2 t_b | x_a + y_a/2 t_a) (x_b - y_b/2 t_b | x_a - y_a/2 t_a)^*. \tag{18.513}$$

Given some initial density matrix $\rho(x_+, x_-; t) = \rho(x + y/2, x - y/2; t)$ at time $t = t_a$, which may actually be in equilibrium and time-independent, as in Eq. (2.367), the functional matrix $U(x_b y_b t_b | x_a y_a t_a)$ allows us to calculate $\rho(x_+, x_-; t)$ at any time by the time evolution equation

$$\rho(x + y/2, x - y/2; t) = \int dx_a dy_a U(x y t | x_a y_a t_a) \rho(x_a + y_a/2, x_a - y_a/2; t_a). \tag{18.514}$$

Recall that the Fourier transform of $\rho(x + y/2, x - y/2; t)$ with respect to y is the Wigner function (1.224).

When considering the change of $U(x y t | x_a y_a t_a)$ over a small time interval ϵ , the momentum variables p and p_y have the same effect as differential operators $-i\partial_{x_b}$ and $-i\partial_{y_b}$, respectively. The last term in H_T , however, is nonlocal in time, thus preventing a derivation of a Schrödinger-like differential equation.

The locality problem can be removed by introducing a noise variable $\eta(t)$ with the correlation function determined by (18.321):

$$\langle \eta(t) \eta(t') \rangle_T = \frac{w}{2} [K^{\text{Ohm}}]^{-1}(t, t'). \tag{18.515}$$

Then we can define a temporally local η -dependent Hamiltonian operator

$$\hat{H}_\eta \equiv \frac{1}{M} (\hat{p}_x + \gamma y) \hat{p}_y + V(x + y/2) - V(x - y/2) - y \eta, \tag{18.516}$$

which governs the evolution of η -dependent versions of the amplitude products (18.513) via the *stochastic Schrödinger equation*

$$i\hbar \partial_t U_\eta(x y t | x_a y_a t_a) = \hat{H}_\eta U_\eta(x y t | x_a y_a t_a). \tag{18.517}$$

The same equation is obeyed by the noise-dependent density matrix $\rho_\eta(x, y; t)$.

Averaging these equation over η with the distribution (18.321) yields for $y_a = y_b = 0$ the same probability distribution as the forward-backward path integral (18.230):

$$|(x_b t_b | x_a t_a)|^2 = U(x_b 0 t_b | x_a 0 t_a) \equiv \langle U(x_b 0 t_b | x_a y_a t_a) \rangle_\eta. \tag{18.518}$$

At high temperatures, the noise averaged stochastic Schrödinger equation (18.517) takes the form

$$i\hbar \partial_t U(x y t | x_a y_a t_a) = \hat{H}_T U(x y t | x_a y_a t_a), \tag{18.519}$$

where \hat{H} is now a local (in the temporal sense)

$$\hat{H}_T \equiv \frac{1}{M} \hat{p}_y \hat{p}_x + \gamma y \hat{p}_y + V(x + y/2) - V(x - y/2) - i \frac{w}{2\hbar} y^2, \tag{18.520}$$

arising from the Hamiltonian (18.512) in the high-temperature limit $K^{\text{Ohm}} \rightarrow 1$ [recall (18.223)]. In terms of the separate path positions $x_{\pm} = x \pm y/2$ where $p_x = \partial_+ + \partial_-$ and $p_y = (\partial_+ - \partial_-)/2$, this takes the more familiar form [24]

$$\hat{H}_T \equiv \frac{1}{2M} (\hat{p}_+^2 - \hat{p}_-^2) + V(x_+) - V(x_-) + \frac{\gamma}{2}(x_+ - x_-)(\hat{p}_+ - \hat{p}_-) - i\frac{w}{2\hbar}(x_+ - x_-)^2. \quad (18.521)$$

The last term is often written as $-i\hbar\Lambda(x_+ - x_-)^2$, where Λ is the so-called *decoherence rate per square distance*

$$\Lambda \equiv \frac{w}{2\hbar^2} = \frac{M\gamma k_B T}{\hbar^2}. \quad (18.522)$$

It is composed of the damping rate γ and the squared thermal length (2.353):

$$\Lambda = \frac{2\pi\gamma}{l_e^2(\hbar\beta)}, \quad (18.523)$$

and controls the decay of interference peaks [25].

Note that the order of the operators in the mixed term of the form $y\hat{p}_y$ in Eq. (18.520) is opposite to the mixed term $-i\hat{p}_y v$ in the differential operator (18.239) of the Fokker-Planck equation. This order is necessary to guarantee the conservation of probability. Indeed, multiplying the time evolution equation (18.519) by $\delta(y)$, and integrating both sides over x and y , the left-hand side vanishes.

The correctness of this order can be verified by calculating the fluctuation determinant of the path integral for the product of amplitudes (18.513) in the Lagrangian form, which looks just like (18.230), except that the difference between forward and backward trajectories $y(t) = x_+(t) - x_-(t)$ is nonzero at the endpoints. For the fluctuation which vanish at the endpoints, this is irrelevant. As explained before, the order is a short-time issue, and we can take $t_b - t_a \rightarrow \infty$. Moreover, since the order is independent of the potential, we may consider only the free case $V(x \pm y/2) \equiv 0$. The relevant fluctuation determinant was calculated in formula (18.254). In the Hamiltonian operator (18.520), this implies an additional energy $-i\gamma/2$ with respect to the symmetrically ordered term $\gamma\{y, \hat{p}_y\}/2$, which brings it to $\gamma y \hat{p}_y$, and thus the order in (18.521).

18.18 Master Equation for Time Evolution

In the high-temperature limit, the Hamiltonian (18.521) becomes local. Then the evolution equation (18.514) for the density matrix $\rho(x_+, x_-; t_a)$ can be converted into an operator equation

$$i\hbar\partial_t\rho(x_+, x_-; t_a) = \hat{H}_T\rho(x_+, x_-; t_a), \quad (18.524)$$

where \hat{H}_T is the operator version of the temperature-dependent Hamiltonian (18.521). Such an equation does not exist at low temperatures, due to the nonlocality of the last term in (18.512). Then one cannot avoid solving the stochastic Schrödinger equation (18.517) with the subsequent averaging (18.518). For moderately high temperatures, however, a Hamiltonian formalism can still be set up, although it requires solving a recursion relation. For this purpose we write down the quasi-Hamiltonian in D dimensions

$$\begin{aligned} \hat{H}_T \equiv & \frac{1}{2M} (\hat{\mathbf{p}}_+^2 - \hat{\mathbf{p}}_-^2) + V(\mathbf{x}_+) - V(\mathbf{x}_-) + \frac{M\gamma}{2} (\hat{\mathbf{x}}_+ - \hat{\mathbf{x}}_-)(\hat{\mathbf{x}}_+ + \hat{\mathbf{x}}_-)^R \\ & - i\frac{w}{2\hbar}(\hat{\mathbf{x}}_+ - \hat{\mathbf{x}}_-)\hat{K}^{\text{Ohm}}(\hat{\mathbf{x}}_+ - \hat{\mathbf{x}}_-), \end{aligned} \quad (18.525)$$

where the Fourier transform of $K^{\text{Ohm}}(t, t')$ is expanded in powers of ω' [recall (18.223)]

$$K^{\text{Ohm}}(\omega') = 1 + \frac{1}{3} \left(\frac{\hbar\omega'}{2k_B T} \right)^2 + \dots \quad (18.526)$$

Each power of ω'^2 stands for the operator $-\overset{\leftarrow}{\partial}_t \partial_t$. In this way we find for the last term the locally looking high-temperature expansion

$$-i(\hat{\mathbf{x}}_+ - \hat{\mathbf{x}}_-) \hat{K}^{\text{Ohm}}(\hat{\mathbf{x}}_+ - \hat{\mathbf{x}}_-) = -i(\hat{\mathbf{x}}_+ - \hat{\mathbf{x}}_-)^2 + i \frac{w\hbar}{24(k_B T)^2} (\hat{\mathbf{x}}_+ - \hat{\mathbf{x}}_-)^2 + \dots \quad (18.527)$$

The expression is not really local, since the operator $\hat{\mathbf{x}}$ is defined implicitly as an abbreviation for the commutator

$$\hat{\mathbf{x}} \equiv \frac{i}{\hbar} [\hat{H}_T, \hat{\mathbf{x}}]. \quad (18.528)$$

If the expansion (18.527) is carried further, higher derivatives of \mathbf{x} arise, which are all defined recursively:

$$\hat{\mathbf{x}} \equiv \frac{i}{\hbar} [\hat{H}_T, \hat{\mathbf{x}}], \quad \hat{\ddot{\mathbf{x}}} \equiv \frac{i}{\hbar} [\hat{H}_T, \hat{\mathbf{x}}], \quad \dots \quad (18.529)$$

Thus Eq. (18.525) with the expansion (18.527) is a recursive equation for the Hamiltonian operator \hat{H}_T . For small γ (and thus $w = 2M\gamma k_B T$), the recursion can be solved iteratively, in the first step by inserting $\hat{\mathbf{x}} \approx \hat{\mathbf{p}}/M$ into Eq. (18.530).

It is useful to re-express (18.524) in the Dirac operator form where the density matrix has a bra-ket representation $\hat{\rho}(t) = \sum_{mn} \rho_{mn}(t) |m\rangle \langle n|$. Denoting $\hat{\mathbf{p}}^2/2M + \hat{V}$ in (18.525) by \hat{H} , we obtain with the expansion (18.527) the local *master equation*:

$$\begin{aligned} i\hbar \partial_t \hat{\rho} = \hat{H}_T \hat{\rho} &\equiv [\hat{H}, \hat{\rho}] + \frac{M\gamma}{2} (\hat{\mathbf{x}} \hat{\mathbf{x}} \hat{\rho} - \hat{\rho} \hat{\mathbf{x}} \hat{\mathbf{x}} + \hat{\mathbf{x}} \hat{\rho} \hat{\mathbf{x}} - \hat{\mathbf{x}} \hat{\rho} \hat{\mathbf{x}}) \\ &- \frac{iw}{2\hbar} [\hat{\mathbf{x}}, [\hat{\mathbf{x}}, \hat{\rho}]] - \frac{iw\hbar^2}{24(k_B T)^2} [\hat{\mathbf{x}}, [\hat{\mathbf{x}}, \hat{\rho}]] + \dots \end{aligned} \quad (18.530)$$

The validity of the above iterative procedure is most easily proved in the time-sliced path integral. The final slice of infinitesimal width ϵ reads

$$\begin{aligned} U(\mathbf{x}_{+b}, \mathbf{x}_{-b}, t_b | \mathbf{x}_{+a}, \mathbf{x}_{-a}, t_b - \epsilon) \\ = \int \frac{d\mathbf{p}_+(t_b)}{(2\pi)^3} \int \frac{d\mathbf{p}_-(t_b)}{(2\pi)^3} e^{\frac{i}{\hbar} \{ \mathbf{p}_+(t_b) [\mathbf{x}_+(t_b) - \mathbf{x}_+(t_b - \epsilon)] - \mathbf{p}_- \cdot \dot{\mathbf{x}}_- - \bar{H}_T(t_b) \}}. \end{aligned} \quad (18.531)$$

Consider now a term of the generic form $\hat{F}_+(\mathbf{x}_+(t)) F_-(\mathbf{x}_-(t))$ in $\bar{H}_T(t)$. When differentiating $U(\mathbf{x}_{+b}, \mathbf{x}_{-b}, t_b | \mathbf{x}_{+a}, \mathbf{x}_{-a}, t_b - \epsilon)$ with respect to the final time t_b , the integrand receives a factor $-\bar{H}_T(t_b)$. At t_b , the term $\hat{F}_+(\mathbf{x}_+(t)) F_-(\mathbf{x}_-(t))$ in $\bar{H}_T(t)$ has the explicit form $\epsilon^{-1} [F_+(\mathbf{x}_+(t_b)) - F_+(\mathbf{x}_+(t_b - \epsilon))] F_-(\mathbf{x}_-(t_b))$. It can be taken out of the integral, yielding

$$\epsilon^{-1} [F_+(\mathbf{x}_+(t_b)) U - U F_+(\mathbf{x}_+(t_b - \epsilon))] F_-(\mathbf{x}_-(t_b)). \quad (18.532)$$

In operator language, the amplitude U is associated with $\hat{U} \approx 1 - i\epsilon \hat{H}_T/\hbar$, such the term $\hat{F}_+(\mathbf{x}_+(t)) F_-(\mathbf{x}_-(t))$ in \bar{H}_T yields a Schrödinger operator

$$\frac{i}{\hbar} \left[\hat{H}_T, \hat{F}_+(\mathbf{x}_+) \right] F_-(\mathbf{x}_-) \quad (18.533)$$

in the time evolution equation (18.530).

For functions of the second derivative $\ddot{\mathbf{x}}$ we have to split off the last two time slices in (18.531) and convert the two intermediate integrals over \mathbf{x} into operator expressions, which obviously leads to the repeated commutator of \hat{H}_T with $\hat{\mathbf{x}}$, and so on.

The operator order in the terms in the parentheses of Eq. (18.530) is fixed by the retardation of $\hat{\mathbf{x}}_{\pm}$ with respect to \mathbf{x}_{\pm} in (18.521). This implies that the associated operator $\hat{\mathbf{x}}(t)$ has a time

argument which lies slightly *before* that of $\hat{\mathbf{x}}_{\pm}$, thus acting upon $\hat{\rho}$ before $\hat{\mathbf{x}}$. This puts $\hat{\mathbf{x}}(t)$ to the right of $\hat{\mathbf{x}}$, i.e., next to $\hat{\rho}$. On the right-hand side of $\hat{\rho}$, the time runs in the opposite direction such that $\hat{\mathbf{x}}$ must lie to the left of $\hat{\mathbf{x}}$, again next to $\hat{\rho}$. In this way we obtain an operator order which ensures that Eq. (18.530) conserves the total probability.

This property and the positivity of $\hat{\rho}$ are actually guaranteed by the observation, that the master equation (18.530) can be written in the *Lindblad form* [26]

$$\partial_t \hat{\rho} = -\frac{i}{\hbar} [\hat{H}, \hat{\rho}] - \sum_{n=1}^2 \left(\frac{1}{2} \hat{L}_n \hat{L}_n^\dagger \hat{\rho} + \frac{1}{2} \hat{\rho} \hat{L}_n \hat{L}_n^\dagger - \hat{L}_n^\dagger \hat{\rho} \hat{L}_n \right), \quad (18.534)$$

with the two Lindblad operators [27]

$$\hat{L}_1 \equiv \frac{\sqrt{w}}{2\hbar} \hat{\mathbf{x}}, \quad \hat{L}_2 \equiv \frac{\sqrt{3w}}{2\hbar} \left(\hat{\mathbf{x}} - i \frac{\hbar}{3k_B T} \dot{\hat{\mathbf{x}}} \right). \quad (18.535)$$

Note that the operator order in Eq. (18.530) prevents the term $\hat{\mathbf{x}} \dot{\hat{\mathbf{x}}} \hat{\rho}$ from being a pure divergence. If we rewrite it as a sum of a commutator and an anticommutator, $[\hat{\mathbf{x}}, \dot{\hat{\mathbf{x}}}] / 2 + \{\hat{\mathbf{x}}, \dot{\hat{\mathbf{x}}}\} / 2$, then the latter term is a pure divergence, and we can think of the first two γ -terms in (18.530) as being due to an additional anti-Hermitian term in the Hamiltonian operator \hat{H} , the *dissipation operator*

$$\hat{H}_\gamma = \gamma M \frac{1}{4} [\dot{\hat{\mathbf{x}}}, \hat{\mathbf{x}}]. \quad (18.536)$$

18.19 Relation to Quantum Langevin Equation

The stochastic Liouville equation (18.517) can also be derived from an operator version of the Langevin equation (18.317), the so-called *Quantum Langevin equation*

$$M \ddot{\hat{\mathbf{x}}}(t) + M \gamma \dot{\hat{\mathbf{x}}}(t) + V'(\hat{\mathbf{x}}(t)) = \hat{\eta}(t), \quad (18.537)$$

where $\hat{\eta}(t)$ is an operator noise variable with the commutation rule

$$[\hat{\eta}_t, \hat{\eta}_{t'}] = w \frac{i\hbar}{k_B T} \partial_t \delta(t - t'), \quad (18.538)$$

and the correlation function [28]

$$\frac{1}{2} \langle [\hat{\eta}_t, \hat{\eta}_{t'}]_+ \rangle_{\hat{\eta}} = w K(t, t'). \quad (18.539)$$

The commutator (18.538) and the correlation function (18.539) are related to each other as required by the fluctuation-dissipation theorem: By omitting the factor $\coth(\hbar\omega/2k_B T)$ in Eq. (18.223), the Fourier integral (18.221) for $K(t, t')$ reduces to $(\hbar/2k_B T) \partial_t \delta(t - t')$. A comparison with the general spectral representation (18.53) shows that the expectation value (18.539) has the spectral function

$$\rho_b(\omega') = 2M\gamma\hbar\omega'. \quad (18.540)$$

By inserting this into the spectral representation (18.53) we obtain the right-hand side of the commutator equation (18.538).

A noise variable with the properties (18.538) and (18.539) can be constructed explicitly by superimposing quantized oscillator velocities of frequencies ω as follows:

$$\hat{\eta}(t) = -i \sqrt{\frac{M\hbar\gamma}{\pi}} \int_0^\infty d\Omega' \sqrt{\Omega'} [a_{\Omega'} e^{-i\omega't} - a_{\Omega'}^\dagger e^{i\omega't}]. \quad (18.541)$$

It is worth pointing out that there exists a direct derivation of the quantum Langevin equation (18.537), whose noise operator $\hat{\eta}(t)$ satisfies the commutator and fluctuation properties (18.538) and (18.539), from Kubo's stochastic Liouville equation, and thus from the forward-backward path integral (18.230) [29].

18.20 Electromagnetic Dissipation and Decoherence

There exists a thermal bath of particular importance: atoms are usually observed at a finite temperature where they interact with a grand-canonical ensemble of photons in thermal equilibrium. This interaction will broaden the natural line width of atomic levels even if all major mechanisms for the broadening are removed. To study this situation, let us set up a forward–backward path integral description for a bath of photons, and derive from it a master equation for the density matrix which describes electromagnetic dissipation and decoherence. As an application, we shall calculate the Wigner-Weisskopf formula for the natural line width of an atomic state at zero temperature, find the finite-temperature effects, and calculate the Lamb shift between atomic s - and p -wave states of principal quantum number $n = 2$ with the term notation $2S_{1/2}$ and $2P_{1/2}$. The master equation may eventually have applications to dilute interstellar gases or to few-particle systems in cavities.

18.20.1 Forward–Backward Path Integral

With the application to atomic physics in mind, we shall consider a three-dimensional quantum system described by a time-dependent quantum-mechanical density matrix $\rho(\mathbf{x}_+, \mathbf{x}_-; t)$. In contrast to Eq. (18.514), we use here the forward and backward variables as arguments, and write the time evolution equation as

$$\rho(\mathbf{x}_{+b}, \mathbf{x}_{-a}; t_b) = \int d\mathbf{x}_{+a} d\mathbf{x}_{-a} U(\mathbf{x}_{+b}, \mathbf{x}_{-b}, t_b | \mathbf{x}_{+a}, \mathbf{x}_{-a}, t_a) \rho(\mathbf{x}_{+a}, \mathbf{x}_{-a}; t_a). \quad (18.542)$$

In an external electromagnetic vector potential $\mathbf{A}(\mathbf{x}, t)$, the time-evolution kernel is determined by a forward–backward path integral of the type (18.192), in which the forward and backward paths start at different initial and final points $\mathbf{x}_{+a}, \mathbf{x}_{-a}$ and $\mathbf{x}_{+b}, \mathbf{x}_{-b}$, respectively:

$$\begin{aligned} U(\mathbf{x}_{+b}, \mathbf{x}_{-b}, t_b | \mathbf{x}_{+a}, \mathbf{x}_{-a}, t_a) &\equiv (\mathbf{x}_{+b}, t_b | \mathbf{x}_{+a}, t_a) (\mathbf{x}_{-b}, t_b | \mathbf{x}_{-a}, t_a)^* = \int \mathcal{D}\mathbf{x}_+ \mathcal{D}\mathbf{x}_- \\ &\times \exp \left\{ \frac{i}{\hbar} \int_{t_a}^{t_b} \left[\frac{M}{2} (\dot{\mathbf{x}}_+^2 - \dot{\mathbf{x}}_-^2) - V(\mathbf{x}_+) + V(\mathbf{x}_-) - \frac{e}{c} \dot{\mathbf{x}}_+ \cdot \mathbf{A}(\mathbf{x}_+, t) + \frac{e}{c} \dot{\mathbf{x}}_- \cdot \mathbf{A}(\mathbf{x}_-, t) \right] \right\}. \end{aligned} \quad (18.543)$$

The vector potential $\mathbf{A}(\mathbf{x}, t)$ is a superposition of oscillators $\mathbf{X}_{\mathbf{k}}(t)$ of frequency $\Omega_{\mathbf{k}} = c|\mathbf{k}|$ in a volume V :

$$\mathbf{A}(\mathbf{x}, t) = \sum_{\mathbf{k}} c_{\mathbf{k}}(\mathbf{x}) \mathbf{X}_{\mathbf{k}}(t), \quad c_{\mathbf{k}} = \frac{e^{i\mathbf{k}\mathbf{x}}}{\sqrt{2\Omega_{\mathbf{k}}V}}, \quad \sum_{\mathbf{k}} = \int \frac{d^3kV}{(2\pi)^3}. \quad (18.544)$$

At a finite temperature T , these oscillators are assumed to be in equilibrium, where we shall write their time-ordered correlation functions as

$$G_{\mathbf{k}\mathbf{k}'}^{ij}(t, t') = \langle \hat{T} \hat{X}_{\mathbf{k}}^i(t), \hat{X}_{-\mathbf{k}'}^j(t') \rangle = \delta_{\mathbf{k}\mathbf{k}'}^{ij \text{tr}} G_{\Omega_{\mathbf{k}}}(t, t') \equiv \delta_{\mathbf{k}\mathbf{k}'} P_{\mathbf{k}}^{\perp ij} G_{\Omega_{\mathbf{k}}}(t, t'). \quad (18.545)$$

The transverse projection matrix is the result of the sum over the transverse polarization vectors of the photons:

$$P_{\mathbf{k}}^{\perp ij} = \sum_{h=\pm} \epsilon^i(\mathbf{k}, h) \epsilon^{j*}(\mathbf{k}, h) = (\delta^{ij} - k^i k^j / \mathbf{k}^2). \quad (18.546)$$

The function $G_{\Omega_{\mathbf{k}}}(t, t')$ on the right-hand side of (18.545) is the Green function (18.185) of a single oscillator of frequency $\Omega_{\mathbf{k}}$. It is decomposed into real and imaginary parts, defining $A_{\Omega_{\mathbf{k}}}(t, t')$ and $C_{\Omega_{\mathbf{k}}}(t, t')$ as in (18.185), which are commutator and anticommutator functions of the oscillator at temperature T : $C_{\Omega_{\mathbf{k}}}(t, t') \equiv \langle [\hat{X}(t), \hat{X}(t')] \rangle_T$ and $A_{\Omega_{\mathbf{k}}}(t, t') \equiv \langle [\hat{X}(t), \hat{X}(t')] \rangle_T$, respectively.

The thermal average of the evolution kernel (18.543) is then given by the forward–backward path integral

$$U(\mathbf{x}_{+b}, \mathbf{x}_{-b}, t_b | \mathbf{x}_{+a}, \mathbf{x}_{-a}, t_a) = \int \mathcal{D}\mathbf{x}_+(t) \int \mathcal{D}\mathbf{x}_-(t) \\ \times \exp \left\{ \frac{i}{\hbar} \int_{t_a}^{t_b} dt \left[\frac{M}{2} (\dot{\mathbf{x}}_+^2 - \dot{\mathbf{x}}_-^2) - (V(\mathbf{x}_+) - V(\mathbf{x}_-)) \right] + \frac{i}{\hbar} \mathcal{A}^{\text{FV}}[\mathbf{x}_+, \mathbf{x}_-] \right\}, \quad (18.547)$$

where $\exp\{i\mathcal{A}^{\text{FV}}[\mathbf{x}_+, \mathbf{x}_-]/\hbar\}$ is the Feynman-Vernon influence functional defined in Eq. (18.200). The influence action $\mathcal{A}^{\text{FV}}[\mathbf{x}_+, \mathbf{x}_-]$ is the sum of a dissipative and a fluctuating part $\mathcal{A}_D^{\text{FV}}[\mathbf{x}_+, \mathbf{x}_-]$ and $\mathcal{A}_F^{\text{FV}}[\mathbf{x}_+, \mathbf{x}_-]$, whose explicit forms are now

$$\mathcal{A}_D^{\text{FV}}[\mathbf{x}_+, \mathbf{x}_-] = \frac{ie^2}{2\hbar c^2} \int dt \int dt' \Theta(t-t') \\ \times \left[\dot{\mathbf{x}}_+(t) \mathbf{C}_b(\mathbf{x}_+ t, \mathbf{x}'_+ t') \dot{\mathbf{x}}_+(t') - \dot{\mathbf{x}}_+(t) \mathbf{C}_b(\mathbf{x}_+ t, \mathbf{x}'_- t') \dot{\mathbf{x}}_-(t') \right. \\ \left. - \dot{\mathbf{x}}_-(t) \mathbf{C}_b(\mathbf{x}_- t, \mathbf{x}'_+ t') \dot{\mathbf{x}}_+(t') + \dot{\mathbf{x}}_-(t) \mathbf{C}_b(\mathbf{x}_- t, \mathbf{x}'_- t') \dot{\mathbf{x}}_-(t') \right], \quad (18.548)$$

and

$$\mathcal{A}_F^{\text{FV}}[\mathbf{x}_+, \mathbf{x}_-] = \frac{ie^2}{2\hbar c^2} \int dt \int dt' \Theta(t-t') \\ \times \left[\dot{\mathbf{x}}_+(t) \mathbf{A}_b(\mathbf{x}_+ t, \mathbf{x}'_+ t') \dot{\mathbf{x}}_+(t') + \dot{\mathbf{x}}_+(t) \mathbf{A}_b(\mathbf{x}_+ t, \mathbf{x}'_- t') \dot{\mathbf{x}}_-(t') \right. \\ \left. + \dot{\mathbf{x}}_-(t) \mathbf{A}_b(\mathbf{x}_- t, \mathbf{x}'_+ t') \dot{\mathbf{x}}_+(t') + \dot{\mathbf{x}}_-(t) \mathbf{A}_b(\mathbf{x}_- t, \mathbf{x}'_- t') \dot{\mathbf{x}}_-(t') \right], \quad (18.549)$$

with $\mathbf{C}_b(\mathbf{x}_- t, \mathbf{x}'_- t')$ and $\mathbf{A}_b(\mathbf{x}_- t, \mathbf{x}'_- t')$ collecting the 3×3 commutator and anticommutator functions of the bath of photons. They are sums of correlation functions over the bath of the oscillators of frequency $\Omega_{\mathbf{k}}$, each contributing with a weight $c_{\mathbf{k}}(\mathbf{x})c_{-\mathbf{k}}(\mathbf{x}') = e^{i\mathbf{k}(\mathbf{x}-\mathbf{x}')}/2\Omega_{\mathbf{k}}V$. Thus we may write, generalizing (18.197) and (18.198),

$$C_b^{ij}(\mathbf{x} t, \mathbf{x}' t') = \sum_{\mathbf{k}} c_{-\mathbf{k}}(\mathbf{x})c_{\mathbf{k}}(\mathbf{x}') \left\langle [\hat{X}_{-\mathbf{k}}^i(t), \hat{X}_{\mathbf{k}}^j(t')] \right\rangle_T \\ = -i\hbar \int \frac{d\omega' d^3k}{(2\pi)^4} \rho_{\mathbf{k}}(\omega') P_{\mathbf{k}}^{\perp ij} e^{i\mathbf{k}(\mathbf{x}-\mathbf{x}')} \sin \omega'(t-t'), \quad (18.550)$$

$$A_b^{ij}(\mathbf{x} t, \mathbf{x}' t') = \sum_{\mathbf{k}} c_{-\mathbf{k}}(\mathbf{x})c_{\mathbf{k}}(\mathbf{x}') \left\langle \left\{ \hat{X}_{-\mathbf{k}}^i(t), \hat{X}_{\mathbf{k}}^j(t') \right\} \right\rangle_T \\ = \hbar \int \frac{d\omega' d^3k}{(2\pi)^4} \rho_{\mathbf{k}}(\omega') P_{\mathbf{k}}^{\perp ij} \coth \frac{\hbar\omega'}{2k_B T} e^{i\mathbf{k}(\mathbf{x}-\mathbf{x}')} \cos \omega'(t-t'), \quad (18.551)$$

where $\rho_{\mathbf{k}}(\omega')$ is the spectral density contributed by the oscillator of momentum \mathbf{k} :

$$\rho_{\mathbf{k}}(\omega') \equiv \frac{2\pi}{2\Omega_{\mathbf{k}}} [\delta(\omega' - \Omega_{\mathbf{k}}) - \delta(\omega' + \Omega_{\mathbf{k}})]. \quad (18.552)$$

At zero temperature, we recognize in (18.550) and (18.551) twice the imaginary and real parts of the Feynman propagator of a massless particle for $t > t'$, which in four-vector notation with $k = (\omega/c, \mathbf{k})$ and $x = (ct, \mathbf{x})$ reads

$$G(x, x') = \frac{1}{2} [A(x, x') + C(x, x')] = \int \frac{d^4k}{(2\pi)^4} e^{ik(x-x')} \frac{i\hbar}{k^2 + i\eta} \\ = \int \frac{d\omega d^3k}{(2\pi)^4} \frac{ic\hbar}{\omega^2 - \Omega_{\mathbf{k}}^2 + i\eta} e^{-i[\omega(t-t') - \mathbf{k}(\mathbf{x}-\mathbf{x}')]}, \quad (18.553)$$

where η is an infinitesimally small number > 0 .

We shall now focus attention upon systems which are so small that the effects of retardation can be neglected. Then we can ignore the \mathbf{x} -dependence in (18.551) and (18.552) and find

$$C_b^{ij}(\mathbf{x}t, \mathbf{x}'t') \approx C_b^{ij}(t, t') = i \frac{\hbar}{2\pi c} \frac{2}{3} \delta^{ij} \partial_t \delta(t - t'). \quad (18.554)$$

Inserting this into (18.548) and integrating by parts, we obtain two contributions. The first is a diverging term

$$\Delta \mathcal{A}_{\text{loc}}[\mathbf{x}_+, \mathbf{x}_-] = \frac{\Delta M}{2} \int_{t_a}^{t_b} dt (\dot{\mathbf{x}}_+^2 - \dot{\mathbf{x}}_-^2)(t), \quad (18.555)$$

where

$$\Delta M \equiv -\frac{e^2}{c^2} \int \frac{d\omega' d^3k}{(2\pi)^4} \frac{\sigma_{\mathbf{k}}(\omega')}{\omega'} \delta_{\mathbf{k}\mathbf{k}}^{ij \text{tr}} = -\frac{e^2}{3\pi^2 c^3} \int_0^\infty dk \quad (18.556)$$

diverges linearly. This simply renormalizes the kinetic terms in the path integral (18.547), renormalizing them to

$$\frac{i}{\hbar} \int_{t_a}^{t_b} dt \frac{M_{\text{ren}}}{2} (\dot{\mathbf{x}}_+^2 - \dot{\mathbf{x}}_-^2). \quad (18.557)$$

By identifying M with M_{ren} this renormalization may be ignored.

The second term has the form [compare (18.205)]

$$\mathcal{A}_D^{\text{FV}}[\mathbf{x}_+, \mathbf{x}_-] = -\gamma \frac{M}{2} \int_{t_a}^{t_b} dt (\dot{\mathbf{x}}_+ - \dot{\mathbf{x}}_-)(t) (\ddot{\mathbf{x}}_+ + \ddot{\mathbf{x}}_-)^R(t), \quad (18.558)$$

with the friction constant of the photon bath encountered before in Eq. (3.444):

$$\gamma \equiv \frac{e^2}{6\pi c^3 M} = \frac{2}{3} \frac{\alpha}{\omega_M}, \quad (18.559)$$

where $\alpha \equiv e^2/\hbar c \approx 1/137$ is the fine-structure constant (1.505) and $\omega_M \equiv Mc^2/\hbar$ the Compton frequency associated with the mass M . Note once more that in contrast to the usual friction constant γ in Section 3.13, this has the dimension 1/frequency.

As discussed in Section 18.8, the retardation enforced by the Heaviside function in the exponent of (18.548) removes the left-hand half of the δ -function [see (18.214)]. It ensures the *causality* of the dissipation forces, which has been shown in Section 18.9.2 to be crucial for producing a probability conserving time evolution of the probability distribution [13]. The superscript R in (18.558) shifts the acceleration $(\ddot{\mathbf{x}}_+ + \ddot{\mathbf{x}}_-)(t)$ slightly towards an earlier time with respect to the velocity factor $(\dot{\mathbf{x}}_+ - \dot{\mathbf{x}}_-)(t)$.

We now turn to the anticommutator function. Inserting (18.552) and the friction constant γ from (18.559), it becomes

$$\frac{e^2}{c^2} A_b(\mathbf{x}t, \mathbf{x}'t') \approx 2\gamma k_B T K^{\text{Ohm}}(t, t'), \quad (18.560)$$

as in Eq. (18.216), with the same function $K^{\text{Ohm}}(t, t')$ as in Eq. (18.223), whose high-temperature expansion starts out as in Eq. (18.526).

In terms of the function $K^{\text{Ohm}}(t, t')$, the fluctuation part of the influence functional in (18.549), (18.548), (18.547) becomes [compare (18.227)]

$$\mathcal{A}_F^{\text{FV}}[\mathbf{x}_+, \mathbf{x}_-] = i \frac{w}{2\hbar} \int_{t_a}^{t_b} dt \int_{t_a}^{t_b} dt' (\dot{\mathbf{x}}_+ - \dot{\mathbf{x}}_-)(t) K^{\text{Ohm}}(t, t') (\dot{\mathbf{x}}_+ - \dot{\mathbf{x}}_-)(t'). \quad (18.561)$$

Here we have used the symmetry of the function $K^{\text{Ohm}}(t, t')$ to remove the Heaviside function $\Theta(t - t')$ from the integrand, extending the range of t' -integration to the entire interval (t_a, t_b) . We also have introduced the constant

$$w \equiv 2Mk_B T \gamma, \tag{18.562}$$

for brevity.

In the high-temperature limit, the time evolution amplitude for the density matrix is given by the path integral

$$\begin{aligned} U(\mathbf{x}_{+b}, \mathbf{x}_{-b}, t_b | \mathbf{x}_{+a}, \mathbf{x}_{-a}, t_a) &= \int \mathcal{D}\mathbf{x}_+(t) \int \mathcal{D}\mathbf{x}_-(t) \\ &\times \exp \left\{ \frac{i}{\hbar} \int_{t_a}^{t_b} dt \left[\frac{M}{2} (\dot{\mathbf{x}}_+^2 - \dot{\mathbf{x}}_-^2) - (V(\mathbf{x}_+) - V(\mathbf{x}_-)) \right] \right\} \\ &\times \exp \left\{ -\frac{i}{2\hbar} M \gamma \int_{t_a}^{t_b} dt (\dot{\mathbf{x}}_+ - \dot{\mathbf{x}}_-)(\ddot{\mathbf{x}}_+ + \ddot{\mathbf{x}}_-)^R - \frac{w}{2\hbar^2} \int_{t_a}^{t_b} dt (\dot{\mathbf{x}}_+ - \dot{\mathbf{x}}_-)^2 \right\}, \end{aligned} \tag{18.563}$$

where the last term is now local since $K^{\text{Ohm}}(t, t') \rightarrow \delta(t - t')$. In this limit (as in the classical limit $\hbar \rightarrow 0$), this term squeezes the forward and backward paths together. The density matrix (18.563) becomes diagonal. The γ -term, however, remains and describes classical radiation damping.

At moderately high temperature, we should include also the first correction term in (18.526) which adds to the exponent an additional term

$$-\frac{w}{24(k_B T)^2} \int_{t_a}^{t_b} dt (\ddot{\mathbf{x}}_+ - \ddot{\mathbf{x}}_-)^2. \tag{18.564}$$

The extended expression is the desired *closed-time path integral* of a particle in contact with a thermal reservoir.

18.20.2 Master Equation for Time Evolution in Photon Bath

It is possible to derive a master equation for the evolution of the density matrix $\rho(\mathbf{x}_{+a}, \mathbf{x}_{-a}; t_a)$ analogous to Eq. (18.530) for a quantum particle in a photon bath. Since the dissipative and fluctuating parts of the influence functional in Eq. (18.555) and (18.561) coincide with the corresponding terms in (18.230), except for an extra dot on top of the coordinates, the associated temperature-dependent Hamiltonian operator is directly obtained from (18.525) with the expansion (18.527) by adding the extra dots: In the high-temperature limit we obtain

$$\hat{\mathcal{H}} \equiv \frac{1}{2M} (\hat{\mathbf{p}}_+^2 - \hat{\mathbf{p}}_-^2) + V(\mathbf{x}_+) - V(\mathbf{x}_-) + \frac{M\gamma}{2} (\hat{\dot{\mathbf{x}}}_+ - \hat{\dot{\mathbf{x}}}_-)(\hat{\ddot{\mathbf{x}}}_+ + \hat{\ddot{\mathbf{x}}}_-)^R - i \frac{w}{2\hbar} (\hat{\dot{\mathbf{x}}}_+ - \hat{\dot{\mathbf{x}}}_-)^2, \tag{18.565}$$

extended at moderately high temperatures by the Hamiltonian corresponding to (18.564):

$$\Delta \hat{H}_T \equiv i \frac{w\hbar}{24(k_B T)^2} (\hat{\ddot{\mathbf{x}}}_+ - \hat{\ddot{\mathbf{x}}}_-)^2. \tag{18.566}$$

The master equation corresponding to the Ohmic equation (18.530) reads now

$$\begin{aligned} i\hbar \partial_t \hat{\rho} = \hat{H}_T \hat{\rho} &\equiv [\hat{H}, \hat{\rho}] + \frac{M\gamma}{2} \left(\hat{\dot{\mathbf{x}}} \hat{\dot{\mathbf{x}}} \hat{\rho} - \hat{\rho} \hat{\dot{\mathbf{x}}} \hat{\dot{\mathbf{x}}} + \hat{\dot{\mathbf{x}}} \hat{\rho} \hat{\dot{\mathbf{x}}} - \hat{\dot{\mathbf{x}}} \hat{\rho} \hat{\dot{\mathbf{x}}} \right) \\ &- \frac{iw}{2\hbar} [\hat{\dot{\mathbf{x}}}, [\hat{\dot{\mathbf{x}}}, \hat{\rho}]] - \frac{iw\hbar^2}{24(k_B T)^2} [\hat{\ddot{\mathbf{x}}}, [\hat{\ddot{\mathbf{x}}}, \hat{\rho}]]. \end{aligned} \tag{18.567}$$

The conservation of total probability and the positivity of $\hat{\rho}$ are ensured by the observation, that Eq. (18.567) can be written in the *Lindblad form*

$$\partial_t \hat{\rho} = -\frac{i}{\hbar} [\hat{H}, \hat{\rho}] - \sum_{n=1}^2 \left(\frac{1}{2} \hat{L}_n \hat{L}_n^\dagger \hat{\rho} + \frac{1}{2} \hat{\rho} \hat{L}_n \hat{L}_n^\dagger - \hat{L}_n^\dagger \hat{\rho} \hat{L}_n \right), \tag{18.568}$$

with the two Lindblad operators

$$\hat{L}_1 \equiv \frac{\sqrt{w}}{2\hbar} \hat{\mathbf{x}}, \quad \hat{L}_2 \equiv \frac{\sqrt{3w}}{2\hbar} \left(\hat{\mathbf{x}} - i \frac{\hbar}{3k_B T} \hat{\mathbf{x}} \right). \quad (18.569)$$

As noted in the discussion of Eq. (18.530), the operator order in (18.567) prevents the term $\hat{\mathbf{x}}\hat{\mathbf{x}}\hat{\rho}$ from being a pure divergence. By rewriting it as a sum of a commutator and an anticommutator, $[\hat{\mathbf{x}}, \hat{\mathbf{x}}]/2 + \{\hat{\mathbf{x}}, \hat{\mathbf{x}}\}/2$, the latter term is a pure divergence, and we can think of the first two γ -terms in (18.567) as being due to an additional anti-Hermitian *dissipation operator*

$$\hat{H}_\gamma = \gamma M \frac{1}{4} [\hat{\mathbf{x}}, \hat{\mathbf{x}}]. \quad (18.570)$$

For a free particle with $V(\mathbf{x}) \equiv 0$ and $[\hat{H}, \hat{\mathbf{p}}] = 0$, one has $\hat{\mathbf{x}}_\pm = \hat{\mathbf{p}}_\pm/M$ to all orders in γ , such that the time evolution equation (18.567) becomes

$$i\hbar\partial_t\hat{\rho} = [\hat{H}, \hat{\rho}] - \frac{iw}{2M^2\hbar} [\hat{\mathbf{p}}, [\hat{\mathbf{p}}, \hat{\rho}]]. \quad (18.571)$$

In the momentum representation of the density matrix $\hat{\rho} = \sum_{\mathbf{p}\mathbf{p}'} \rho_{\mathbf{p}\mathbf{p}'} |\mathbf{p}\rangle\langle\mathbf{p}'|$, the last term simplifies to $-i\Gamma \equiv -iw(\mathbf{p} - \mathbf{p}')^2/2M^2\hbar^2$ multiplying $\hat{\rho}$, which shows that a free particle does not dissipate energy by radiation, and that the off-diagonal matrix elements decay with the rate Γ .

For small e^2 , the implicit equation Eq. (18.565) with the expansion term (18.566) can be solved approximately in a single iteration step, inserting $\hat{\mathbf{x}} \approx \hat{\mathbf{p}}/M$ and $\hat{\mathbf{x}} \approx -\nabla V/M$.

18.20.3 Line Width

Let us apply the master equation (18.567) to atoms, where $V(\mathbf{x})$ is the Coulomb potential, assuming it to be initially in an eigenstate $|i\rangle$ of H , with a density matrix $\hat{\rho}(0) = |i\rangle\langle i|$. Since atoms decay rather slowly, we may treat the γ -term in (18.567) perturbatively. It leads to a time derivative of the density matrix

$$\begin{aligned} \partial_t \langle i | \hat{\rho}(t) | i \rangle &= -\frac{\gamma}{\hbar M} \langle i | [\hat{H}, \hat{\mathbf{p}}] \hat{\mathbf{p}} \hat{\rho}(0) | i \rangle = \frac{\gamma}{M} \sum_{f \neq i} \omega_{if} \langle i | \mathbf{p} | f \rangle \langle f | \mathbf{p} | i \rangle \\ &= -M\gamma \sum_f \omega_{if}^3 |\mathbf{x}_{fi}|^2, \end{aligned} \quad (18.572)$$

where $\hbar\omega_{if} \equiv E_i - E_f$, and $\mathbf{x}_{fi} \equiv \langle f | \mathbf{x} | i \rangle$ are the matrix elements of the dipole operator.

An extra width comes from the last two terms in (18.567):

$$\begin{aligned} \partial_t \langle i | \hat{\rho}(t) | i \rangle &= -\frac{w}{M^2\hbar^2} \langle i | \mathbf{p}^2 | i \rangle - \frac{w}{12M^2(k_B T)^2} \langle i | \hat{\mathbf{p}}^2 | i \rangle \\ &= -w \sum_n \omega_{if}^2 \left[1 + \frac{\hbar^2 \omega_{if}^2}{12(k_B T)^2} \right] |\mathbf{x}_{fi}|^2. \end{aligned} \quad (18.573)$$

This time dependence is caused by spontaneous emission and induced emission and absorption. To identify the different contributions, we rewrite the spectral decompositions (18.550) and (18.551) in the \mathbf{x} -independent approximation as

$$\begin{aligned} C_b(t, t') + A_b(t, t') & \quad (18.574) \\ &= \frac{4\pi}{3} \hbar \int \frac{d\omega' d^3k}{(2\pi)^4} \frac{\pi}{2M\Omega_{\mathbf{k}}} \left\{ 1 + \coth \frac{\hbar\omega'}{2k_B T} \right\} [\delta(\omega' - \Omega_{\mathbf{k}}) - \delta(\omega' + \Omega_{\mathbf{k}})] e^{-i\omega'(t-t')}, \end{aligned}$$

or

$$\begin{aligned} C_b(t, t') + A_b(t, t') & \quad (18.575) \\ &= \frac{4\pi}{3} \hbar \int \frac{d\omega' d^3k}{(2\pi)^4} \frac{\pi}{2M\Omega_{\mathbf{k}}} \left\{ 2\delta(\omega' - \Omega_{\mathbf{k}}) + \frac{2}{e^{\hbar\Omega_{\mathbf{k}}/k_B T} - 1} [\delta(\omega' - \Omega_{\mathbf{k}}) + \delta(\omega' + \Omega_{\mathbf{k}})] \right\} e^{-i\omega'(t-t')}. \end{aligned}$$

Following Einstein's intuitive interpretation, the first term in curly brackets is due to spontaneous emission, the other two terms accompanied by the Bose occupation function account for induced emission and absorption. For high and intermediate temperatures, (18.575) has the expansion

$$\frac{4\pi}{3}\hbar \int \frac{d\omega' d^3k}{(2\pi)^4} \frac{\pi}{2M\Omega_{\mathbf{k}}} \left\{ 2\delta(\omega' - \Omega_{\mathbf{k}}) + \left(\frac{2k_B T}{\hbar\Omega_{\mathbf{k}}} - 1 + \frac{1}{6} \frac{\hbar\Omega_{\mathbf{k}}}{k_B T} \right) [\delta(\omega' - \Omega_{\mathbf{k}}) + \delta(\omega' + \Omega_{\mathbf{k}})] \right\} e^{-i\omega'(t-t')}. \quad (18.576)$$

The first term in curly brackets corresponds to the spontaneous emission. It contributes to the rate of change $\partial_t \langle i|\hat{\rho}(t)|i \rangle$ a term $-2M\gamma \sum_{f<i} \omega_{if}^3 |\mathbf{x}_{fi}|^2$. This differs from the right-hand side of Eq. (18.572) in two important respects. First, the sum is restricted to the lower states $f < i$ with $\omega_{if} > 0$, since the δ -function allows only for decays. Second, there is an extra factor 2. Indeed, by comparing (18.574) with (18.576) we see that the spontaneous emission receives equal contributions from the 1 and the $\coth(\hbar\omega'/2k_B T)$ in the curly brackets of (18.574), i.e., from dissipation and fluctuation terms $C_b(t, t')$ and $A_b(t, t')$.

Thus our master equation yields for the natural line width of atomic levels the equation

$$\Gamma = 2M\gamma \sum_{f<i} \omega_{if}^3 |\mathbf{x}_{fi}|^2, \quad (18.577)$$

in agreement with the historic *Wigner-Weisskopf formula*.

In terms of Γ , the rate (18.572) can therefore be written as

$$\partial_t \langle i|\hat{\rho}(t)|i \rangle = -\Gamma + M\gamma \sum_{f<i} \omega_{if}^3 |\mathbf{x}_{fi}|^2 + M\gamma \sum_{f>i} |\omega_{if}|^3 |\mathbf{x}_{fi}|^2. \quad (18.578)$$

The second and third terms do not contribute to the total rate of change of $\langle i|\hat{\rho}(t)|i \rangle$ since they are canceled by the induced emission and absorption terms associated with the -1 in the big parentheses of the fluctuation part of (18.576). The finite lifetime changes the time dependence of the state $|i, t\rangle$ from $|i, 0\rangle e^{-iEt}$ to $|i, 0\rangle e^{-iEt - \Gamma t/2}$.

Note that due to the restriction to $f < i$ in (18.577), there is no operator local in time whose expectation value is Γ . Only the combination of spontaneous and induced emissions and absorptions in (18.578) can be obtained from a local operator, which is in fact the dissipation operator (18.570).

For all temperatures, the spontaneous and induced transitions together lead to the rate of change of $\langle i|\hat{\rho}(t)|i \rangle$:

$$\partial_t \langle i|\hat{\rho}(t)|i \rangle = -2M\gamma \left(\sum_{f<i} \omega_{if}^3 + \sum_f \omega_{if}^3 \frac{1}{e^{\hbar\omega_{if}/k_B T} - 1} \right) |\mathbf{x}_{fi}|^2. \quad (18.579)$$

For a state with principal quantum number n the temperature effects become detectable only if T becomes larger than $-1/(n+1)^2 + 1/n^2 \approx 2/n^3$ times the Rydberg temperature $T_{\text{Ry}} = 157886.601K$. Thus we have to go to $n \gtrsim 20$ to have observable effects at room temperature.

18.20.4 Lamb shift

For atoms, the Feynman influence functional (18.547) allows us to calculate the celebrated Lamb shift. Being interested in the time behavior of the pure-state density matrix $\rho = |i\rangle\langle i|$, we may calculate the effect of the actions (18.548) and (18.549) perturbatively. For this, consider the dissipative part of the influence action (18.548), and in it the first term involving $\mathbf{x}_+(t)$ and $\mathbf{x}_+(t')$,

and integrate the external positions in the path integral (18.547) over the initial wave functions, forming

$$U_{ii,t_b;ii,t_a} = \int d\mathbf{x}_{+b} d\mathbf{x}_{-b} \int d\mathbf{x}_{+a} d\mathbf{x}_{-a} \langle i|\mathbf{x}_{+b}\rangle \langle i|\mathbf{x}_{-b}\rangle \\ \times U(\mathbf{x}_{+b}, \mathbf{x}_{-b}, t_b | \mathbf{x}_{+a}, \mathbf{x}_{-a}, t_a) \langle \mathbf{x}_{+b}|i\rangle \langle \mathbf{x}_{-b}|i\rangle. \quad (18.580)$$

To lowest order in γ , the effect of the \mathbf{C}_b -term in (18.548) can be evaluated in the local approximation (18.554) as follows. We take the linear approximation to the exponential $\exp[\int dt dt' \mathcal{O}(t, t')] \approx 1 + \int dt dt' \mathcal{O}(t, t')$ and propagate the initial state with the help of the amplitude $U_{ii,t';ii,t_a}$ to the first time t' , then with $U_{fi,t;fi,t'}$ to the later time t , and finally with $U_{ii,t_a;ii,t}$ to the final time t_b . The intermediate state between the times t and t' are arbitrary and must be summed. Details how to do such a perturbation expansion are given in Section 3.17. Thus we find

$$\Delta_C U_{ii,t_b;ii,t_a} = i \frac{e^2}{2\hbar^2 c^2} \int_{t_a}^{t_b} dt dt' \sum_f \int d\mathbf{x}_+ \int d\mathbf{x}'_+ U_{ii,t_a;ii,t} \langle i|\mathbf{x}_+\rangle \mathbf{x}_+ \langle \mathbf{x}_+|f\rangle \\ \times [\partial_t \partial_{t'} \mathbf{C}_b(t, t')] U_{fi,t;fi,t'} \langle f|\mathbf{x}'_+\rangle \mathbf{x}'_+ \langle \mathbf{x}'_+|i\rangle U_{ii,t';ii,t_a}. \quad (18.581)$$

Inserting $U_{ii,t_a;ii,t} = e^{-iE_i(t_a-t)/\hbar}$ etc., this becomes

$$\Delta_C U_{ii,t_b;ii,t_a} = -\frac{e^2}{2\hbar^2 c^2} \int_{t_a}^{t_b} dt dt' \langle i|\hat{\mathbf{x}}(t) [\partial_t \partial_{t'} \mathbf{C}_b(t, t')] \hat{\mathbf{x}}(t')|i\rangle \\ = -\frac{e^2}{2\hbar^2 c^2} \sum_f \int_{t_a}^{t_b} dt dt' e^{i\omega_{if}(t-t')} \langle i|\hat{\mathbf{x}}|f\rangle \mathbf{C}_b(t, t') \langle f|\hat{\mathbf{x}}|i\rangle. \quad (18.582)$$

Expressing $C_b^{ij}(t, t')$ of Eq. (18.554) in the form

$$C_b^{ij}(t, t') = \frac{\hbar}{2\pi c} \frac{2}{3} \delta^{ij} \int \frac{d\omega}{2\pi} \omega e^{-i\omega(t-t')}, \quad (18.583)$$

the integration over t and t' yields

$$\Delta_C U_{ii,t_b;ii,t_a} = -i \frac{e^2}{4\pi\hbar c^3} \frac{2}{3} \int_{t_a}^{t_b} dt \int \frac{d\omega}{2\pi} \sum_f \frac{\omega}{\omega - \omega_{if} - i\eta} |\hat{\mathbf{x}}_{fi}|^2. \quad (18.584)$$

The same treatment is applied to the A_b in the action (18.549), where the first term involving $\mathbf{x}_+(t)$ and $\mathbf{x}_+(t')$ changes (18.585) to

$$\Delta U_{ii,t_b;ii,t_a} = -i \frac{e^2}{4\pi\hbar c^3} \frac{2}{3} \int_{t_a}^{t_b} dt \int \frac{d\omega}{2\pi} \sum_f \frac{\omega}{\omega - \omega_{if} + i\eta} \left(1 + \coth \frac{\hbar\omega}{2k_B T}\right) |\hat{\mathbf{x}}_{fi}|^2. \quad (18.585)$$

The ω -integral is conveniently split into a zero-temperature part

$$I(\omega_{if}, 0) \equiv \int_0^\infty \frac{d\omega}{\pi} \sum_f \frac{\omega}{\omega - \omega_{if} + i\eta}, \quad (18.586)$$

and a finite-temperature correction

$$\Delta I_T(\omega_{if}, T) \equiv 2 \int_0^\infty \frac{d\omega}{\pi} \sum_f \frac{\omega}{\omega - \omega_{if} + i\eta} \frac{1}{e^{\hbar\omega/k_B T} - 1}. \quad (18.587)$$

Decomposing $1/(\omega_{if} - \omega + i\eta) = \mathcal{P}/(\omega - \omega_{if}) - i\pi\delta(\omega_{if} - \omega)$, the imaginary part of the ω -integral yields half of the natural line width in (18.572). The other half comes from the part of the integral

(18.548) involving $\mathbf{x}_-(t)$ and $\mathbf{x}_-(t')$. The principal-value part of the zero-temperature integral diverges linearly, the divergence yielding again the mass renormalization (18.556). Subtracting this divergence from $I(\omega_{if}, 0)$, the remaining integral has the same form as $I(\omega_{if}, 0)$, but with ω in the numerator replaced by $\omega_{if} = 0$. This integral diverges logarithmically like $(\omega_{if}/\pi) \log[(\Lambda - \omega_{if})/|\omega_{if}|]$, where Λ is Bethe's cutoff [30]. For $\Lambda \gg |\omega_{if}|$, the result (18.585) implies an energy shift of the atomic level $|i\rangle$:

$$\Delta E_i = \frac{e^2}{4\pi c^3} \frac{2}{3\pi} \sum_f \omega_{if}^3 |\hat{\mathbf{x}}_{fi}|^2 \log \frac{\Lambda}{|\omega_{if}|}, \quad (18.588)$$

which is the *Lamb shift*.

Usually, the weakly varying logarithm is approximated by a weighted average $L = \log[\Lambda/\langle|\omega_{if}|\rangle]$ over energy levels and taken out of the integral. Then contribution of the term (18.585) can be attributed to an extra term

$$\hat{H}_{\text{LS}} \approx -i \frac{L}{\pi} \gamma M \frac{1}{4} [\hat{\mathbf{x}}, \hat{\mathbf{x}}] \quad (18.589)$$

in the Hamiltonian (18.567). In this form, the Lamb shift appears as a Hermitian logarithmically divergent correction to the operator (18.570) governing the spontaneous emission of photons.

To lowest order in γ , the commutator is for a Coulomb potential $V(\mathbf{x}) = -e^2/r$ equal to

$$-\frac{i}{M^2} [\hat{\mathbf{p}}, \hat{\mathbf{p}}] = \frac{\hbar}{M^2} \nabla^2 V(\mathbf{x}) = \frac{\hbar^2 c \alpha}{M^2} 4\pi \delta^{(3)}(\mathbf{x}), \quad (18.590)$$

leading to

$$\Delta E_i = \frac{4\alpha^2 \hbar^3}{3M^2 c} \langle i | \delta^{(3)}(\mathbf{x}) | i \rangle. \quad (18.591)$$

For an atomic state of principal quantum number n with a wave function $\psi_n(\mathbf{x})$, this becomes

$$\Delta E_n = \frac{4\alpha \hbar^3}{3M^2 c^2} \alpha L |\psi_n(\mathbf{0})|^2. \quad (18.592)$$

Only atomic s -states can contribute, since the wave functions of all other angular momenta vanish at the origin. Explicitly, the s -states of the hydrogen atom (13.219) have the value at the origin

$$\psi_n(\mathbf{0}) = \frac{1}{\sqrt{n^3 \pi}} \left(\frac{1}{a_H} \right)^{3/2}, \quad (18.593)$$

where $a_H = \hbar/Mc\alpha$ is the Bohr radius (4.376). If the nuclear charge is Z , then a_B , is diminished by this factor. Thus we obtain the energy shift

$$\Delta E_n = \frac{4\alpha^2 \hbar^3}{3M^2 c} \left(\frac{Mc\alpha}{\hbar} \right)^3 \frac{L}{n^3 \pi}. \quad (18.594)$$

For a hydrogen atom with $n = 2$, this becomes

$$\Delta E_2 = \frac{\alpha^3}{6\pi} \alpha^2 M c^2 L. \quad (18.595)$$

The quantity $M c^2 \alpha^2$ is the unit energy of atomic physics determining the hydrogen spectrum to be $E_n = -M c^2 \alpha^2 / 2n^2$. Thus

$$M \alpha^2 = 4.36 \times 10^{-11} \text{erg} = 27.21 \text{eV} = 2 \text{Ry} = 2 \cdot 3.288 \times 10^{15} \text{Hz}. \quad (18.596)$$

Inserting this together with $\alpha \approx 1/137.036$ into (18.595) yields¹⁰

$$\Delta E_2 \approx 135.6 \text{MHz} \times L. \quad (18.597)$$

The constant L can be calculated approximately as

$$L \approx 9.3, \quad (18.598)$$

leading to the estimate

$$\Delta E_2 \approx 1261 \text{MHz}. \quad (18.599)$$

The experimental Lamb shift

$$\Delta E_{\text{Lamb shift}} \approx 1057 \text{MHz} \quad (18.600)$$

is indeed contained in this range. In this calculation, two effects have been ignored: the vacuum polarization of the photon and the form factor of the electron caused by radiative corrections. They reduce the frequency (18.599) by $(27.3 + 51)\text{MHz}$ bringing the theoretical number closer to experiment. The vacuum polarization will be discussed in detail in Section 19.4.

At finite temperature, (18.588) changes to

$$\Delta E_i = \frac{e^2}{4\pi c^3} \frac{2}{3\pi} \sum_f \omega_{if}^3 |\hat{\mathbf{x}}_{fi}|^2 \left[\log \frac{\Lambda}{|\omega_{if}|} + \left(\frac{k_B T}{\hbar \omega_{ij}} \right)^2 J \left(\frac{\hbar \omega_{if}}{k_B T} \right) \right], \quad (18.601)$$

where $J(z)$ denotes the integral

$$J(z) \equiv z \int_0^\infty dz \frac{\mathcal{P}}{z' - z} \frac{z'}{e^{z'} - 1}, \quad (18.602)$$

which has the low-temperature (large- z) expansion $J(z) = -\pi^2/6 - 2\zeta(3)/z + \dots$, and goes to zero for high temperature (small z) like $-z \log z$, as shown in Fig. 18.2.

Figure 18.2 Behavior of function $6J(z)/\pi^2$ in finite-temperature Lamb shift.

The above equations may have applications to dilute interstellar gases or, after a reformulation in a finite volume, to few-particle systems contained in cavities. So far, a master equation has been set up only for a finite number of modes [31].

¹⁰The precise value of the Lamb constant $\alpha^4 M/6\pi$ is 135.641 ± 0.004 MHz.

18.20.5 Langevin Equations

For high γT , the last term in the forward–backward path integral (18.563) makes the size of the fluctuations in the difference between the paths $\mathbf{y}(t) \equiv \mathbf{x}_+(t) - \mathbf{x}_-(t)$ very small. It is then convenient to introduce the average of the two paths as $\mathbf{x}(t) \equiv [\mathbf{x}_+(t) + \mathbf{x}_-(t)]/2$, and expand

$$V\left(\mathbf{x} + \frac{\mathbf{y}}{2}\right) - V\left(\mathbf{x} - \frac{\mathbf{y}}{2}\right) \sim \mathbf{y} \cdot \nabla V(\mathbf{x}) + \mathcal{O}(\mathbf{y}^3) \dots, \quad (18.603)$$

keeping only the first term. We further introduce an auxiliary quantity $\boldsymbol{\eta}(t)$ by

$$\dot{\boldsymbol{\eta}}(t) \equiv M\ddot{\mathbf{x}}(t) - M\gamma\dot{\mathbf{x}}(t) + \nabla V(\mathbf{x}(t)). \quad (18.604)$$

With this, the exponential function in (18.563) becomes

$$\exp\left[-\frac{i}{\hbar} \int_{t_a}^{t_b} dt \dot{\mathbf{x}} \boldsymbol{\eta} - \frac{w}{2\hbar^2} \int_{t_a}^{t_b} dt \dot{\mathbf{y}}^2(t)\right], \quad (18.605)$$

where w is the constant (18.562).

Consider now the diagonal part of the amplitude (18.603) with $\mathbf{x}_{+b} = \mathbf{x}_{-b} \equiv \mathbf{x}_b$ and $\mathbf{x}_{+a} = \mathbf{x}_{-a} \equiv \mathbf{x}_a$, implying that $\mathbf{y}_b = \mathbf{y}_a = 0$. It represents a probability distribution

$$P(\mathbf{x}_b, t_b | \mathbf{x}_a, t_a) \equiv |(\mathbf{x}_b, t_b | \mathbf{x}_a, t_a)|^2 \equiv U(\mathbf{x}_b, \mathbf{x}_b, t_b | \mathbf{x}_a, \mathbf{x}_a, t_a). \quad (18.606)$$

Now the variable \mathbf{y} can simply be integrated out in (18.605), and we find the probability distribution

$$P[\boldsymbol{\eta}] \propto \exp\left[-\frac{1}{2w} \int_{t_a}^{t_b} dt \boldsymbol{\eta}^2(t)\right]. \quad (18.607)$$

The expectation value of an arbitrary functional of $F[x]$ can be calculated from the path integral

$$\langle F[\mathbf{x}] \rangle_{\boldsymbol{\eta}} \equiv \mathcal{N} \int \mathcal{D}\mathbf{x} P[\boldsymbol{\eta}] F[\mathbf{x}], \quad (18.608)$$

where the normalization factor \mathcal{N} is fixed by the condition $\langle 1 \rangle = 1$. By a change of integration variables from $x(t)$ to $\eta(t)$, the expectation value (18.608) can be rewritten as a functional integral

$$\langle F[\mathbf{x}] \rangle_{\boldsymbol{\eta}} \equiv \mathcal{N} \int \mathcal{D}\boldsymbol{\eta} P[\boldsymbol{\eta}] F[\mathbf{x}]. \quad (18.609)$$

Note that the probability distribution (18.607) is \hbar -independent. Hence in the approximation (18.603) we obtain the classical Langevin equation. In principle, the integrand contains a factor $J^{-1}[x]$, where $J[x]$ is the functional Jacobian

$$J[\mathbf{x}] \equiv \text{Det}[\delta\eta^i(t)/\delta x^j(t')] = \det[(M\partial_t^2 - M\gamma\partial_t^{3R})\delta_{ij} + \nabla_i \nabla_j V(\mathbf{x}(t))]. \quad (18.610)$$

By the same procedure as in Section 18.9.2 it can be shown that the determinant is unity, due to the retardation of the friction term, thus justifying its omission in (18.609).

The path integral (18.609) may be interpreted as an expectation value with respect to the solutions of a *stochastic differential equation* (18.604) driven by a Gaussian random *noise* variable $\eta(t)$ with a correlation function

$$\langle \eta^i(t) \eta^j(t') \rangle_T = \delta^{ij} w \delta(t - t'). \quad (18.611)$$

Since the dissipation carries a third time derivative, the treatment of the initial conditions is nontrivial and will be discussed elsewhere. In most physical applications γ leads to slow decay rates. In this case the simplest procedure to solve (18.604) is to write the stochastic equation as

$$M\ddot{\mathbf{x}}(t) + \nabla V(\mathbf{x}(t)) = \dot{\boldsymbol{\eta}}(t) + M\gamma\dot{\mathbf{x}}(t), \quad (18.612)$$

and solve it iteratively, first without the γ -term, inserting the solution on the right-hand side, and such a procedure is equivalent to a perturbative expansion in γ in Eq. (18.563).

Note that the lowest iteration of Eq. (18.612) with $\boldsymbol{\eta} \equiv 0$ can be multiplied by $\dot{\mathbf{x}}$ and leads to the equation for the energy change of the particle

$$\frac{d}{dt} \left[\frac{M}{2} \dot{\mathbf{x}}^2 + V(\mathbf{x}) - M\gamma \dot{\mathbf{x}}\ddot{\mathbf{x}} \right] = -M\gamma \ddot{\mathbf{x}}^2. \quad (18.613)$$

The right-hand side is the classical electromagnetic power radiated by an accelerated particle. The extra term in the brackets is known as *Schott term* [32].

18.21 Fokker-Planck Equation in Spaces with Curvature and Torsion

According to the new equivalence principle found in Chapter 10, equations of motion can be transformed by a nonholonomic transformation $dx^i = e^i{}_\mu(q) dq^\mu$ into spaces with curvature and torsion, where they are applicable to the diffusion of atoms in crystals with defects [33]. If we denote $g_{\mu\nu} \dot{q}^\nu$ by v_μ , the Langevin equation (18.317) goes over into

$$\dot{v}_\mu = F_\mu(q, v) + e^i{}_\mu(q) \eta_i \quad (18.614)$$

where $F_\mu(q, v)$ is the sum of all forces after the nonholonomic transformation:

$$F_\mu(q, v) \equiv M [\Gamma_{\nu\lambda\mu}(q) v^\nu v^\lambda - \gamma v_\mu] - \partial_\mu V(q). \quad (18.615)$$

In addition to the transformed force (18.384), $F_\mu(q, v)$ contains the apparent forces resulting from the coordinate transformation. For a distribution

$$P_\eta(qv t | q_a v_a t_a) = \delta(q_\eta(t) - q) \delta(\dot{q}_\eta - v_\mu) \quad (18.616)$$

one obtains, instead of (18.383), the Kubo equation

$$\partial_t P_\eta(qv t | q_a v_a t_a) = \left\{ -\partial_\mu g^{\mu\nu}(q) v_\nu - \frac{1}{M} \partial_\mu^v [e^i{}_\mu(q) \eta_i + F_\mu(q, v)] \right\} P_\eta(qv t | q_a v_a t_a), \quad (18.617)$$

and from this the generalization of the Fokker-Planck equation (18.393) to spaces with curvature and torsion:

$$\partial_t P(xv t | x_a v_a t_a) = \left\{ -\partial_\mu g^{\mu\nu} v_\nu + \frac{1}{M} \partial_\mu^v \left[\frac{w}{2M} \partial_\mu^v - F_\mu(q, v) \right] \right\} P(xv t | x_a v_a t_a). \quad (18.618)$$

In the overdamped limit, the integrated probability distributions

$$P(qt | q_a t_a) \equiv \int d^D v P(qv t | q_a v_a t_a) \quad (18.619)$$

satisfies the equation [generalizing (18.399)]

$$\partial_t P(qt | q_a t) = \left[D \partial_\mu e_i{}^\mu \partial_\nu e_i{}^\nu + \frac{1}{M\gamma} \partial_\nu g^{\mu\nu} V_\nu(q) \right] P(qt | q_a t), \quad (18.620)$$

where $V_\nu(q) \equiv \partial_\nu V(q)$.

In the Fokker-Planck equations (18.617) and (18.620), the probability distributions $P(qv t | q_a v_a t_a)$ and $P(qt | q_a t)$ have the unit normalizations

$$\int d^D q d^D v P(qv t | q_a v_a t_a) = 1, \quad \int d^D q P(qt | q_a t) = 1, \quad (18.621)$$

as can be seen from the definitions (18.616) and (18.619). For distributions normalized with the invariant volume integral $\int d^D q \sqrt{g}$, to be denoted by $P^{\text{inv}}(qt|q_a t_a) \equiv \sqrt{g}^{-1} P(qt|q_a t)$, we obtain from (18.620) the following invariant Fokker-Planck equation:

$$\partial_t P^{\text{inv}}(qt|q_a t_a) = \left\{ \frac{D}{\sqrt{g}} \partial_\mu g^{\mu\nu} \sqrt{g} \left[\partial_\nu + 2S_\nu + \frac{1}{k_B T} V_\nu(x) \right] \right\} P^{\text{inv}}(qt|q_a t_a). \quad (18.622)$$

The first term on the right-hand side contains the Laplace-Beltrami operator (11.13).

With the help of the covariant derivative D_μ^* defined in Eq. (11.96), which arises from D_μ by a partial integration, this equation can also be written as

$$\partial_t P^{\text{inv}}(qt|q_a t_a) = \left[D g^{\mu\nu} D_\mu^* D_\nu^* + \frac{1}{M\gamma} \bar{D}_\mu V^\mu(x) \right] P^{\text{inv}}(qt|q_a t_a), \quad (18.623)$$

where \bar{D}_μ is the covariant derivative (10.37) associated with the Christoffel symbol.

18.22 Stochastic Interpretation of Quantum-Mechanical Amplitudes

In the last section we have seen that the probability distribution $|(x_b, t_b|x_a, t_a)|^2$ is the result of a stochastic differential equation describing a classical path disturbed by a noise term $\eta(t)$ with the correlation function (18.320). It is interesting to observe that the quantum-mechanical amplitude $(x_b, t_b|x_a, t_a)$ possesses quite a similar stochastic interpretation, albeit with some imaginary factors i and an unsatisfactory aspect as we shall see. Recall the path integral representation of the time evolution amplitude in Eq. (2.712). It involves the action $A(x, t; x_a, t_a)$ from the initial point x_a to the actual particle position x . Recalling the definition of the fluctuation factor $F(x_b, x_a; t_b - t_a)$ in Eq. (4.97), we see that this factor is given by the path integral

$$F(x_b, x_a; t_b - t_a) = \int_{(x_a, t_a) \rightsquigarrow (x_b, t_b)} \mathcal{D}x \exp \left[\frac{i}{\hbar} \int_{t_a}^{t_b} dt \frac{M}{2} (\dot{x} - v)^2 \right], \quad (18.624)$$

where $v(x, t) = (1/M) \partial_x A(x, x_a; t_b - t_a)$ is the classical particle velocity. Up to a factor i and the absence of the retardation symbol, this path integral has the same form as the one for the probability (18.290) at large damping. As in (2.713) we introduce the momentum variable $p(t)$ and obtain the canonical path integral

$$F(x_b, x_a; t_b - t_a) = \int_{(x_a, t_a) \rightsquigarrow (x_b, t_b)} \mathcal{D}'x \frac{\mathcal{D}p}{2\pi\hbar} e^{(i/\hbar) \int_{t_a}^{t_b} dt \{ p(t)[\dot{x}(t) - v(x(t), t)] - p^2(t)/2M \}}, \quad (18.625)$$

which looks similar to the stochastic path integral (18.290). The role of the diffusion constant $D = k_B T/M\gamma$ is now played by $\hbar/2$. By analogy with the path integral of a particle in a magnetic field in (2.654), the fluctuation factor satisfies a Schrödinger-like equation

$$\left(\frac{\hat{p}_b^2}{2M} + \frac{1}{2} \{ \hat{p}_b, v_b \} \right) F(x_b, x_a; t_b - t_a) = i\hbar F(x_b, x_a; t_b - t_a). \quad (18.626)$$

This can easily be verified for the free particle, where $v_b = (x_b - x_a)/(t_b - t_a)$, and the fluctuation factor is from (2.130) $F(x_b, x_a; t_b - t_a) = \sqrt{2\pi i\hbar(t_b - t_a)}$. Note the symmetric operator order of the product $\hat{p}v$ in accordance with the time slicing in Section 10.5, and the ensuing operator order observed in Eq. (11.88). By reordering the Hamiltonian operator on the left-hand side of (18.626) to position \hat{p} to the left of the velocity,

$$\hat{H} \rightarrow \frac{\hat{p}^2}{2M} + \hat{p}v + \frac{i}{2} \nabla v. \quad (18.627)$$

Without the last term, the path integral (18.625) would describe fluctuating paths obeying the stochastic differential equation analogous to the classical Langevin equation (18.338) [34]:

$$\dot{x}(t) - v(x(t), t) = p(t)/M. \quad (18.628)$$

The momentum variable $p(t)$ plays the role of the noise variable $\eta(t)$. Up to a factor i , this *quantum noise* has the same correlation functions as a white-noise variable:

$$\langle p(t)p(t') \rangle = -iM\hbar\delta(t-t'). \quad (18.629)$$

The “Fokker-Planck equation” associated with this “process” would be the ordinary Schrödinger equation for the amplitude $(x_b t_b | x_a t_a)$.

For a free particle, the ordering problem can be solved by noting that in the path integral (18.624), the constant v can be removed from the path integral leaving

$$F(x_b, x_a; t_b - t_a) = e^{-iA(x_b, x_a; t_b - t_a)/\hbar} \int_{(x_a, t_a) \rightsquigarrow (x_b, t_b)} \mathcal{D}x \exp\left(\frac{i}{\hbar} \int_{t_a}^{t_b} dt \frac{M}{2} \dot{x}^2\right), \quad (18.630)$$

the right-hand factor being the path integral for the amplitude $(x_b t_b | x_a t_a)$ itself. This is identical with the path integral for the probability distribution of Brownian motion, and quantum-mechanical fluctuations are determined by the process

$$\dot{x}(t) = p(t)/M, \quad (18.631)$$

with the quantum noise (18.629).

But also in the presence of a potential, it is possible to specify a process which properly represents quantum-mechanical fluctuations, although the situation is more involved [35]. To find it we rewrite the action in (18.624) as

$$\mathcal{A} = \int_{t_a}^{t_b} dt \frac{M}{2} (\dot{x} - v)^2 = \int_{t_a}^{t_b} dt \frac{M}{2} \left[(\dot{x} - s)^2 - \frac{i\hbar}{2} s'^2 \right], \quad (18.632)$$

with some as yet unknown function $s(x)$. The associated Hamiltonian is now

$$\hat{H} \rightarrow \frac{\hat{p}^2}{2M} + \frac{1}{2}\{\hat{p}, s\} + i\hbar s'^2 = \frac{\hat{p}^2}{2M} + \hat{p}s, \quad (18.633)$$

with the proper operator order. In order for (18.632) to hold, the function $s(x)$ must satisfy the equations

$$v = s', \quad -i\hbar s'^2 + s^2 = v^2. \quad (18.634)$$

Recalling Eqs. (4.12) and (4.5) we see that the equations in (18.634) can be satisfied with the help of the full eikonal $S(x)$:

$$s(x) = S(x)/M. \quad (18.635)$$

The process which describes the quantum-mechanical fluctuations is therefore

$$\dot{x}(t) - S(x)/M = p(t)/M. \quad (18.636)$$

The analogy is, however, not really satisfactory, since the full eikonal contains information on all fluctuations. Indeed, by the definition (4.4), it is given by the logarithm of the amplitude $(x t | x_a t_a)$, or any superposition $\psi(x, t) = \int dx_a (x t | x_a t_a) \psi(x_a t_a)$ of it:

$$S(x) = -i\hbar \log(x t | x_a t_a). \quad (18.637)$$

For the fluctuation factor this implies

$$s(x) - v(x) = \delta v(x) \equiv -\frac{i}{M} \hbar F(x|t|x_a t_a). \quad (18.638)$$

The path integral representation (18.624) for the fluctuation factor which has maximal analogy with the stochastic path integral (18.300) is therefore

$$F(x_b t_b, x_a t_a) = \int_{(x_a, t_a) \sim (x_b, t_b)} \mathcal{D}x \exp \left\{ \frac{i}{\hbar} \int_{t_a}^{t_b} dt \frac{M}{2} \left[\dot{x}^R - v + \frac{i}{M} \hbar \log F(x_b t_b, x_a t_a) \right]^2 \right\}. \quad (18.639)$$

Since we have to know $F(x_b t_b, x_a t_a)$ to describe quantum-mechanical fluctuations as a process, this representation is of little practical use. The initial representation (18.624) which does not correspond to a proper process can, however, be used to solve quantum-mechanical problems.

18.23 Stochastic Equation for Schrödinger Wave Function

It is possible to write a stochastic type of path integral for the Schrödinger wave function $\psi(\mathbf{x}, t)$ in D dimensions. By close analogy with Eq. (18.403), it reads

$$\psi(\mathbf{x}_b, t_b) = \int \mathcal{D}\mathbf{v} e^{(i/\hbar) \int_{t_a}^{t_b} dt [(M/2)\mathbf{v}^2(t) - V(\mathbf{x}_v(t_b, t))]} \psi(\mathbf{x}_v(t_b, t_a), t_a), \quad (18.640)$$

where

$$\mathbf{x}_v(t_b, t) \equiv \mathbf{x}(t_b) - \int_t^{t_b} dt' \mathbf{v}(t') \quad (18.641)$$

is a functional of $\mathbf{v}(t')$ parameterizing all possible fluctuating paths arriving at the fixed final point $\mathbf{x}(t_b)$ after having started from an arbitrary initial point $\mathbf{x}(t)$. They are *Brownian bridges* between the two points. The variables $\mathbf{v}(t)$ are the independently fluctuating velocities of the particle. The natural appearance of the velocities in the measure of the stochastic path integral (18.640) is in agreement with our observation in Eq. (10.141) that the time-sliced measure should contain the coordinate *differences* $\Delta \mathbf{x}_n$ as the integration variables rather than the coordinates themselves, which was the starting point for the nonholonomic coordinate transformations to spaces with curvature and torsion.

We easily verify that (18.640) satisfies the Schrödinger equation by calculating the wave function at a slightly later time $t_b + \epsilon$, and expanding the right-hand side in powers of ϵ . Using the correlation functions

$$\langle v^i(t) \rangle = 0, \quad \langle v^i(t) v^j(t') \rangle = i\hbar \delta^{ij} \delta(t - t'), \quad (18.642)$$

we find, via a similar intermediate step as in (18.404), the desired result:

$$i\partial_t \psi(\mathbf{x}, t) = \left[-\frac{\hbar^2}{2M} \partial_{\mathbf{x}}^2 + V(\mathbf{x}) \right] \psi(\mathbf{x}, t). \quad (18.643)$$

One may also write down a corresponding path integral for the time evolution amplitude

$$(\mathbf{x}_b t_b | \mathbf{x}_a t_a) = \int \mathcal{D}\mathbf{v} e^{(i/\hbar) \int_{t_a}^{t_b} dt [(M/2)\mathbf{v}^2(t) - V(\mathbf{x}_v(t_b, t))]} \delta^{(D)}(\mathbf{x}_a - \mathbf{x}_b + \int_{t_a}^{t_b} dt \mathbf{v}(t)), \quad (18.644)$$

which returns the Schrödinger amplitude (18.640) after convolution with $\psi(\mathbf{x}_a, t_a)$ (and reduces to $\delta^{(D)}(\mathbf{x}_a - \mathbf{x}_b)$ for $t_b \rightarrow t_a$, as it should).

The addition of an interaction with a vector potential is nontrivial. The electromagnetic interaction in (10.168)

$$\mathcal{A}_{\text{em}} = \int_{t_a}^t dt \mathbf{A}(\mathbf{x}(t)) \cdot \dot{\mathbf{x}} \quad (18.645)$$

cannot be simply inserted into the exponent of the path integral (18.640) since in the evaluation via the correlation functions (18.642) assumes the independence of the noise variables $\mathbf{v}(t)$. This, however, is not true in the interaction (18.645). Recall the discussion in Section 10.6 which showed that the time-sliced version of the interaction (18.645) must contain the midpoint ordering of the vector potential with respect to the intervals $\Delta\mathbf{x}$ to be compatible with the classical field equation. In Section 11.3 we have furthermore seen that this guaranteed gauge invariance. For the time-sliced short-time action, this implies that (18.645) has the form [see (10.179)]

$$\mathcal{A}_{\text{em}}^{\epsilon} = \mathbf{A}(\bar{\mathbf{x}}) \cdot \Delta\mathbf{x}. \quad (18.646)$$

In this expression, a variation of $\Delta\mathbf{x}$ changes also $\bar{\mathbf{x}}$, implying that in the sum over all sliced actions, the $\Delta\mathbf{x}$ are not independent. This is only achieved by the re-expanded postpoint interaction [see 10.178]. In the continuum, we shall indicate the postpoint product as before in (18.231) by a retardation symbol R , and rewrite (18.645) as

$$\mathcal{A}_{\text{em}} = \int_{t_a}^t dt \left[\mathbf{A}(\mathbf{x}(t)) \dot{\mathbf{x}}^R(t) - i\epsilon \frac{\hbar}{2M} \nabla \cdot \mathbf{A}(\mathbf{x}(t)) \right]. \quad (18.647)$$

In the theory of stochastic differential equations, this postpoint expression is called an *Itô integral*. The ordinary midpoint integral (18.645) is referred to as *Stratonovich integral*.

The Itô integral can now be added to the action in (18.644) with $\dot{\mathbf{x}}(t)$ replaced by $\mathbf{v}(t)$, and we obtain

$$\begin{aligned} (\mathbf{x}_b t_b | \mathbf{x}_a t_a) &= \int \mathcal{D}\mathbf{v} \exp \left\{ \frac{i}{\hbar} \int_{t_a}^{t_b} dt \left[\frac{M}{2} \mathbf{v}^2(t) + \mathbf{A}(\mathbf{x}_{\mathbf{v}}(t_b, t)) \mathbf{v}^R(t) - V(\mathbf{x}_{\mathbf{v}}(t_b, t)) \right] \right\} \\ &\times \exp \left\{ \frac{i}{\hbar} \int_{t_a}^{t_b} dt \left[-i\epsilon \frac{\hbar}{2M} \nabla \cdot \mathbf{A}(\mathbf{x}_{\mathbf{v}}(t_b, t)) \right] \right\} \delta^{(D)}(\mathbf{x}_a - \mathbf{x}_b + \int_{t_a}^{t_b} dt \mathbf{v}(t)). \end{aligned} \quad (18.648)$$

Expanding the functional integrand in powers of $\mathbf{v}(t)$ as in (18.403) and using the correlation functions (18.642) we obtain the Schrödinger equation

$$i\partial_t (\mathbf{x} t | \mathbf{x}_a t_a) = \left[-\frac{\hbar^2}{2M} [\nabla - i\mathbf{A}(\mathbf{x})]^2 + V(\mathbf{x}) \right] (\mathbf{x} t | \mathbf{x}_a t_a). \quad (18.649)$$

The advantage of the Itô integral is that such a calculation becomes quite simple using the correlation functions (18.642). The integral itself, however, is awkward to handle since it cannot be modified by partial integration. This is only possible for the ordinary, Stratonovich integral.

18.24 Real Stochastic and Deterministic Equation for Schrödinger Wave Function

The noise variable in the previous stochastic differential equation had an imaginary correlation function (18.629). It is possible to set up a completely real stochastic differential equation and modify this into a simple deterministic model which possesses the quantum properties of a particle in an arbitrary potential. In particular, the model has a discrete energy spectrum with a definite ground state energy, in this respect going beyond an earlier model by 't Hooft [36], whose spectrum was unbounded from below.

Let $\mathbf{u}(\mathbf{x}) = (u^1(\mathbf{x}), u^2(\mathbf{x}))$ be a time-independent field in two dimensions to be called *mother field*. The reparametrization freedom of the spatial coordinates is fixed by choosing harmonic coordinates in which

$$\nabla^2 u(\mathbf{x}) = 0, \quad (18.650)$$

where ∇^2 is the Laplace operator. Equivalently, the components $u^1(\mathbf{x})$ and $u^2(\mathbf{x})$ may be assumed to satisfy the Cauchy-Riemann equations

$$\partial_\mu u^\nu = \epsilon_{\mu\rho} \epsilon^\nu{}_\sigma \partial_\rho u^\sigma, \quad (\mu, \nu, \dots = 1, 2), \quad (18.651)$$

where $\epsilon_{\mu\nu}$ is the antisymmetric Levi-Civita pseudotensor. The metric is $\delta_{\mu\nu}$, so that indices can be sub- or superscripts.

18.24.1 Stochastic Differential Equation

Consider now a point particle in contact with a heat bath of “temperature” \hbar . Its classical orbit $\mathbf{x}(t)$ is assumed to follow a stochastic differential equation consisting of a fixed rotation and a random translation in the diagonal direction $\mathbf{n} \equiv (1, 1)$:

$$\dot{\mathbf{x}}(t) = \boldsymbol{\omega} \times \mathbf{x}(t) + \mathbf{n} \eta(t), \quad (18.652)$$

where $\boldsymbol{\omega}$ is the rotation vector of length ω pointing orthogonal to the plane, and $\eta(t)$ a white-noise variable with zero expectation and the correlation function

$$\langle \eta(t) \eta(t') \rangle = \hbar \delta(t - t'). \quad (18.653)$$

For a particle starting at $\mathbf{x}(0) = \mathbf{x}$, the position $\mathbf{x}(t)$ at a later time t is a function of \mathbf{x} and a *functional* of the noise variable $\eta(t')$ for $0 < t' < t$:

$$\mathbf{x}(t) = \mathbf{X}_\eta(\mathbf{x}, t). \quad (18.654)$$

As earlier in Section 18.13, a subscript η is used to indicate the functional dependence on the noise variable ν .

We now use the orbits ending at all possible final points $\mathbf{x} = \mathbf{x}(t)$ to define a time-dependent field $\mathbf{u}(\mathbf{x}; t)$ which is equal to $\mathbf{u}(\mathbf{x})$ at $t = 0$, and evolves with time as follows:

$$\mathbf{u}(\mathbf{x}; t) = \mathbf{u}_t[\mathbf{x}; \eta] \equiv \mathbf{u}(\mathbf{X}_0[t, \mathbf{x}; \eta]), \quad (18.655)$$

where the notation $\mathbf{u}_t[\mathbf{x}; \eta]$ indicates the variables as in (18.654).

As a consequence of the dynamic equation (20A.1), the change of the field $\mathbf{u}(\mathbf{x}, t)$ in a small time interval from $t = 0$ to $t = \Delta t$ has the expansion

$$\begin{aligned} \Delta \mathbf{u}_\eta(\mathbf{x}, 0) &= \Delta t [\boldsymbol{\omega} \times \mathbf{x}] \cdot \nabla \mathbf{u}_\eta(\mathbf{x}, 0) + \int_0^{\Delta t} dt' \eta(t') (\mathbf{n} \cdot \nabla) \mathbf{u}_\eta(\mathbf{x}, 0) \\ &+ \frac{1}{2} \int_0^{\Delta t} dt' \int_0^{\Delta t} dt'' \eta(t') \eta(t'') (\mathbf{n} \cdot \nabla)^2 \mathbf{u}_\eta(\mathbf{x}, 0) + \dots \end{aligned} \quad (18.656)$$

The omitted terms are of order $\Delta t^{3/2}$.

18.24.2 Equation for Noise Average

We now perform the noise average of Eq. (20A.2), defining the average field

$$\mathbf{u}(\mathbf{x}, t) \equiv \langle \mathbf{u}_\eta(\mathbf{x}, t) \rangle. \quad (18.657)$$

Using the vanishing average of $\eta(t)$ and the correlation function (18.653), we obtain in the limit $\Delta t \rightarrow 0$ the time derivative

$$\partial_t \mathbf{u}(\mathbf{x}, t) = \hat{\mathcal{H}} \mathbf{u}(\mathbf{x}, t), \quad \text{at } t = 0, \quad (18.658)$$

with the time evolution operator

$$\hat{\mathcal{H}} \equiv \{[\boldsymbol{\omega} \times \mathbf{x}] \cdot \nabla\} + \frac{\hbar}{2}(\mathbf{n} \cdot \nabla)^2. \quad (18.659)$$

The average over η has made the operator $\hat{\mathcal{H}}$ time-independent. For this reason, the average field $\mathbf{u}(\mathbf{x}, t)$ at an arbitrary time t is obtained by the operation

$$\mathbf{u}(\mathbf{x}, t) = \hat{U}(t)\mathbf{u}(\mathbf{x}, 0), \quad (18.660)$$

where $\hat{U}(t)$ is a simple exponential

$$\hat{U}(t) \equiv e^{\hat{\mathcal{H}}t}, \quad (18.661)$$

as follows immediately from (18.658) and the trivial property $\hat{\mathcal{H}}\hat{U}(t) = \hat{U}(t)\hat{\mathcal{H}}$.

Note that the operator $\hat{\mathcal{H}}$ commutes with the Laplace operator ∇^2 , thus ensuring that the harmonic property (18.650) of $\mathbf{u}(\mathbf{x})$ remains true for all times, i.e.,

$$\nabla^2 \mathbf{u}(\mathbf{x}, t) \equiv 0. \quad (18.662)$$

18.24.3 Harmonic Oscillator

We now show that Eq. (18.658) describes the quantum mechanics of a harmonic oscillator. Let us restrict our attention to the line with arbitrary $x_1 \equiv x$ and $x_2 = 0$. Applying the Cauchy-Riemann equations (18.651), we can rewrite Eq. (18.658) in the pure x -form

$$\partial_t u^1(x, t) = \omega x \partial_x u^2(x, t) - \frac{\hbar}{2} \partial_x^2 u^2(x, t), \quad (18.663)$$

$$\partial_t u^2(x, t) = -\omega x \partial_x u^1(x, t) + \frac{\hbar}{2} \partial_x^2 u^1(x, t), \quad (18.664)$$

where we have omitted the second spatial coordinates $x_2 = 0$. Now we introduce a complex field

$$\psi(x, t) \equiv e^{-\omega x^2/2\hbar} [u^1(x, t) + iu^2(x, t)]. \quad (18.665)$$

This satisfies the differential equation

$$i\hbar \partial_t \psi(x, t) = \left(-\frac{\hbar^2}{2} \partial_x^2 + \frac{\omega^2}{2} x^2 - \frac{\hbar\omega}{2} \right) \psi(x, t), \quad (18.666)$$

which is the Schrödinger equation of a harmonic oscillator with the discrete energy spectrum $E_n = (n + 1/2)\hbar\omega$, $n = 0, 1, 2, \dots$.

18.24.4 General Potential

The method can easily be generalized to an arbitrary potential. We simply replace (18.652) by

$$\begin{aligned} \dot{x}^1(t) &= -\partial_2 S^1(\mathbf{x}(t)) + n^1 \eta(t), \\ \dot{x}^2(t) &= -\partial_1 S^1(\mathbf{x}(t)) + n^2 \eta(t), \end{aligned} \quad (18.667)$$

where $\mathbf{S}(\mathbf{x})$ shares with $\mathbf{u}(\mathbf{x})$ the harmonic property (18.650):

$$\nabla^2 \mathbf{S}(\mathbf{x}) = 0, \quad (18.668)$$

i.e., the functions $S^\mu(\mathbf{x})$ with $\mu = 1, 2$ fulfill Cauchy-Riemann equations like $u^\mu(\mathbf{x})$ in (18.651). Repeating the above steps we find, instead of the operator (18.659),

$$\hat{\mathcal{H}} \equiv -(\partial_2 S^1) \partial_1 - (\partial_1 S^1) \partial_2 + \frac{\hbar}{2} (\mathbf{n} \cdot \nabla)^2, \quad (18.669)$$

and Eqs. (18.663) and (18.664) become:

$$\partial_t u^1(x, t) = (\partial_x S^1) \partial_x u^2(x, t) - \frac{\hbar}{2} \partial_x^2 u^2(x, t), \quad (18.670)$$

$$\partial_t u^2(x, t) = -(\partial_x S^1) \partial_x u^1(x, t) + \frac{\hbar}{2} \partial_x^2 u^1(x, t). \quad (18.671)$$

This time evolution preserves the harmonic nature of $\mathbf{u}(\mathbf{x})$. Indeed, using the harmonic property $\nabla^2 \mathbf{S}(\mathbf{x}) = 0$ we can easily derive the following time dependence of the Cauchy-Riemann combinations in Eq. (18.651):

$$\begin{aligned} \partial_t (\partial_1 u^1 - \partial_2 u^2) &= \hat{\mathcal{H}} (\partial_1 u^1 - \partial_2 u^2) - \partial_2 \partial_1 S^1 (\partial_1 u^1 - \partial_2 u^2) + \partial_2^2 S^1 (\partial_2 u^1 + \partial_1 u^2), \\ \partial_t (\partial_2 u^1 + \partial_1 u^2) &= \hat{\mathcal{H}} (\partial_2 u^1 + \partial_1 u^2) - \partial_2 \partial_1 S^1 (\partial_2 u^1 + \partial_1 u^2) - \partial_2^2 S^1 (\partial_1 u^1 - \partial_2 u^2). \end{aligned}$$

Thus $\partial_1 u^1 - \partial_2 u^2$ and $\partial_2 u^1 + \partial_1 u^2$ which are zero at any time remain zero at all times.

On account of Eqs. (18.671), the combination

$$\psi(x, t) \equiv e^{-S^1(x)/\hbar} [u^1(x, t) + iu^2(x, t)] \quad (18.672)$$

satisfies the Schrödinger equation

$$i\hbar \partial_t \psi(x, t) = \left[-\frac{\hbar^2}{2} \partial_x^2 + V(x) \right] \psi(x, t), \quad (18.673)$$

where the potential is related to $S^1(x)$ by the Riccati differential equation

$$V(x) = \frac{1}{2} [\partial_x S^1(x)]^2 - \frac{\hbar}{2} \partial_x^2 S^1(x). \quad (18.674)$$

The harmonic oscillator is recovered for the pair of functions

$$S^1(\mathbf{x}) + iS^2(\mathbf{x}) = \omega(x^1 + ix^2)^2/2. \quad (18.675)$$

18.24.5 Deterministic Equation

The noise $\eta(t)$ in the stochastic differential equation Eq. (18.667) can also be replaced by a source composed of deterministic classical oscillators $q_k(t)$, $k = 1, 2, \dots$ with the equations of motion

$$\dot{q}_k = p_k, \quad \dot{p}_k = -\omega_k^2 q_k, \quad (18.676)$$

as

$$\eta(t) \equiv \sum_k \dot{q}_k(t). \quad (18.677)$$

The initial positions $q_k(0)$ and momenta $p_k(0)$ are assumed to be randomly distributed with a Boltzmann factor $e^{-\beta H_{\text{osc}}/\hbar}$, such that

$$\langle q_k(0) q_k(0) \rangle = \hbar/\omega_k^2, \quad \langle p_k(0) p_k(0) \rangle = \hbar. \quad (18.678)$$

Using the equation of motion

$$\dot{q}_k(t) = \omega_k q_k(0) \sin \omega_k t + p_k(0) \cos \omega_k t, \quad (18.679)$$

we find the correlation function

$$\begin{aligned}\langle \dot{q}_k(t)\dot{q}_k(t') \rangle &= \omega_k^2 \cos \omega_k t \cos \omega_k t' \langle q_k(0)q_k(0) \rangle + \sin \omega_k t \sin \omega_k t' \langle p_k(0)p_k(0) \rangle \\ &= \cos \omega_k(t-t').\end{aligned}\quad (18.680)$$

We may now assume that the oscillators $q_k(t)$ are the Fourier components of a massless field, for instance the gravitational field whose frequencies are $\omega_k = k$, and whose random initial conditions are caused by the big bang. If the sum over k is simply a momentum integral $\int_{-\infty}^{\infty} dk$, then (18.680) yields a white-noise correlation function (18.653) for $\eta(t)$.

Thus it is indeed possible to simulate the quantum-mechanical wave functions $\psi(x, t)$ and the energy spectrum of an arbitrary potential problem by deterministic equations with random initial conditions at the beginning of the universe.

It remains to solve the open problem of finding a classical origin of the second important ingredient of quantum theory: the theory of quantum measurement to be extracted from the wave function $\psi(x, t)$. Only then shall we understand how God throws dice [37].

Appendix 18A Inequalities for Diagonal Green Functions

Let us introduce several diagonal Green functions consisting of thermal averages of equal-time commutators and anticommutators of bosonic and fermionic field operators, elementary or composite. For brevity, we write

$$\langle \dots \rangle_T = \text{Tr} \left[\exp(-\hat{H}/T) \dots \right] / \text{Tr} \left[\exp(-\hat{H}/T) \right] = \langle \dots \rangle_T \quad (18A.1)$$

and define the averages with obvious spectral representations

$$\begin{aligned}c &\equiv \langle [\hat{\psi}, \hat{\psi}^\dagger]_{\mp} \rangle_T = \int_{-\infty}^{\infty} \frac{d\omega}{2\pi} \rho_{12}(\omega), \\ a &\equiv \langle [\hat{\psi}, \hat{\psi}^\dagger]_{\pm} \rangle_T = \int_{-\infty}^{\infty} \frac{d\omega}{2\pi} \rho_{12}(\omega) \tanh^{\mp 1} \frac{\omega}{2T}.\end{aligned}\quad (18A.2)$$

We shall also introduce a quantity obtained by integrating the imaginary-time Green function over a period $\tau \in [0, 1/T)$. This gives for boson and fermion fields the nonnegative expression [see (18.23)]

$$\begin{aligned}g &\equiv G(\omega_m = 0) = \int_0^{1/T} d\tau \langle \hat{\psi}(\tau)\hat{\psi}^\dagger(0) \rangle_T \\ &= \int_{-\infty}^{\infty} \frac{d\omega}{2\pi} \rho_{12}(\omega) \frac{1}{\omega} \left\{ \frac{1}{\tanh(\omega/2T)} \right\} \geq 0.\end{aligned}\quad (18A.3)$$

Note that for fermion fields, the spectral weight in this integral is accompanied by an extra factor $\tanh(\omega/2T)$. This is due to the fact that $\omega_m = 0$ is *no* fermionic Matsubara frequency, but a “wrong” bosonic one. In fact, the sum (18.23) for $G(\omega_m)$ contains a factor $1 - e^{(E_n - E_{n'})/T}$ for both bosons and fermions, while $\rho_{12}(\omega)$ in the spectral representation (18A.3) introduces, via (18.59), a factor $1 - e^{-\omega/T}$ for bosons and a factor $1 + e^{\omega/T}$ for fermions, thus explaining the relative factor $\tanh(\omega/2T)$ in (18A.3).

The integration over τ leads to the factor $1/\omega$ in (18A.3). This factor is also found by integrating the retarded Green function $G_{12}(t)$ and the commutator function $C_{12}(t)$ over all real times, resulting in the spectral representations

$$\begin{aligned}i \int_{-\infty}^{\infty} dt \Theta(t) \langle [\hat{\psi}(t), \hat{\psi}^\dagger(0)]_{\mp} \rangle_T &= \int \frac{d\omega}{2\pi} \rho_{12}(\omega) \frac{1}{\omega}, \\ i \int_{-\infty}^{\infty} dt \Theta(t) \langle [\hat{\psi}(t), \hat{\psi}^\dagger(0)]_{\pm} \rangle_T &= \int \frac{d\omega}{2\pi} \rho_{12}(\omega) \frac{1}{\omega} \tanh^{\mp 1} \frac{\omega}{2T}.\end{aligned}\quad (18A.4)$$

Another set of thermal expectation values involves products of field operators with time derivatives rather than integrals. Their spectral representations contain an extra factor ω . For example, the τ -derivative of the expectation value in (18A.3) leads to

$$-\langle \dot{\hat{\psi}}(0), \hat{\psi}^\dagger(0) \rangle_T = \int_{-\infty}^{\infty} \frac{d\omega}{2\pi} \rho_{12}(\omega) \omega (1 \pm n_\omega). \quad (18A.5)$$

The real-time derivatives of the expectation values in (18A.4) have the spectral integrals

$$\begin{aligned} d &\equiv i \langle [\dot{\hat{\psi}}(0), \hat{\psi}^\dagger(0)]_{\mp} \rangle_T = \int_{-\infty}^{\infty} \frac{d\omega}{2\pi} \rho_{12}(\omega) \omega, \\ e &\equiv i \langle [\dot{\hat{\psi}}(0), \hat{\psi}^\dagger(0)]_{\pm} \rangle_T = \int_{-\infty}^{\infty} \frac{d\omega}{2\pi} \rho_{12}(\omega) \omega \tanh^{\mp 1} \frac{\omega}{2T}. \end{aligned} \quad (18A.6)$$

The expectation values c , a , g , d , e satisfy several rigorous inequalities. To derive these, we observe that

$$\mu(\omega) = \frac{1}{g} \frac{1}{2\pi} \rho_{12}(\omega) \frac{1}{\omega} \left\{ \begin{array}{c} 1 \\ \tanh(\omega/2T) \end{array} \right\} \quad (18A.7)$$

is a positive function. This follows directly from (18.59), according to which $\rho_{12}(\omega)$ at negative ω is negative for bosons and positive for fermions. Having divided out the total integral g defined in (18A.3), the integral over $\mu(\omega)$ is normalized to unity,

$$\int_{-\infty}^{\infty} d\omega \mu(\omega) = 1, \quad (18A.8)$$

for both bosons and fermions. Using $\mu(\omega)$, we form the following ratios:

$$\frac{c}{g} = \int_{-\infty}^{\infty} d\omega \mu(\omega) \omega \left\{ \begin{array}{c} 1 \\ \coth(\omega/2T) \end{array} \right\}, \quad (18A.9)$$

$$\frac{a}{g} = \int_{-\infty}^{\infty} d\omega \mu(\omega) \omega \left\{ \begin{array}{c} \coth(\omega/2T) \\ 1 \end{array} \right\}, \quad (18A.10)$$

$$\frac{d}{g} = \int_{-\infty}^{\infty} d\omega \mu(\omega) \omega^2 \left\{ \begin{array}{c} 1 \\ \coth(\omega/2T) \end{array} \right\}, \quad (18A.11)$$

$$\frac{e}{g} = \int_{-\infty}^{\infty} d\omega \mu(\omega) \omega^2 \left\{ \begin{array}{c} \coth(\omega/2T) \\ 1 \end{array} \right\}. \quad (18A.12)$$

The inequalities to be derived are based on the Jensen-Peierls inequality for convex functions derived in Chapter [5]. Recall that a convex function $f(\omega)$ satisfies

$$f\left(\frac{\omega_1 + \omega_2}{2}\right) \leq \frac{f(\omega_1) + f(\omega_2)}{2}, \quad (18A.13)$$

which is generalized to

$$f\left(\sum_i \mu_i \omega_i\right) \leq \sum_i \mu_i f(\omega_i), \quad (18A.14)$$

where μ_i is an arbitrary set of positive numbers with $\sum_i \mu_i = 1$. In the continuum limit, this becomes

$$f\left(\int_{-\infty}^{\infty} d\omega \mu(\omega) \omega\right) \leq \int_{-\infty}^{\infty} d\omega \mu(\omega) f(\omega). \quad (18A.15)$$

It is obvious that a similar Jensen-Peierls inequality holds also for concave functions with inequality sign in the opposite direction.

The Jensen-Peierls inequality (18A.15) is now applied to the function

$$f(\omega) = \omega \coth \frac{\omega}{2T}, \tag{18A.16}$$

which looks like a slightly distorted hyperbola coming in from infinity along the diagonal lines $|\omega|$ and crossing the f -axis at $\omega = 0$, $f(0) = 2T$. The second derivative of $f(\omega)$ is positive everywhere, ensuring the convexity. The function (18A.16) appears in the integrand of the boson part of Eq. (18A.10). The right-hand side of (18A.15) can therefore be written as a/g . The left-hand side is obviously equal to $(c/g) \coth(c/2Tg)$. Hence we arrive at the inequality

$$c \coth \frac{c}{2Tg} \leq a. \tag{18A.17}$$

In terms of the original field operators, this amounts to

$$\langle [\hat{\psi}, \hat{\psi}^\dagger]_+ \rangle_T \geq \langle [\hat{\psi}, \hat{\psi}^\dagger]_- \rangle_T \coth \frac{\langle [\hat{\psi}, \hat{\psi}^\dagger]_- \rangle_T}{2T \int_0^{1/T} d\tau \langle \hat{\psi}(\tau) \hat{\psi}^\dagger(0) \rangle_T}. \tag{18A.18}$$

In the special case that $\hat{\psi}$ is a *canonical* interacting boson field of momentum \mathbf{p} , the commutator is simply $[\hat{\psi}, \hat{\psi}^\dagger]_- = 1$, and the inequality becomes

$$1 + 2 \langle \hat{\psi}_\mathbf{p}^\dagger \hat{\psi}_\mathbf{p} \rangle_T \geq \coth(1/2Tg) = 1 + \frac{2}{e^{1/gT} - 1} = 1 + 2n_{g^{-1}}, \tag{18A.19}$$

i.e.,

$$\langle \hat{\psi}_\mathbf{p}^\dagger \hat{\psi}_\mathbf{p} \rangle_T \geq \frac{1}{e^{1/gT} - 1} \equiv n_{g^{-1}}, \tag{18A.20}$$

where $n_{g^{-1}}$ is the free-boson distribution function (18.36) for an energy g^{-1} .

This is quite an interesting relation. The quantity g is the Euclidean equilibrium Green function $G(\omega_m, \mathbf{p})$ at $\omega_m = 0$. For free particles in contact with a reservoir, it is given by

$$g^{-1} = G(0, \mathbf{p})^{-1} = \frac{\mathbf{p}^2}{2M} - \mu \equiv \xi(\mathbf{p}), \tag{18A.21}$$

i.e., it is equal to the particle energy measured with respect to the chemical potential μ . Moreover, we know that for free particles

$$\langle \hat{\psi}_\mathbf{p}^\dagger \hat{\psi}_\mathbf{p} \rangle_T = n_{\xi(\mathbf{p})}, \tag{18A.22}$$

so that the inequality (18A.20) becomes an equality. The content of the inequality (18A.20) may therefore be phrased as follows: For any interaction, the occupation of a state with momentum \mathbf{p} is never *smaller* than for a free boson level of energy $g^{-1} = G(0, \mathbf{p})$.

Another inequality can be derived from the concave function

$$\bar{f}(y) = \sqrt{y} \coth \frac{\sqrt{y}}{2T}, \tag{18A.23}$$

using $y = \omega^2$ and the measure

$$\int_{-\infty}^{\infty} d\omega \mu(\omega) = \int_0^{\infty} \frac{dy}{\sqrt{y}} \mu(\sqrt{y}) = 1. \tag{18A.24}$$

As argued before, concave functions satisfy the inequality opposite to (18A.15), from which we derive the inequality

$$\bar{f} \left(\int_0^\infty \frac{dy}{\sqrt{y}} \mu(\sqrt{y})y \right) \geq \int_0^\infty \frac{dy}{\sqrt{y}} \mu(\sqrt{y})\bar{f}(y), \quad (18A.25)$$

which can be rewritten as

$$\bar{f} \left(\int_{-\infty}^\infty d\omega \mu(\omega)\omega^2 \right) \geq \int_{-\infty}^\infty d\omega \mu(\omega)\bar{f}(\omega^2). \quad (18A.26)$$

Again, the right-hand side is a/g , but now it is bounded from above by

$$\frac{a}{g} \leq \sqrt{\frac{d}{g}} \coth \left(\frac{1}{2T} \sqrt{\frac{d}{g}} \right). \quad (18A.27)$$

The combined inequality

$$c \coth \frac{c}{2Tg} \leq a \leq \sqrt{dg} \coth \left(\frac{1}{2T} \sqrt{\frac{d}{g}} \right) \quad (18A.28)$$

may be used to derive further inequalities:

$$\begin{aligned} c^2 &\leq dg, \\ c \coth(d/2Tc) &\leq a, \\ g &\leq \coth(c/2Ta), \\ c &\leq d \tanh(c/2Ta), \\ c &\leq a \tanh(d/2Tc). \end{aligned} \quad (18A.29)$$

For fermion fields we see that an inequality like (18A.17) holds with c and a interchanged, i.e.,

$$a \coth \frac{a}{2Tg} \leq c, \quad (18A.30)$$

which leads to

$$\langle [\hat{\psi}, \hat{\psi}^\dagger]_- \rangle_T \leq \langle [\hat{\psi}, \hat{\psi}^\dagger]_+ \rangle_T \tanh \frac{\langle [\hat{\psi}, \hat{\psi}^\dagger]_+ \rangle_T}{2T \int_0^{1/T} d\tau \langle \hat{\psi}(\tau) \hat{\psi}^\dagger(0) \rangle_T}. \quad (18A.31)$$

For canonical fermion fields with $[\hat{\psi}, \hat{\psi}^\dagger]_+ = 1$, this becomes

$$1 - 2 \langle \hat{\psi}^\dagger \hat{\psi} \rangle_T \leq \tanh(1/2gT) = 1 - \frac{2}{e^{1/gT} + 1}, \quad (18A.32)$$

i.e., the fermionic counterpart of (18A.20):

$$\langle \hat{\psi}_{\mathbf{p}}^\dagger \hat{\psi}_{\mathbf{p}} \rangle_T \leq \frac{1}{e^{1/gT} + 1} = n_{g^{-1}}, \quad (18A.33)$$

where $n_{g^{-1}}$ is the free-fermion distribution function (18.36) at an energy g^{-1} . As in the Bose case, free particles fulfill

$$\langle \hat{\psi}_{\mathbf{p}}^\dagger \hat{\psi}_{\mathbf{p}} \rangle_T = n_{\xi(\mathbf{p})}, \quad (18A.34)$$

with $g^{-1} = \xi(\mathbf{p})$, so that the inequality (18A.33) becomes an equality. The inequality implies that an interacting Fermi level is never occupied *more* than a free fermion level of energy $g^{-1} = G(0, \mathbf{p})^{-1}$.

Also the second inequality in (18A.29) can be taken over to fermions which amounts to (18A.30), but with a and d replaced by c and e .

Appendix 18B General Generating Functional

For a field operator $a(t)$ of frequency Ω and its Hermitian conjugate $a^\dagger(t)$, the retarded and advanced Green functions and the expectation values of commutators and anticommutators were derived in Eqs. (18.68)–(18.77):

$$\begin{aligned} G_\Omega^R(t, t') &= \Theta(t - t')e^{-i\Omega(t-t')}, \\ G_\Omega^A(t, t') &= -\Theta(t' - t)e^{-i\Omega(t-t')}, \\ C_\Omega(t, t') &= e^{-i\Omega(t-t')}, \\ A_\Omega(t, t') &= \left(\tanh \frac{\Omega}{2T}\right)^{\mp 1} e^{-i\Omega(t-t')}. \end{aligned} \quad (18B.1)$$

Introducing complex sources $\eta(t)$ and $\eta^\dagger(t)$ associated with these operators, the generating functional for these functions is

$$Z_0[\eta_P, \eta_P^\dagger] = \text{Tr} \left\{ \hat{\rho} \hat{T}_P \exp \left[-i \int_{t_a}^{t_b} dt (\hat{a}^\dagger \eta + \eta^\dagger \hat{a}) \right] \right\}. \quad (18B.2)$$

The complex sources are distinguished according to the closed-time contour branches by a subscript P. The generating functional can then be written down immediately as

$$Z_0[\eta_P, \eta_P^\dagger] = \exp \left\{ - \int dt \int dt' \eta_P^\dagger(t) G_P(t, t') \eta_P(t') \right\}, \quad (18B.3)$$

generalizing (18.179), where the matrix

$$G_P = \frac{1}{2} \begin{pmatrix} A_\Omega + G_\Omega^R + G_\Omega^A & A_\Omega - G_\Omega^R + G_\Omega^A \\ A_\Omega + G_\Omega^R - G_\Omega^A & A_\Omega - G_\Omega^R - G_\Omega^A \end{pmatrix} \quad (18B.4)$$

contains the following operator expectations on the two time branches:

$$\begin{aligned} G_P(t, t') &= \begin{pmatrix} \langle \hat{T}_P \hat{a}_H(t_+) \hat{a}_H^\dagger(t'_+) \rangle_T & \langle \hat{T}_P \hat{a}_H(t_+) \hat{a}_H^\dagger(t'_-) \rangle_T \\ \langle \hat{T}_P \hat{a}_H(t_-) \hat{a}_H^\dagger(t'_+) \rangle_T & \langle \hat{T}_P \hat{a}_H(t_-) \hat{a}_H^\dagger(t'_-) \rangle_T \end{pmatrix} \\ &= \begin{pmatrix} \langle \hat{T} \hat{a}_H(t_+) \hat{a}_H^\dagger(t'_+) \rangle_T & \pm \langle \hat{a}_H^\dagger(t'_-) \hat{a}_H(t_+) \rangle_T \\ \langle \hat{a}_H(t_-) \hat{a}_H^\dagger(t'_+) \rangle_T & \langle \hat{T} \hat{a}_H(t_-) \hat{a}_H^\dagger(t'_-) \rangle_T \end{pmatrix}. \end{aligned} \quad (18B.5)$$

Note that $\hat{a}_H(t_+)$, $\hat{a}_H^\dagger(t_+)$ and $\hat{a}_H(t_-)$, $\hat{a}_H^\dagger(t_-)$ obey the Heisenberg equations of motion with the Hamiltonians

$$\begin{aligned} \hat{H}_+ &\equiv \frac{\Omega}{2} \left[\hat{a}_H^\dagger(t_+) \hat{a}_H(t_+) \pm \hat{a}_H(t_+) \hat{a}_H^\dagger(t_+) \right], \\ \hat{H}_- &\equiv -\frac{\Omega}{2} \left[\hat{a}_H^\dagger(t_-) \hat{a}_H(t_-) \pm \hat{a}_H(t_-) \hat{a}_H^\dagger(t_-) \right]. \end{aligned} \quad (18B.6)$$

In the second-quantized field interpretation, they read

$$\begin{aligned} \hat{H}_+ &\equiv \frac{\Omega}{2} \hat{a}_H^\dagger(t_+) \hat{a}_H(t_+), \\ \hat{H}_- &\equiv -\frac{\Omega}{2} \hat{a}_H^\dagger(t_-) \hat{a}_H(t_-). \end{aligned}$$

The explicit time dependence of the matrix elements of $G_P(t, t')$ in Eq. (18B.5) is

$$G_P(t, t') = e^{-i\Omega(t-t')} \begin{pmatrix} \Theta(t - t') \pm n_\Omega & \pm n_\Omega \\ 1 \pm n_\Omega & \Theta(t' - t) \pm n_\Omega \end{pmatrix}, \quad (18B.7)$$

with $n_\Omega = (e^{\Omega/T} \pm 1)^{-1}$.

This Green function can, incidentally, be decomposed as

$$G_{\mathbb{P}}^0(t, t') + G_{\mathbb{P}}^N(t, t'), \quad (18B.8)$$

where $G_{\mathbb{P}}^0(t, t')$ is the Green function at zero temperature, i.e., the expression (18B.7) for $n_\Omega \equiv 0$. The matrix $G^N(t, t')$ contains the expectations of the *normal products*:

$$\begin{aligned} G_{\mathbb{P}}^N(t, t') &\equiv \begin{pmatrix} \langle \hat{N} \hat{a}_H(t_+) \hat{a}_H^\dagger(t'_+) \rangle_T & \langle \hat{N} \hat{a}_H(t_+) \hat{a}_H^\dagger(t'_-) \rangle_T \\ \langle \hat{N} \hat{a}_H(t_-) \hat{a}_H^\dagger(t'_+) \rangle_T & \langle \hat{N} \hat{a}_H(t_-) \hat{a}_H^\dagger(t'_-) \rangle_T \end{pmatrix} \\ &\equiv \pm \begin{pmatrix} \langle \hat{a}_H^\dagger(t'_+) \hat{a}_H(t_+) \rangle_T & \langle \hat{a}_H^\dagger(t'_-) \hat{a}_H(t_+) \rangle_T \\ \langle \hat{a}_H^\dagger(t'_+) \hat{a}_H(t_-) \rangle_T & \langle \hat{a}_H^\dagger(t'_-) \hat{a}_H(t_-) \rangle_T \end{pmatrix}. \end{aligned} \quad (18B.9)$$

For an arbitrary product of operators, the normal product $\hat{N}(\dots)$ is defined by reordering the operators so that all annihilation operators come to act first upon the state on the right-hand side. At the end, the product receives the phase factor $(-)^F$, where F is the number of fermion permutations to arrive at the normal order. A similar decomposition exists at the operator level *before* taking expectation values. For any pair of operators $\hat{A}(t), \hat{B}(t')$ which are linear combinations of creation and annihilation operators, the time-ordered product can be decomposed as

$$\hat{T} \hat{A}(t) \hat{B}(t') = \langle \hat{T} \hat{A}(t) \hat{B}(t') \rangle_0 + \hat{N} \hat{A}(t) \hat{B}(t'), \quad (18B.10)$$

where $\langle \dots \rangle_0 \equiv \text{Tr}(|0\rangle\langle 0| \dots)$ denotes the zero-temperature expectation. This decomposition is proved in Appendix 18C, where it is also generalized to products of more than two operators.

Let us also go to the Keldysh basis here:

$$\tilde{\eta}_{\mathbb{P}} = Q \eta_{\mathbb{P}} = \frac{1}{\sqrt{2}} \begin{pmatrix} 1 & -1 \\ 1 & 1 \end{pmatrix} \hat{\eta}_{\mathbb{P}}. \quad (18B.11)$$

Then the generating functional becomes [instead of (18.180)]:

$$\begin{aligned} Z_0[\eta_{\mathbb{P}}^*, \eta_{\mathbb{P}}] &= \exp \left[- \int dt \int dt' (\eta_+^*, -\eta_-^*) Q^{-1} \begin{pmatrix} 0 & G_\Omega^A \\ G_\Omega^R & A \end{pmatrix} Q \begin{pmatrix} \eta_+ \\ -\eta_- \end{pmatrix} \right] \\ &= \exp \left\{ - \frac{1}{2} \int dt \int dt' [(\eta_+^* - \eta_-^*)(t) G_\Omega^R(t-t') (\eta_+ + \eta_-)(t') \right. \\ &\quad \left. + (\eta_+^* + \eta_-^*)(t) G_\Omega^A(t-t') (\eta_+ - \eta_-)(t') \right. \\ &\quad \left. + (\eta_-^* - \eta_-^*)(t) A_\Omega(t-t') (\eta_+ - \eta_-)(t') \right\}, \end{aligned} \quad (18B.12)$$

where we have used the notation

$$\eta_+(t) \equiv \eta(t_+), \quad \eta_-(t) \equiv \eta(t_-). \quad (18B.13)$$

Expression (18B.12) can be simplified [as before (18.180)] using the time reversal relation (18.62) in the form

$$A_\Omega(t, t') = \Theta(t, t') A_\Omega(t, t') \pm \Theta(t' - t) A_\Omega(t', t), \quad (18B.14)$$

leading to

$$\begin{aligned} Z_0[\eta_{\mathbb{P}}^*, \eta_{\mathbb{P}}] &= \exp \left\{ - \frac{1}{2} \int_{-\infty}^{\infty} dt \int_{-\infty}^t dt' \right. \\ &\quad \times \left[(\eta_+ - \eta_-)^*(t) G_\Omega^R(t, t') (\eta_+ + \eta_-)(t') \right. \\ &\quad \left. - (\eta_+ - \eta_-)(t) G_\Omega^R(t, t')^* (\eta_+ + \eta_-)^*(t') \right. \\ &\quad \left. + (\eta_+ - \eta_-)^*(t) A_\Omega(t, t') (\eta_+ - \eta_-)(t') \right. \\ &\quad \left. + (\eta_+ - \eta_-)(t) A_\Omega(t, t')^* (\eta_+ - \eta_-)^*(t') \right\}. \end{aligned} \quad (18B.15)$$

For the case of a second-quantized field, this is the most useful generating functional.

The expression (18B.15) can be used to derive the generating functional for correlation functions between one or more $\varphi(t)$ and the associated canonically-conjugate momenta. As an example, consider immediately a harmonic oscillator with $\varphi(t) = x(t)$ and the momentum $p(t)$. We would like to find the generating functional

$$Z[j_P, k_P] = \text{Tr} \left(\hat{\rho} \hat{T}_P \exp \left\{ i \int_P dx [j_P(t)x_P(t) + k_P(t)p_P(t)] \right\} \right). \quad (18B.16)$$

The position variable $x(t)$ is decomposed as in (18.92) into a sum of creation and an annihilation operators:

$$\hat{x}(t) = \sqrt{\frac{\hbar}{2M\Omega}} [\hat{a}e^{-i\Omega t} + \hat{a}^\dagger e^{i\Omega t}]. \quad (18B.17)$$

The inverse of this decomposition is

$$\left\{ \begin{array}{c} \hat{a} \\ \hat{a}^\dagger \end{array} \right\} = (M\Omega \hat{\varphi} \pm i\hat{p})/\sqrt{2M\Omega\hbar}, \quad (18B.18)$$

and there is an analogous relation of the complex sources:

$$\left\{ \begin{array}{c} \eta \\ \eta^\dagger \end{array} \right\} = (j \pm iM\Omega k)/\sqrt{2M\Omega\hbar}. \quad (18B.19)$$

Inserting these sources into (18B.15), we obtain the generating functional

$$\begin{aligned} Z_0[j_P, k_P] = \exp \left\{ -\frac{1}{2M\Omega} \int_{-\infty}^{\infty} dt \int_{-\infty}^t dt' (j_+ - j_-)(t) \right. \\ \times \{ [\text{Re } A_\Omega(t, t') + i\text{Im } G_\Omega^R(t, t')]j_+(t') \\ \left. - [\text{Re } A_\Omega(t, t') - i\text{Im } G_\Omega^R(t, t')]j_-(t') \} \\ -\frac{1}{2} \int_{-\infty}^{\infty} dt \int_{-\infty}^t dt' (k_+ - k_-)(t) \{ [\text{Im } A_\Omega(t, t') - i\text{Re } G_\Omega^R(t, t')]j_+(t') \right. \\ \left. - [\text{Im } A_\Omega(t, t') + i\text{Re } G_\Omega^R(t, t')]j_-(t') \} + (j \leftrightarrow kM\Omega) \right\}. \end{aligned} \quad (18B.20)$$

Here it is useful to introduce the quantities

$$\begin{aligned} \alpha(t, t') &= \frac{1}{2M\Omega} [\text{Re } A_\Omega(t, t') + i\text{Im } G_\Omega^R(t, t')], \\ \beta(t, t') &= \frac{1}{2M\Omega} [\text{Im } A_\Omega(t, t') - i\text{Re } G_\Omega^R(t, t')]. \end{aligned} \quad (18B.21)$$

Then the generating functional reads

$$\begin{aligned} Z_0[j_+, j_-, k_+, k_-] = \exp \left\{ -\int_{-\infty}^{\infty} dt \int_{-\infty}^t dt' (j_+ - j_-)(t) [\alpha(t, t')j_+(t') - \alpha^*(t, t')j_-(t')] + (j \leftrightarrow kM\Omega) \right. \\ \left. -M\Omega \int_{-\infty}^{\infty} dt \int_{-\infty}^t dt' (k_+ - k_-)(t) [\beta(t, t')j_+(t') - \beta^*(t, t')j_-(t')] + (j \leftrightarrow kM\Omega) \right\}. \end{aligned} \quad (18B.22)$$

If the oscillator is coupled only to the real source j , i.e., if its generating functional reads

$$Z[j_P] = \text{Tr} \left\{ \hat{\rho} \hat{T}_P \exp \left[i \int_P dx j_P(t)\hat{x}_P(t) \right] \right\}, \quad (18B.23)$$

we can drop all but the first line in the exponent of (18B.22) and have

$$Z_0[j_+, j_-] = \exp \left\{ - \int_{-\infty}^{\infty} dt \int_{-\infty}^t dt' (j_+ - j_-)(t) [\alpha(t, t') j_+(t') - \alpha^*(t, t') j_-(t')] \right\}. \quad (18B.24)$$

Since (18B.22) and (18B.24) contain only the causal temporal order $t > t'$, the retarded Green function $G_{\Omega}^R(t, t')$ in (18B.21) can be replaced by the expectation value of the commutator [see (18.40), (18.41), and (18.42)]. Thus, for $t > t'$, the functions $\alpha(t, t')$ and $\beta(t, t')$ are equal to¹¹

$$\begin{aligned} \alpha(t, t') &= \frac{1}{2M\Omega} [\operatorname{Re} A_{\Omega}(t, t') + i \operatorname{Im} C_{\Omega}(t, t')], & t > t', \\ \beta(t, t') &= \frac{1}{2M\Omega} [\operatorname{Im} A_{\Omega}(t, t') - i \operatorname{Re} C_{\Omega}(t, t')], & t > t'. \end{aligned} \quad (18B.25)$$

For a single oscillator of frequency Ω , we use the spectral function (18.74) properties (18.44) and (18.53) of $A_{\Omega}(t, t')$ and $C_{\Omega}(t, t')$, and find the simple expressions:

$$\begin{aligned} \alpha(t, t') &= \frac{1}{2M\Omega} \left[\operatorname{Re} e^{-i\Omega(t-t')} \left\{ \frac{\coth \frac{\Omega}{2T}}{\tanh \frac{\Omega}{2T}} \right\} + i \operatorname{Im} e^{-i\Omega(t-t')} \right] \\ &= \frac{1}{2M\Omega} \left[\cos \Omega(t-t') \left\{ \frac{\coth \frac{\Omega}{2T}}{\tanh \frac{\Omega}{2T}} \right\} - i \sin \Omega(t-t') \right], \end{aligned} \quad (18B.26)$$

$$\begin{aligned} \beta(t, t') &= \frac{1}{2M\Omega} \left[\operatorname{Im} e^{-i\Omega(t-t')} \left\{ \frac{\coth \frac{\Omega}{2T}}{\tanh \frac{\Omega}{2T}} \right\} - i \operatorname{Re} e^{-i\Omega(t-t')} \right] \\ &= -\frac{1}{2M\Omega} \left[\sin \Omega(t-t') \left\{ \frac{\coth \frac{\Omega}{2T}}{\tanh \frac{\Omega}{2T}} \right\} + i \cos \Omega(t-t') \right]. \end{aligned} \quad (18B.27)$$

Note that real and imaginary parts of the functions $\bar{\alpha}(t-t')$ can be combined into a single expression ($\beta = 1/T$)

$$\bar{\alpha}(t-t') = \frac{1}{2M\Omega} \begin{cases} \frac{\cosh[\Omega(\beta/2 - i(t-t'))]}{\sinh(\Omega\beta/2)} & \text{for bosons,} \\ \frac{\sinh[\Omega(\beta/2 - i(t-t'))]}{\cosh(\Omega\beta/2)} & \text{for fermions.} \end{cases} \quad (18B.28)$$

The bosonic function agrees with the time-ordered Green function (18.101) for $t > t'$ and continues it analytically to $t < t'$.

In Fourier space, the functions (18B.26) and (18B.27) correspond to

$$\begin{aligned} \alpha(\omega') &= \frac{\pi}{2M\Omega} \left(\coth^{\pm 1} \frac{\omega'}{2T} + 1 \right) [\delta(\omega' - \Omega) - \delta(\omega' + \Omega)], \\ \beta(\omega') &= -\frac{i\pi}{2M\Omega} \left(\coth^{\pm 1} \frac{\omega'}{2T} + 1 \right) [\delta(\omega' - \Omega) + \delta(\omega' + \Omega)]. \end{aligned}$$

Let us split these functions into a zero-temperature contribution plus a remainder

$$\begin{aligned} \alpha(\omega') &= \frac{\pi}{M\Omega} \left\{ \delta(\omega' - \Omega) \pm \frac{1}{e^{\Omega/T} \mp 1} [\delta(\omega' - \Omega) + \delta(\omega' + \Omega)] \right\}, \\ \beta(\omega') &= \frac{\pi}{M\Omega} \left\{ \delta(\omega' - \Omega) \pm \frac{1}{e^{\Omega/T} \mp 1} [\delta(\omega' - \Omega) - \delta(\omega' + \Omega)] \right\}. \end{aligned}$$

¹¹Note that $\alpha(t, t') = \langle x(t)x(t') \rangle_T$.

On the basis of this formula, Einstein first explained the induced emission and absorption of light by atoms which he considered as harmonically oscillating dipoles in contact with a thermal reservoir. He imagined them to be harmonically oscillating dipole moments coupled to a thermal bath consisting of the Fourier components of the electromagnetic field in thermal equilibrium. Such a thermal bath is called a *black body*. The first purely dissipative and temperature-independent term in $\alpha(\omega')$ was attributed by Einstein to the *spontaneous emission* of photons. The second term is caused by the bath fluctuations, making energy go in and out via *induced emission and absorption* of photons. It is proportional to the occupation number of the oscillator state $n_\Omega = (e^{-\Omega/T} \mp 1)^{-1}$. The equality of the prefactors in front of the two terms is the important manifestation of the fluctuation-dissipation theorem found earlier [see (18.53)].

Appendix 18C Wick Decomposition of Operator Products

Consider two operators $\hat{A}(t)$ and $\hat{B}(t)$ which are linear combinations of creation and annihilation operators

$$\begin{aligned}\hat{A}(t) &= \alpha_1 \hat{a}(t) + \alpha_2 \hat{a}^\dagger(t), \\ \hat{B}(t) &= \beta_1 \hat{a}(t) + \beta_2 \hat{a}^\dagger(t).\end{aligned}\tag{18C.1}$$

We want to show that the time-ordered product of two operators has the decomposition quoted in Eq. (18B.10):

$$\hat{T}\hat{A}(t)\hat{B}(t) = \langle \hat{T}\hat{A}(t)\hat{B}(t) \rangle_0 + \hat{N}\hat{A}(t)\hat{B}(t).\tag{18C.2}$$

The first term on the right-hand side is the thermal expectation of the time-ordered product at zero temperature; the second term is the normal product of the two operators.

If \hat{A} and \hat{B} are both creation or annihilation operators, the statement is trivial with $\langle \hat{T}\hat{A}\hat{B} \rangle_0 = 0$. If one of the two, say $\hat{A}(t)$, is a creation operator and the other, $\hat{B}(t)$, an annihilation operator, then

$$\begin{aligned}\hat{T}\hat{a}(t)\hat{a}^\dagger(t') &= \Theta(t-t')\hat{a}(t)\hat{a}^\dagger(t') \pm \Theta(t'-t)\hat{a}^\dagger(t')\hat{a}(t) \\ &= \Theta(t-t')[\hat{a}(t)\hat{a}^\dagger(t')]_{\mp} \pm \hat{a}^\dagger(t')\hat{a}(t).\end{aligned}\tag{18C.3}$$

Due to the commutator (anticommutator) the first term is a *c*-number. As such it is equal to the expectation value of the time-ordered product at zero temperature. The second term is a normal product, so that we can write

$$\hat{T}\hat{a}(t)\hat{a}^\dagger(t') = \langle \hat{T}\hat{a}(t)\hat{a}^\dagger(t') \rangle_0 + \hat{N}\hat{a}(t)\hat{a}^\dagger(t').\tag{18C.4}$$

The same thing is true if a and a^\dagger are interchanged (such an interchange produces merely a sign change on both sides of the equation). The general statement for $\hat{A}(t)\hat{B}(t')$ follows from the bilinearity of the product.

The decomposition (18C.2) of the time-ordered product of two operators can be extended to a product of n operators, where it reads

$$\hat{T}\hat{A}(t_1)\dots\hat{A}(t_n) = \sum_{i=2}^n \hat{N}\hat{A}(t_1)\dots\hat{A}(t_i)\dots\hat{A}(t_n).\tag{18C.5}$$

A common pair of dots on top of a pair of operators denotes a *Wick contraction* of Section 3.10. It indicates that the pair of operators has been replaced by the expectation $\langle \hat{T}\hat{A}(t_1)\hat{A}(t_i) \rangle_0$, multiplied by a factor $(-)^F$, if F = fermion permutations were necessary to bring the contracted operator to the adjacent positions. The remaining factors are contracted further in the same way. In this way, any time-ordered product

$$\hat{T}\hat{A}(t_1)\dots\hat{A}(t_n)\tag{18C.6}$$

can be expanded into a sum of normal products of these operators containing successively one, two, three, etc. pairs of contracted operators.

The expansion rule can be phrased most compactly by means of a generating functional

$$\hat{T}e^{i\int_{-\infty}^{\infty} dt\hat{A}(t)j(t)} = e^{-\frac{i}{2}\int_{-\infty}^{\infty} dt dt' j(t)\langle\hat{T}\hat{A}(t)\hat{A}(t')\rangle_0 j(t')} \hat{N}\left(e^{i\int_{-\infty}^{\infty} dt\hat{A}(t)j(t)}\right). \quad (18C.7)$$

Differentiations with respect to the source $j(t)$ on both sides produce precisely the above decompositions.

By going to thermal expectation values of (18C.7) at a temperature T , we find

$$\left\langle\hat{T}e^{i\int_{-\infty}^{\infty} dt\hat{A}(t)j(t)}\right\rangle_T = e^{-\frac{i}{2}\int_{-\infty}^{\infty} dt dt' j(t)G(t,t')j(t')}, \quad (18C.8)$$

with

$$G(t,t') = \langle\hat{T}\hat{A}(t)\hat{A}(t')\rangle_0 + \langle\hat{N}\hat{A}(t)\hat{A}(t')\rangle_T. \quad (18C.9)$$

The first term on the right-hand side is calculated at zero temperature. All finite temperature effects reside in the second term.

Notes and References

The fluctuation-dissipation theorem was first formulated by

H.B. Callen and T.A. Welton, *Phys. Rev.* **83**, 34 (1951).

It generalizes the relation between the diffusion constant and the viscosity discovered by

A. Einstein, *Ann. Phys. (Leipzig)* **17**, 549 (1905),

and an analogous relation for induced light emission in

A. Einstein, "Strahlungs-Emission und -Absorption nach der Quantentheorie", *Verhandlungen der Deutschen Physikalischen Gesellschaft* **18**, 318 (1916),

where he derived Planck's black-body formula. See also the functioning of this theorem in the thermal noise in a resistor:

S.A. Adelman, *Chem. Phys. Lett.* **40**, 495 (1976);

and especially

A. Schmid, *J. Low Temp. Phys.* **49**, 609 (1982).

To solve the operator ordering problem, Schmid assumes that a time-sliced derivation of the forward-backward path integral would yield a sliced version of the stochastic differential equation (18.317) $\eta_n \equiv (M/\epsilon)(x_n - 2x_{n-1} + x_{n-2}) + (M\gamma/2)(x_n - x_{n-2}) + \epsilon V'(x_{n-1})$. The matrix $\partial\eta/\partial x$ has a constant determinant $(M/\epsilon)^N(1 + \epsilon\gamma/2)^N$. His argument [cited also in the textbook by

U. Weiss, *Quantum Dissipative Systems*, World Scientific, 1993,

in the discussion following Eq. (5.93)] is unacceptable for two reasons: First, his slicing is not derived. Second, the resulting determinant has the wrong continuum limit proportional to

$\exp [\int dt \gamma/2]$ for $\epsilon \rightarrow 0$, $N = (t_b - t_a)/\epsilon \rightarrow \infty$, corresponding to the unretarded functional determinant (18.274), whereas the correct limit should be γ -independent, by Eq. (18.282).
The above textbook by U. Weiss contains many applications of nonequilibrium path integrals.

Relativistic Particle Orbits

Particles moving at large velocities near the speed of light are called *relativistic* particles. If such particles interact with each other or with an external potential, they exhibit quantum effects which cannot be described by fluctuations of a single particle orbit. Within short time intervals, additional particles or pairs of particles and antiparticles are created or annihilated, and the total number of particle orbits is no longer invariant. Ordinary quantum mechanics which always assumes a fixed number of particles cannot describe such processes. The associated path integral has the same problem since it is a sum over a given set of particle orbits. Thus, even if relativistic kinematics is properly incorporated, a path integral cannot yield an accurate description of relativistic particles. An extension becomes necessary which includes an arbitrary number of mutually linked and *branching* fluctuating orbits.

Fortunately, there exists a more efficient way of dealing with relativistic particles. It is provided by *quantum field theory*. We have demonstrated in Section 7.14 that a grand-canonical ensemble of particle orbits can be described by a functional integral of a single fluctuating field. Branch points of newly created particle lines are accounted for by anharmonic terms in the field action. The calculation of their effects proceeds by perturbation theory which is systematically performed in terms of Feynman diagrams with calculation rules very similar to those in Section 3.18. There are again lines and interaction vertices, and the main difference lies in the lines which are correlation functions of fields rather than position variables $x(t)$. The lines and vertices represent direct pictures of the topology of the worldlines of the particles and their possible collisions and creations.

Quantum field theory has been so successful that it is generally advantageous to describe the statistical mechanics of many completely different types of line-like objects in terms of fluctuating fields. One important example is the polymer field theory in Section 15.12. Another important domain where field theory has been extremely successful is in the theory of line-like defects in crystals, superfluids, and superconductors. In the latter two systems, the defects occur in the form of quantized vortex lines or quantized magnetic flux lines, respectively. The entropy of their classical shape fluctuations determines the temperature where the phase transitions take place. Instead of the usual way of describing these systems as ensembles of

particles with their interactions, a field theory has been developed whose Feynman diagrams are the direct pictures of the line-like defects, called *disorder field theory* [1].

The most important advantage of field theory is that it can describe most easily phase transitions, in which particles form a condensate. The disorder theory is therefore particularly suited to understand phase transitions in which defect-, vortex-, or flux-lines proliferate, which happens in the processes of crystal melting, superfluid to normal, or superconductor to normal transitions, respectively. In fact, the disorder theory is so far the only theory in which the critical behavior of the superconductor near the transition is properly understood [2].

A particular quantum field theory, called *quantum electrodynamics* describes with great success the electromagnetic interactions of electrons, muons, quarks, and photons. It has been extended successfully to include the weak interactions among these particles and, in addition, neutrinos, using only a few quantized Dirac fields and a quantized electromagnetic vector potential. The inclusion of a nonabelian gauge field, the gluon field, is a good candidate for explaining all known features of strong interactions.

It is certainly unnecessary to reproduce in an orbital formulation the great amount of results obtained in the past from the existing field theory of weak, electromagnetic, and strong interactions. The orbital formulation was, in fact, proposed by Feynman back in 1950 [3], but never pursued very far due to the success of quantum field theory. Recently, however, this program was revived in a number of publications [4, 5]. The main motivation for this lies in another field of fundamental research: the *string theory* of fundamental particles. In this theory, all elementary particles are supposed to be excitations of a single line-like object with tension, and various difficulties in obtaining a consistent theory in the physical spacetime have led to an extension by fermionic degrees of freedom, the result being the so-called *superstring*. Strings moving in spacetime form worldsheets rather than worldlines. They do not possess a second-quantized field theoretic formulation. Elaborate rules have been developed for the functional integrals describing the splitting and merging of strings. If one cancels one degree of freedom in such a superstring, one has a theory of splitting and merging particle worldlines. As an application of the calculation rules for strings, processes which have been known from calculations within the quantum field theory have been recalculated using these reduced superstring rules. In this textbook, we shall give a small taste of such calculations by evaluating the change in the vacuum energy of electromagnetic fields caused by fluctuating relativistic spinless and spin-1/2 particles.

It should be noted that since up to now, no physical result has emerged from superstring theory,¹ there is at present no urgency to dwell deeper into the subject.

By giving a short introduction into this subject we shall be able to pay tribute to some historic developments in quantum mechanics, where the relativistic generaliza-

¹This theory really deserves a prize for having the highest popularity-per-physicality ratio in the history of science, enjoying a great amount of financial support. The situation is very similar to the geocentric medieval picture of the world.

tion of the Schrödinger equation was an important step towards the development of quantum field theory [6]. For this reason, many textbooks on quantum field theory begin with a discussion of relativistic quantum mechanics. By analogy, we shall incorporate relativistic kinematics into path integrals.

It should be noted that an esthetic possibility to give a path Fermi statistics is based on the Chern-Simons theory of entanglement of Chapter 16. However, this approach is still restricted to $2 + 1$ spacetime dimensions [7], and an extension to the physical $3 + 1$ spacetime dimensions is not yet in sight.

19.1 Special Features of Relativistic Path Integrals

Consider a free point particle of mass M moving through the $3 + 1$ spacetime dimensions of Minkowski space at relativistic velocity. Its path integral description is conveniently formulated in four-dimensional Euclidean spacetime where the fluctuating worldlines look very similar to the fluctuating polymers discussed in Chapter 15.

Thus, time is taken to be imaginary, i.e.,

$$t = -i\tau = -ix^4/c, \quad (19.1)$$

and the length of a four-vector $x = (\mathbf{x}, x^4)$ is given by

$$x^2 = \mathbf{x}^2 + (x^4)^2 = \mathbf{x}^2 + c^2\tau^2. \quad (19.2)$$

If $x^\mu(\lambda)$ is an arbitrarily parametrized orbit, the well-known classical Euclidean action is proportional to the invariant length of the orbit in spacetime:

$$S = \int_{\lambda_a}^{\lambda_b} d\lambda \sqrt{x'^2(\lambda)}, \quad (19.3)$$

and reads

$$\mathcal{A}_{\text{cl,e}} = McS, \quad (19.4)$$

or, explicitly,

$$\mathcal{A}_{\text{cl,e}} = Mc \int_{\lambda_a}^{\lambda_b} ds(\lambda), \quad (19.5)$$

with

$$ds(\lambda) \equiv d\lambda \sqrt{x'^2(\lambda)} = d\lambda \sqrt{\mathbf{x}'^2(\lambda) + c^2\tau'^2(\lambda)}. \quad (19.6)$$

The prime denotes the derivative with respect to the parameter λ . The action is independent of the choice of the parametrization. If λ is replaced by a new parameter

$$\lambda \rightarrow \bar{\lambda} = f(\lambda), \quad (19.7)$$

then

$$x'^2 \rightarrow \frac{1}{f'^2} x'^2, \quad (19.8)$$

$$d\lambda \rightarrow d\lambda f', \quad (19.9)$$

so that ds and the action remain invariant.

We now calculate the Euclidean amplitude for the worldline of the particle to run from the spacetime point $x_a = (\mathbf{x}_a, c\tau_a)$ to $x_b = (\mathbf{x}_b, c\tau_b)$. For the sake of generality, we treat the case of D Euclidean spacetime dimensions. Before starting we observe that the action (19.5) does not lend itself easily to a calculation of the path integral over $e^{-\mathcal{A}_{\text{cl},e}/\hbar}$. There exists an alternative form for the classical action that is more suitable for this purpose. It involves an auxiliary field $h(\lambda)$ and reads:

$$\bar{\mathcal{A}}_e = \int_{\lambda_a}^{\lambda_b} d\lambda \left[\frac{Mc}{2h(\lambda)} x'^2(\lambda) + h(\lambda) \frac{Mc}{2} \right]. \quad (19.10)$$

This has the advantage of containing the particle orbit quadratically as in a free nonrelativistic action. The auxiliary field $h(\lambda)$ has been inserted to make sure that the classical orbits of the action (19.10) coincide with those of the original action (19.5). Indeed, extremizing $\bar{\mathcal{A}}_e$ in $h(\lambda)$ gives the relation

$$h(\lambda) = \sqrt{x'^2(\lambda)}. \quad (19.11)$$

Inserting this back into $\bar{\mathcal{A}}_e$ renders the classical action

$$\mathcal{A}_{\text{cl},e} = Mc \int_{\lambda_a}^{\lambda_b} d\lambda \sqrt{x'^2(\lambda)}, \quad (19.12)$$

which is the same as (19.5).

At this point the reader will worry that although the new action (19.10) describes the same classical physics as the original action (19.12), it may lead to a completely different quantum physics of a relativistic particle. With a little effort, however, it can be shown that this is not so. Since the proof is quite technical, it will be given in Appendix 19A.

The new action (19.10) shares with the old action (19.12) the reparametrization invariance (19.7) for arbitrary fluctuating path configurations. We only have to assign an appropriate transformation behavior to the extra field $h(\lambda)$. If λ is replaced by a new parameter $\bar{\lambda} = f(\lambda)$, then x'^2 and $d\lambda$ transform as in (19.8) and (19.9), and the action remains invariant, if $h(\lambda)$ is simultaneously changed as

$$h \rightarrow h/f'. \quad (19.13)$$

We now set up the path integral of a relativistic particle associated with the action (19.10). First we sum over the orbital fluctuations at a *fixed* $h(\lambda)$. To find

the correct measure of integration, we use the canonical formulation in which the Euclidean action reads

$$\bar{\mathcal{A}}_e[p, x] = \int_{\lambda_a}^{\lambda_b} d\lambda \left[-ipx' + \frac{h(\lambda)}{2Mc} (p^2 + M^2c^2) \right]. \quad (19.14)$$

This must be sliced in the length parameter λ . We form $N + 1$ slices as usual, choosing arbitrary small parameter differences $\epsilon_n = \lambda_n - \lambda_{n-1}$ depending on n , and write the sliced action as

$$\bar{\mathcal{A}}_e^N[p, x] = \sum_{n=1}^{N+1} \left[-ip_n(x_n - x_{n-1}) + h_n \epsilon_n \frac{p_n^2}{2Mc} + \epsilon_n h_n \frac{Mc}{2} \right]. \quad (19.15)$$

This path integral has a universal phase space measure [recall (2.28)]

$$\int \mathcal{D}^D x \int \frac{\mathcal{D}^D p}{(2\pi\hbar)^D} e^{-\bar{\mathcal{A}}_e[p, x]/\hbar} \approx \prod_{n=1}^N \left[\int d^D x_n \right] \prod_{n=1}^{N+1} \left[\int \frac{d^D p_n}{(2\pi\hbar)^D} e^{-\bar{\mathcal{A}}_e^N[p, x]/\hbar} \right]. \quad (19.16)$$

The momentum variables p_n are integrated out to give the configuration space integrals (setting $\lambda_{N+1} \equiv \lambda_b$, $h_{N+1} \equiv h_b$) [compare (2.79)]

$$\frac{1}{\sqrt{2\pi\hbar\epsilon_b h_b/Mc}^D} \prod_{n=1}^N \left[\int \frac{d^D x_n}{\sqrt{2\pi\hbar\epsilon_n h_n/Mc}^D} \right] \exp\left(-\frac{1}{\hbar} \bar{\mathcal{A}}_e^N[x]\right), \quad (19.17)$$

with the time-sliced action in configuration space

$$\bar{\mathcal{A}}_e^N[x] = \sum_{n=1}^{N+1} \left[\frac{Mc}{2h_n \epsilon_n} (\Delta x_n)^2 + \epsilon_n h_n \frac{Mc}{2} \right]. \quad (19.18)$$

The Gaussian integrals over x_n in (19.17) can now be done successively using Formula (2.75), and we find [as in (2.80)]

$$\frac{1}{\sqrt{2\pi\hbar S/Mc}^D} \exp\left[-\frac{Mc}{2\hbar} \frac{(x_b - x_a)^2}{S} - \frac{Mc}{2\hbar} S\right], \quad (19.19)$$

where S is the total sliced length of the orbit

$$S \equiv \sum_{n=1}^{N+1} \epsilon_n h_n, \quad (19.20)$$

whose continuum limit is

$$S = \int_{\lambda_a}^{\lambda_b} d\lambda h(\lambda). \quad (19.21)$$

The result (19.19) does not depend on the function $h(\lambda)$ but only on S , this being a consequence of the reparametrization invariance of the path integral. While

the total λ -interval changes under the transformation, the total length S of (19.21) is invariant under the joint transformations (19.7) and (19.13). This invariance permits only the invariant length S to appear in the integrated expression (19.19), and the path integral over $h(\lambda)$ can be reduced to a simple integral over S . The appropriate path integral for the time evolution amplitude reads

$$(x_b|x_a) = \mathcal{N} \int_0^\infty dS \int \mathcal{D}h \Phi[h] \int \mathcal{D}^D x e^{-\bar{\mathcal{A}}_e/\hbar}, \quad (19.22)$$

where \mathcal{N} is some normalization factor and $\Phi[h]$ an appropriate *gauge-fixing functional*.

19.1.1 Simplest Gauge Fixing

The simplest choice for the gauge-fixing functional is a δ -functional,

$$\Phi[h] = \delta[h - 1], \quad (19.23)$$

which fixes $h(\lambda)$ to be equal to the light velocity everywhere, and relates

$$S = \lambda_b - \lambda_a. \quad (19.24)$$

This Lorentz-invariant length parameter is the so-called proper length of special relativity, equal to c times the *proper time*. By analogy with the discussion of thermodynamics in Chapter 2 we shall then denote $\lambda_b - \lambda_a$ by $c\hbar\beta$ and write (19.24) as

$$S = \lambda_b - \lambda_a \equiv c\hbar\beta. \quad (19.25)$$

If we further use translational invariance to set $\lambda_a = 0$, we arrive at the gauge-fixed path integral

$$(x_b|x_a) = \mathcal{N} c \hbar \int_0^\infty d\beta e^{-\beta M c^2/2} \int \mathcal{D}^D x e^{-\mathcal{A}_{0,e}/\hbar}, \quad (19.26)$$

with

$$\mathcal{A}_{0,e} = \int_0^{\hbar\beta} d\lambda \frac{M}{2} \dot{x}^2. \quad (19.27)$$

Here we have gone to a timelike parameter $\tau = \lambda/c$ and therefore used a dot to denote the derivative: $\dot{x}(\tau) \equiv dx(\lambda)/d\tau$. Remarkably, the gauge-fixed action coincides with the action of a free nonrelativistic particle in D Euclidean spacetime dimensions. Having taken the trivial term $\int_0^{\hbar\beta} d\tau M c^2/2\hbar$ out of the action (19.14), the expression (19.26) contains a Boltzmann weight $e^{-\beta M c^2/2}$ for each particle orbit of mass M .

The solution of the path integral is then given by

$$(x_b|x_a) = \mathcal{N} c \hbar \int_0^\infty d\beta \frac{1}{\sqrt{2\pi\hbar^2\beta/M}^D} \exp \left[-\frac{M}{2\hbar} \frac{(x_b - x_a)^2}{\hbar\beta} - \beta \frac{M c^2}{2} \right]. \quad (19.28)$$

By Fourier-transforming the x -dependence, this amplitude can also be written as

$$(x_b|x_a) = \mathcal{N} c \hbar \int_0^\infty d\beta e^{-\beta M c^2/2} \int \frac{d^D k}{(2\pi)^D} \exp \left[ik(x_b - x_a) - \beta \frac{\hbar^2 k^2}{2M} \right], \quad (19.29)$$

and evaluated to

$$(x_b|x_a) = \mathcal{N} \frac{2Mc}{\hbar} \int \frac{d^D k}{(2\pi)^D} \frac{1}{k^2 + M^2 c^2/\hbar^2} e^{ik(x_b - x_a)}. \quad (19.30)$$

Upon setting $\mathcal{N} = \lambda_M^C/2$, where

$$\lambda_M^C \equiv \hbar/Mc, \quad (19.31)$$

is the well-known Compton wavelength of a particle of mass M [recall Eq. (4.377)], this becomes the Green function of the Klein-Gordon field equation in Euclidean time:

$$(-\partial_b^2 + M^2 c^2/\hbar^2)(x_b|x_a) = \delta^{(D)}(x_b - x_a). \quad (19.32)$$

In the Fourier representation (19.30), the integral over k [or the integral over β in (19.28)] can be performed with the explicit result for the Green function

$$(x_b|x_a) = \frac{1}{(2\pi)^{D/2}} \left(\frac{Mc}{\hbar\sqrt{x^2}} \right)^{D/2-1} K_{D/2-1} \left(Mc\sqrt{x^2}/\hbar \right), \quad (19.33)$$

where $K_\nu(z)$ denotes the modified Bessel function and $x \equiv x_b - x_a$. In the nonrelativistic limit $c \rightarrow \infty$, the asymptotic behavior $K_\nu(z) \rightarrow \sqrt{\pi/2z} e^{-z}$ [see Eq. (1.357)] leads to

$$(x_b|x_a) = (\mathbf{x}_b \tau_b | \mathbf{x}_a \tau_a) \xrightarrow{c \rightarrow \infty} \frac{\hbar}{2Mc} e^{-Mc^2(\tau_b - \tau_a)/\hbar} (\mathbf{x}_b \tau_b | \mathbf{x}_a \tau_a)_{\text{Schr}}, \quad (19.34)$$

with the usual Euclidean time evolution amplitude of the free Schrödinger equation

$$(\mathbf{x}_b \tau_b | \mathbf{x}_a \tau_a)_{\text{Schr}} = \frac{1}{\sqrt{2\pi\hbar(\tau_b - \tau_a)/M}} e^{-\frac{M(\mathbf{x}_b - \mathbf{x}_a)^2}{2\hbar(\tau_b - \tau_a)}}. \quad (19.35)$$

The exponential prefactor in (19.34) contains the effect of the rest energy Mc^2 which is ignored in the nonrelativistic Schrödinger theory.

Note that the same limit may be calculated conveniently in the saddle point approximation to the β -integral (19.28). For $c \rightarrow \infty$, the exponent has a sharp extremum at

$$\beta = \frac{\sqrt{(x_b - x_a)^2}}{c\hbar} = \frac{\sqrt{(\mathbf{x}_b - \mathbf{x}_a)^2 + c^2(\tau_b - \tau_a)^2}}{c\hbar} \xrightarrow{c \rightarrow \infty} \frac{\tau_b - \tau_a}{\hbar} + \frac{(\mathbf{x}_b - \mathbf{x}_a)^2}{2c^2\hbar(\tau_b - \tau_a)} + \dots, \quad (19.36)$$

and the β -integral can be evaluated in a quadratic approximation around this value. This yields once again (19.34).

19.1.2 Partition Function of Ensemble of Closed Particle Loops

The diagonal amplitude (19.26) with $x_b = x_a$ contains the sum over all lengths and shapes of a *closed* particle loop in spacetime. This sum can be made a partition function of a closed loop if we remove a degeneracy factor proportional to $1/L$ from the integral over L . Then all cyclic permutations of the points of the loop are counted only once. Apart from an arbitrary normalization factor to be fixed later, the partition function of a single closed loop reads

$$Z_1 = \int_0^\infty \frac{d\beta}{\beta} e^{-\beta M c^2/2} \int \mathcal{D}^D x e^{-\mathcal{A}_{0,e}/\hbar}. \quad (19.37)$$

Inserting the right-hand integral in (19.29) for the path integral (with $x_b = x_a$), this becomes

$$Z_1 = V_D \int_0^\infty \frac{d\beta}{\beta} e^{-\beta M c^2/2} \int \frac{d^D k}{(2\pi)^D} \exp\left(-\beta \frac{\hbar^2 k^2}{2M}\right), \quad (19.38)$$

where V_D is the total volume of spacetime. This can be evaluated immediately. The Gaussian integral gives for each of the D dimensions a factor $1/\sqrt{2\pi\hbar^2\beta/M}$, after which formula (2.498) leads to

$$Z_1 = V_D \int_0^\infty \frac{d\beta}{\beta} e^{-\beta M c^2/2} \frac{1}{\sqrt{2\pi\hbar^2\beta/M}^D} = \frac{V_D}{\lambda_M^C{}^D} \frac{\Gamma(1-D/2)}{(4\pi)^{D/2}}, \quad (19.39)$$

where λ_M^C is the Compton wavelength (19.31). With the help of the sloppy formula (2.506) of analytic regularization which implies the minimal subtraction explained in Subsection 2.15.1, the right-hand side of (19.38) can also be written as

$$Z_1 = -V_D \int \frac{d^D k}{(2\pi)^D} \log\left(k^2 + M^2 c^2/\hbar^2\right). \quad (19.40)$$

The right-hand side can be expressed in functional form as

$$Z_1 = -\text{Tr} \log\left(-\partial^2 + M^2 c^2/\hbar^2\right) = -\text{Tr} \log\left(-\hbar^2 \partial^2 + M^2 c^2\right), \quad (19.41)$$

the two expressions being equal in the analytic regularization of Section 2.15, since a constant inside the logarithm gives no contribution by Veltman's rule (2.508).

The partition function of a grand-canonical ensemble is obtained by exponentiating this:

$$Z = e^{Z_1} = e^{-\text{Tr} \log(-\hbar^2 \partial^2 + M^2 c^2)}. \quad (19.42)$$

In order to interpret this expression physically, we separate the integral $\int d^D k/(2\pi)^D$ into an integral over the temporal component k^D and a spatial remainder, and write

$$k^2 + M^2 c^2/\hbar^2 = \left(k^D\right)^2 + \omega_{\mathbf{k}}^2/c^2, \quad (19.43)$$

with the frequencies

$$\omega_{\mathbf{k}} \equiv c\sqrt{\mathbf{k}^2 + M^2c^2/\hbar^2}. \quad (19.44)$$

Recalling the result (2.505) of the integral (2.491) we obtain

$$Z_1 = -2V_D \int \frac{d^{D-1}k}{(2\pi)^{D-1}} \frac{\hbar\omega_{\mathbf{k}}}{2c}. \quad (19.45)$$

The exponent is the sum of two ground state energies of oscillators of energy $\hbar\omega_{\mathbf{k}}/2$, which are the vacuum energies associated with two relativistic particles. In quantum field theory one learns that these are particles and antiparticles. Many neutral particles are identical to their antiparticles, for example photons, gravitons, and the pion with zero charge. For these, the factor 2 is absent. Then the integral (19.38) contains a factor 1/2 accounting for the fact that paths running along the same curve in spacetime but in the opposite sense are identified.

Comparing (19.42) with (3.559) and (3.622) for $j = 0$ we identify $-Z_1\hbar$ with $-W[0]$ and the Euclidean effective action Γ of the ensemble of loops:

$$-Z_1 = -W[0]/\hbar = \Gamma_e/\hbar. \quad (19.46)$$

19.1.3 Fixed-Energy Amplitude

The fixed-energy amplitude is related to (19.22) by a Laplace transformation:

$$(\mathbf{x}_b|\mathbf{x}_a)_E \equiv -i \int_{\tau_a}^{\infty} d\tau_b e^{E(\tau_b - \tau_a)/\hbar} (x_b|x_a), \quad (19.47)$$

where τ_b, τ_a are once more the time components in x_b, x_a . As explained in Chapter 9, the poles and the cut along the energy axis in this amplitude contain all information on the bound and continuous eigenstates of the system. The fixed-energy amplitude has the reparametrization-invariant path integral representation which reads with the conventions of Eq. (19.10):

$$(\mathbf{x}_b|\mathbf{x}_a)_E = \frac{\hbar}{2Mc} \int_0^{\infty} dL \int \mathcal{D}h \Phi[h] \int \mathcal{D}^D x e^{-\bar{\mathcal{A}}_{e,E}/\hbar}, \quad (19.48)$$

with the Euclidean action

$$\bar{\mathcal{A}}_{e,E} = \int_{\lambda_a}^{\lambda_b} d\lambda \left[\frac{Mc}{2h(\lambda)} \mathbf{x}'^2(\lambda) - h(\lambda) \frac{E^2}{2Mc^3} + h(\lambda) \frac{Mc}{2} \right]. \quad (19.49)$$

To prove this, we write the temporal x^D -part of the sliced D -dimensional action (19.18) in the canonical form (19.15). In the associated path integral (19.16), we integrate out all x_n^D -variables, producing N δ -functions. These remove the integrals over N momentum variables p_n^D , leaving only a single integral over a common p^D . The Laplace transform (19.47), finally, eliminates also this integral making p^D equal to $-iE/c$. In the continuum limit, we thus obtain the action (19.49).

The path integral (19.48) forms the basis for studying relativistic potential problems. Only the physically most relevant example will be treated here.

19.2 Tunneling in Relativistic Physics

Relativistic harbors several new tunneling phenomena, of which we want to discuss two especially interesting ones.

19.2.1 Decay Rate of Vacuum in Electric Field

In relativistic physics, an empty Minkowski space with a constant electric field \mathbf{E} is unstable. There is a finite probability that a particle-antiparticle pair can be created. For particles of mass M , this requires the energy

$$E_{\text{pair}} = 2Mc^2. \quad (19.50)$$

This energy can be supplied by the external electric field. If the pair of charge $\pm e$ is separated by a distance which is roughly twice the Compton wavelength $\lambda_M^C = \hbar/Mc$ of Eq. (19.31), it gains an energy $2|\mathbf{E}|\lambda_M^C e$. The decay will therefore become significant when

$$|\mathbf{E}| > E_c = \frac{M^2 c^3}{e\hbar}. \quad (19.51)$$

Euclidean Action

In Chapter 17 we have shown that in the semiclassical limit where the decay-rate is small, it is proportional to a Boltzmann-like factor $e^{-\mathcal{A}_{\text{cl},e}/\hbar}$, where $\mathcal{A}_{\text{cl},e}$ is the action of a Euclidean classical solution mediating the decay. Such a solution is easily found. We use the classical action in the form (19.12) and choose the parameter λ to measure the imaginary time $\lambda = \tau = it = x^4/c$. Then the action takes the form

$$\mathcal{A}_{\text{cl},e} = \int_{\tau_a}^{\tau_b} d\tau \left[Mc^2 \sqrt{1 + \dot{\mathbf{x}}^2(\tau)/c^2} - e \mathbf{E} \cdot \mathbf{x}(\tau) \right]. \quad (19.52)$$

This is extremized by the classical equation of motion

$$M \frac{d}{d\tau} \frac{\dot{\mathbf{x}}(\tau)}{\sqrt{1 + \dot{\mathbf{x}}^2(\tau)/c^2}} = -e\mathbf{E}, \quad (19.53)$$

whose solutions are circles in spacetime of a fixed E -dependent radius l_E :

$$(\mathbf{x} - \mathbf{x}_0)^2 + c^2(\tau - \tau_0)^2 = l_E^2 \equiv \left(\frac{Mc^2}{eE} \right)^2, \quad E \equiv |\mathbf{E}|. \quad (19.54)$$

To calculate their action we parametrize the circles in the $\hat{\mathbf{E}} - \tau$ -plane, where $\hat{\mathbf{E}}$ is the unit vector in the direction of \mathbf{E} , by an angle θ as

$$\mathbf{x}(\theta) = l_E \hat{\mathbf{E}} \cos \theta + \mathbf{x}_0, \quad \tau(\theta) = \frac{l_E}{c} \sin \theta + \tau_0. \quad (19.55)$$

A closed circle has an action

$$\mathcal{A}_{\text{cl},e} = Mc^2 \frac{l_E}{c} \int_0^{2\pi} d\theta \cos \theta \left[\frac{1}{\cos \theta} - \cos \theta \right] = Mc l_E \pi = \hbar \frac{E_c}{E} \pi. \quad (19.56)$$

The decay rate of the vacuum is therefore proportional to

$$\Gamma \propto e^{-\pi E_c/E}. \quad (19.57)$$

The circles (19.54) are, of course, the space-time pictures of the creation and the annihilation of particle-antiparticle pairs at times $\tau_0 - l_E/c$ and $\tau_0 + l_E/c$ and positions \mathbf{x}_0 , respectively (see Fig. 19.1). A particle can also run around the circle

Figure 19.1 Spacetime picture of pair creation at the point \mathbf{x}_0 and time $\tau_0 - l_E/c$ and annihilation at the later time $\tau_0 + l_E/c$.

repeatedly. This leads to the formula

$$\Gamma \propto \sum_{n=1}^{\infty} F_n e^{-n\pi E_c/E}, \quad (19.58)$$

with fluctuation factors F_n which we are now going to determine.

Fluctuations

As explained above, fluctuations must be calculated with the relativistic Euclidean action (19.10), in which we have to include the electric field by minimal coupling:

$$\bar{\mathcal{A}}_e = \int_{\lambda_a}^{\lambda_b} d\lambda \left[\frac{M}{2h(\lambda)} x'^2(\lambda) + h(\lambda) \frac{Mc}{2} - i \frac{e}{c} A(x(\lambda)) x'(\lambda) \right]. \quad (19.59)$$

The vacuum will decay by the creation of an ensemble of pairs which in Euclidean spacetime corresponds to an ensemble of particle loops. For free particles, the partition function Z was given in (19.42) as an exponential of the one-loop partition function Z_1 in (19.37). The corresponding Z_1 in the presence of an electromagnetic field has the one-loop partition function

$$Z_1 = \int_0^\infty \frac{d\beta}{\beta} e^{-\beta Mc^2/2} \int \mathcal{D}^A x e^{-\bar{\mathcal{A}}_e/\hbar}, \quad (19.60)$$

with the Euclidean action

$$\bar{\mathcal{A}}_e = \int_0^{\hbar\beta} d\tau \left[\frac{M}{2} x'^2(\tau) - i \frac{e}{c} A(x(\tau)) x'(\tau) \right]. \quad (19.61)$$

The equations of motion are now

$$\mathbf{x}'' = \frac{e}{Mc} (x'_4 \mathbf{E} - i \mathbf{x}' \times \mathbf{B}), \quad x''_4 = -\frac{e}{Mc} \mathbf{x}' \cdot \mathbf{E}, \quad (19.62)$$

If both a constant electric and a constant magnetic field are present, the vector potential is $A_\mu = -F_{\mu\nu} x^\nu/2$ and the action (19.61) takes the simple quadratic form

$$\bar{\mathcal{A}}_e = \int_0^{\hbar\beta} d\tau \left[\frac{M}{2} x'^2 - i \frac{e}{2c} F_{\mu\nu} x^\mu x'^\nu \right], \quad (19.63)$$

and the equations of motion (19.62) are

$$x''^\mu = -i \frac{e}{c} F^{\mu\nu} x'_\nu, \quad \text{with } F_{ij} = -\epsilon_{ijk} B^k, \quad F^{i4} = iF^{i0} = iE^i. \quad (19.64)$$

In a purely electric field, the solutions are circular orbits:

$$\mathbf{x}(\tau) = \hat{\mathbf{E}} A \cos \omega_L^E (\tau - \tau_0) + c_2, \quad x_4(\tau) = A \sin \omega_L^E (\tau - \tau_0) + c_4, \quad (19.65)$$

with the electric version of the Landau or cyclotron frequency (2.648)

$$\omega_L^E \equiv \frac{eE}{Mc}. \quad (19.66)$$

The circular orbits are the same as those in the previous formulation (19.55). If \mathbf{E} points in the z -direction, the action (19.63) decomposes into two decoupled quadratic actions $\bar{\mathcal{A}}_e^{(12)} + \bar{\mathcal{A}}_e^{(34)}$ for the motion in the $x^1 - x^2$ and $x^3 - x^4$ -planes, respectively, and the one-loop partition function (19.60) factorizes as follows:

$$\begin{aligned} Z_1 &= \int_0^\infty \frac{d\beta}{\beta} e^{-\beta Mc^2/2} \int \mathcal{D}^2 x^{(12)} e^{-\bar{\mathcal{A}}_e^{(12)}/\hbar} \int \mathcal{D}^2 x^{(34)} e^{-\bar{\mathcal{A}}_e^{(34)}/\hbar} \\ &\equiv \int_0^\infty \frac{d\beta}{\beta} e^{-\beta Mc^2/2} Z^{(12)}(0) Z^{(34)}(E). \end{aligned} \quad (19.67)$$

The path integral for $Z^{(12)}(0)$ collecting the fluctuations in the $x^1 - x^2$ -plane have the trivial action

$$\bar{\mathcal{A}}_e^{(12)} = \int_0^{\hbar\beta} d\tau \frac{M}{2} (x_1'^2 + x_2'^2), \quad (19.68)$$

with the trivial fluctuation determinant $\text{Det}(-\partial_\tau^2) = 1$, so that we obtain for $Z^{(12)}(0)$ the free-particle partition function in two dimensions

$$Z^{(12)}(0) = \Delta x_1 \Delta x_2 \sqrt{\frac{M}{2\pi\hbar^2\beta}}. \quad (19.69)$$

The factor $\Delta x_1 \Delta x_2$ is the total area of the system in the $x^1 - x^2$ -plane. Note that upper and lower indices are the same in the present Euclidean metric.

For the motion in the $x^3 - x^4$ -plane, the quadratic fluctuations with periodic boundary conditions have a functional determinant

$$\text{Det} \begin{pmatrix} -\partial_\tau^2 & -\omega_L^E \partial_\tau \\ \omega_L^E \partial_\tau & -\partial_\tau^2 \end{pmatrix} = \text{Det} (-\partial_\tau^2) \times \text{Det} (-\partial_\tau^2 - \omega_L^E) = 1 \times \frac{\sin \hbar \omega_L^E \beta / 2}{\hbar \omega_L^E \beta / 2}, \quad (19.70)$$

leading to the partition function

$$Z^{(34)}(E) = \Delta x_3 \Delta x_4 \sqrt{\frac{M}{2\pi \hbar^2 \beta}} \frac{\sin \hbar \omega_L^E \beta / 2}{\hbar \omega_L^E \beta / 2}, \quad (19.71)$$

This result can, of course, also be obtained without calculation from the observation that the Euclidean electric path integral is completely analogous to the real-time magnetic path integral solved in Section 2.18. Indeed, with the \mathbf{E} -field pointing in the z -direction, the action (19.63) becomes for the motion in the $x^3 - x^4$ -plane

$$\bar{A}_e^{(34)} = \int_0^{\hbar\beta} d\tau \frac{M}{2} \left[x_3'^2 + x_4'^2 + \frac{e}{c} E (x_3 x_4' - x_4 x_3') \right]. \quad (19.72)$$

This coincides with the magnetic action (2.635) in real time, if we insert there the magnetic vector potential (2.636) and replace B by E . The equations of motion (19.62) reduces to

$$x_3'' = \omega_L^E x_4', \quad x_4'' = -\omega_L^E x_3', \quad (19.73)$$

in agreement with the magnetic equations of motion (2.672) in real time. Thus the motion in the $x_3 - x_4$ -plane as a function of the pseudotime τ is the same as the real-time motion in the $x - y$ -plane, if the magnetic field B in the z -direction is exchanged by an E -field of the same size pointing in the x_3 -axis. The amplitude can therefore be taken directly from (2.668), — we must merely replace the real time difference $t_b - t_a$ by $\hbar\beta$. Anyhow, it is zero for any closed orbit.

Yet another way of obtaining the result (19.71) is by summing over the imaginary-time Boltzmann factors $e^{i\beta \mathcal{E}_m}$ of the energies $\mathcal{E}_m = (m + \frac{1}{2})\hbar\omega_L^E$ of the Hamiltonian associated with the Euclidean action (19.72):

$$Z^{(34)}(E) = \Delta x_3 \Delta x_4 \sqrt{\frac{M}{2\pi \hbar^2 \beta}} \hbar \omega_L^E \beta \sum_{m=0}^{\infty} e^{-i(m+\frac{1}{2})\hbar\omega_L^E}. \quad (19.74)$$

Inserting (19.69) and (19.71) into (19.67), we obtain the partition function of a single closed particle orbit in four Euclidean spacetime dimensions:

$$Z_1 = \Delta x_4 V \int_0^\infty \frac{d\beta}{\beta} \sqrt{\frac{M}{2\pi \hbar^2 \beta}} \frac{\omega_L^E \hbar \beta / 2}{\sin \omega_L^E \hbar \beta / 2} e^{-\beta M c^2 / 2}, \quad (19.75)$$

where $V \equiv \Delta x_1 \Delta x_2 \Delta x_3$ is the total spatial volume. We now go over to real times by setting $\Delta x_4 = ic\Delta t$. By exponentiating the subtracted expression (19.75) as in Eq. (19.42), we go to a grand-canonical ensemble, and may identify Z_1 with i times the effective electromagnetic action caused by fluctuating ensemble of particle loops

$$Z_1 = i\Delta\mathcal{A}^{\text{eff}}/\hbar = i\Delta t V \Delta\mathcal{L}^{\text{eff}}/\hbar. \quad (19.76)$$

The integral over β in (19.75) is divergent. In order to make it convergent, we perform two subtractions. In the subtracted expression we change the integration variable to the dimensionless $\zeta = \beta Mc^2/2$, and obtain the effective Lagrangian density

$$\Delta\mathcal{L}^{\text{eff}} = \hbar c \left(\frac{Mc}{\hbar}\right)^4 \frac{1}{4(2\pi)^2} \int_0^\infty \frac{d\zeta}{\zeta^3} \left[\frac{E\zeta/E_c}{\sin E\zeta/E_c} - 1 - \frac{1}{6} \left(\frac{E}{E_c}\right)^2 \right] e^{-\zeta}. \quad (19.77)$$

The first subtraction has removed the divergence coming from the $1/\zeta^3$ -singularity in the integrand. This produces a real infinite field-independent contribution to the effective action which can be omitted since it is unobservable by electromagnetic experiments.² After subtracting this divergence, the integral still contains a logarithmic divergence. It can be interpreted as a contribution proportional to E^2 to the Lagrangian density

$$\Delta\mathcal{L}_{\text{div}}^{\text{eff}} = \hbar c \left(\frac{Mc}{\hbar}\right)^4 \frac{1}{24(2\pi)^2} \left(\frac{E}{E_c}\right)^2 \int_0^\infty \frac{d\zeta}{\zeta} e^{-\zeta} = \frac{\alpha}{24\pi} \int_0^\infty \frac{d\zeta}{\zeta} e^{-\zeta}, \quad (19.78)$$

which changes the original Maxwell term $E^2/2$ to $Z_A E^2/2$ with

$$Z_A = 1 + \frac{\alpha}{12\pi} \int_0^\infty \frac{d\zeta}{\zeta} e^{-\zeta}. \quad (19.79)$$

According to the rules of renormalization theory, the prefactor is removed by renormalizing the field strength, replacing $E \rightarrow E/Z_A^{1/2}$, and identifying the replaced field with the physical, *renormalized* field $E/Z_A^{1/2} \equiv E_R$.

Due to the presence of the affective action, the vacuum is no longer time independent, put depends on time like $e^{-i(H-i\Gamma\hbar/2)\Delta t/\hbar}$. Thus the decay rate of the vacuum per unit volume is given by the imaginary part of the effective Lagrangian density

$$\frac{\Gamma}{V} = \frac{2}{\hbar} \text{Im} \Delta\mathcal{L}^{\text{eff}}. \quad (19.80)$$

In order to calculate this we replace $E\zeta/E_c$ by z in (19.77), and expand in the integrand

$$\frac{z}{\sin z} = 1 + 2 \sum_{n=1}^{\infty} (-1)^n \frac{z^2}{z^2 - n^2\pi^2} = 2 \sum_{n=1}^{\infty} (-1)^n \frac{\zeta^2}{\zeta^2 - \zeta_n^2}, \quad \zeta_n \equiv n\pi \frac{E_c}{E}. \quad (19.81)$$

²This energy would, however, be observable in the cosmological evolution to be discussed in Subsection 19.2.3.

Adding to the poles the usual infinitesimal $i\eta$ -shifts in the complex plane (see p. 115), we replace with the help of the decomposition (1.329)

$$\frac{\zeta}{\zeta^2 - \zeta_n^2} \rightarrow \frac{\zeta}{\zeta^2 - \zeta_n^2 + i\eta} = i \frac{\pi}{2} \delta(\zeta + \zeta_n) - i \frac{\pi}{2} \delta(\zeta - \zeta_n) + \zeta \frac{\mathcal{P}}{\zeta^2 - \zeta_n^2}. \quad (19.82)$$

The δ -functions yield imaginary parts and thus directly the decay rate

$$\begin{aligned} \frac{\Gamma}{V} &= \frac{2}{\hbar} \text{Im} \mathcal{L}^{\text{eff}} = c \left(\frac{Mc}{\hbar} \right)^4 \left(\frac{E}{E_c} \right)^2 \frac{1}{4\pi^3} \frac{1}{2} \sum_{n=1}^{\infty} (-1)^{n-1} \frac{(-1)^{n-1}}{n^2} e^{-n\pi E_c/E} \\ &= \frac{1}{8\pi^3} \frac{e^2}{\hbar c} E^2 \sum_{n=1}^{\infty} \frac{(-1)^{n-1}}{n^2} e^{-n\pi E_c/E}. \end{aligned} \quad (19.83)$$

The principal values produce a real effective Lagrangian density

$$\Delta \mathcal{L}_{\mathcal{P}}^{\text{eff}} = \hbar c \left(\frac{Mc}{\hbar} \right)^4 \frac{1}{4(2\pi)^2} \mathcal{P} \int_0^{\infty} \frac{d\zeta}{\zeta^3} \left(\frac{E\zeta/E_c}{\sin E\zeta/E_c} - 1 - \frac{E^2\zeta^2}{6E_c^2} \right) e^{-\zeta}. \quad (19.84)$$

If we expand

$$\frac{z}{\sin z} = 1 + \frac{z^2}{6} + \frac{7}{360} z^4 + \frac{31}{15120} z^6 + \dots \quad (19.85)$$

and perform the integrals over ζ , we find

$$\Delta \mathcal{L}^{\text{eff}} = \hbar c \left(\frac{Mc}{\hbar} \right)^4 \frac{1}{4(2\pi)^2} \left[\frac{7}{360} \left(\frac{E}{E_c} \right)^4 + \frac{31}{2520} \left(\frac{E}{E_c} \right)^6 + \dots \right], \quad (19.86)$$

or

$$\mathcal{L}^{\text{eff}} = \frac{1}{2} \left\{ E^2 + \frac{7\alpha^2}{180} \frac{(\hbar c)^3}{(Mc^2)^4} E^4 + \frac{31\pi\alpha^3}{315} \left[\frac{(\hbar c)^3}{(Mc^2)^4} \right]^2 E^6 + \dots \right\}, \quad (19.87)$$

The subscript \mathcal{P} of \mathcal{L} has been omitted since the imaginary part of the effective Lagrangian density (19.83) has a vanishing Taylor expansion. Each coefficient in (19.87) is exact to leading order in α .

The extra expansion terms in (19.87) imply that the physical vacuum has a nontrivial E -dependent dielectric constant $\epsilon(E)$. This is caused by the virtual creation and annihilation of particle-antiparticle pairs. Since the dielectric displacement $D(E)$ is obtained from the first derivative of \mathcal{L}^{eff} , the dielectric constant is given by $\epsilon(E) = D(E)/E = \partial \mathcal{L}^{\text{eff}} / E \partial E$. From (19.87) we find the lowest expansion terms

$$\epsilon(E) = 1 + \frac{7\alpha^2}{90} \frac{(\hbar c)^3}{(Mc^2)^4} E^2 + \frac{31\pi\alpha^3}{105} \left[\frac{(\hbar c)^3}{(Mc^2)^4} \right]^2 E^4 + \dots \quad (19.88)$$

Such a term gives rise to a small amplitude for photon-photon scattering in the vacuum, a process which has been observed in the laboratory.

Another way of evaluating (19.83) is based on the representation (19.74) of the partition function in terms of the energy eigenvalues $\mathcal{E}_m = (m + \frac{1}{2})\hbar\omega_L^E$ of the Hamiltonian associated with (19.72). Then Z_1 is given by

$$Z_1 = \Delta x_4 V \int_0^\infty d\beta \sqrt{\frac{M}{2\pi\hbar^2\beta}} \omega_L^E \hbar \sum_{n=0}^\infty e^{-i(n+\frac{1}{2})\hbar\omega_L^E\beta}, \tag{19.89}$$

Then the integral representation (19.77) becomes (before the subtraction)

$$\Delta\mathcal{L}^{\text{eff}} = \hbar c \left(\frac{Mc}{\hbar}\right)^4 \frac{1}{2(2\pi)^2} \int_0^\infty \frac{d\zeta}{\zeta^2} \frac{E}{E_c} \left[\sum_{m=0}^\infty e^{i(m+\frac{1}{2})2E\zeta/E_c} \right] e^{-\zeta}. \tag{19.90}$$

This can be rewritten as

$$\Delta\mathcal{L}_{\text{reg}}^{\text{eff}} = \hbar c \left(\frac{Mc}{\hbar}\right)^4 \frac{i}{2(2\pi)^2} \left[\sum_{k=4,6,\dots}^\infty \frac{(-1)^{k/2-1}}{(k-1)(k-2)} (2^{1-k}-1)\zeta(1-k)2^{k-1} \left(\frac{E}{E_c}\right)^k \right]_{\alpha=1}, \tag{19.91}$$

Expanding the terms in the sum in powers of E/E_c yields two divergent terms plus a regular series

$$\begin{aligned} \Delta\mathcal{L}_{\text{reg}}^{\text{eff}} &= \hbar c \left(\frac{Mc}{\hbar}\right)^4 \frac{i}{2(2\pi)^2} \left[\int d\alpha \int d\alpha \sum_{k=4,6,\dots}^\infty \right. \\ &\quad \times \left. \sum_{m=0}^\infty \frac{(-1)^{k/2-1}}{\alpha^k} (-1)^{k/2-1} [(m + \frac{1}{2})]^{k-1} 2^{k-1} \left(\frac{E}{E_c}\right)^k \right]_{\alpha=1}. \end{aligned} \tag{19.92}$$

Performing the sum over m using Riemann’s zetafunctions (2.521), this becomes

$$\Delta\mathcal{L}_{\text{reg}}^{\text{eff}} = \hbar c \left(\frac{Mc}{\hbar}\right)^4 \frac{i}{2(2\pi)^2} \left[\sum_{k=4,6,\dots}^\infty \frac{(-1)^{k/2-1}}{(k-1)(k-2)} (2^{1-k}-1)\zeta(1-k)2^{k-1} \left(\frac{E}{E_c}\right)^k \right]_{\alpha=1} \tag{19.93}$$

and coincides with the previous result (19.87).

Including Constant Magnetic Field parallel to Electric Field

Let us see how the decay rate (19.83) and the effective Lagrangian (19.77) are influenced by the presence of an additional constant \mathbf{B} -field. This will at first be assumed to be parallel to the \mathbf{E} -field, with both fields pointing in the z -direction. Then the action (19.68) for the motion in the $x^1 - x^2$ -plane becomes

$$\bar{\mathcal{A}}_e^{(12)} = \int_0^{\hbar\beta} d\tau \frac{M}{2} \left[x_1'^2 + x_2'^2 + \frac{e}{c} iB(x_1x_2' - x_2x_1') \right]. \tag{19.94}$$

The partition function in the $x^1 - x^2$ -plane will therefore have the same form as (19.71), except with ω_L^E replaced by $i\omega_L^B$:

$$Z^{(12)}(B) = Z^{(34)}(iB). \tag{19.95}$$

Thus the B -field changes the partition function (19.89) of a single closed orbit to

$$Z_1 = \Delta x_4 V \int_0^\infty \frac{d\beta}{\beta} \sqrt{\frac{M}{2\pi\hbar^2\beta}} \frac{\omega_L^E \hbar\beta/2}{\sin \omega_L^E \hbar\beta/2} \frac{\omega_L^B \hbar\beta/2}{\sinh \omega_L^B \hbar\beta/2} e^{-\beta M c^2/2}, \quad (19.96)$$

and the effective Lagrangian (19.77) becomes

$$\Delta\mathcal{L}^{\text{eff}} = \hbar c \left(\frac{Mc}{\hbar}\right)^4 \frac{1}{4(2\pi)^2} \int_0^\infty \frac{d\zeta}{\zeta^3} \left[\frac{E\zeta/E_c}{\sin E\zeta/E_c} \frac{B\zeta/E_c}{\sinh B\zeta/E_c} - 1 - \frac{(E^2 - B^2)\zeta^2}{6E_c^3} \right] e^{-\zeta}. \quad (19.97)$$

In the subtracted free-field term (19.78), the term E^2 is changed to the Lorentz-invariant combination $E^2 - B^2$. The decay rate (19.83) is modified to

$$\frac{\Gamma}{V} = \frac{2}{\hbar} \text{Im} \Delta\mathcal{L}^{\text{eff}} = c \left(\frac{Mc}{\hbar}\right)^4 \left(\frac{E}{E_c}\right)^2 \frac{1}{4\pi^3} \frac{1}{2} \sum_{n=1}^{\infty} (-1)^{n-1} \frac{1}{n^2} \frac{n\pi B/E}{\sinh n\pi B/E} e^{-n\pi E_c/E}. \quad (19.98)$$

In Eqs. (7.521)–(7.525) we have shown that all results derived for parallel constant electric and magnetic fields remain valid if we replace $E \rightarrow \mathcal{E}$, $B \rightarrow \mathcal{B}$, where \mathcal{E} and \mathcal{B} are given in Eq. (7.524). After this we may expand the integrand in (19.97) in powers of ε and β using Eq. (19.85),

$$\begin{aligned} \frac{1}{\tau^3} \frac{e\beta\tau}{\sin e\beta\tau} \frac{e\varepsilon\tau}{\sinh e\varepsilon\tau} &= \frac{1}{\tau^3} - \frac{e^2}{6\tau} (\varepsilon^2 - \beta^2) + e^4 \frac{\tau}{360} (7\varepsilon^4 - 10\varepsilon^2\beta^2 + 7\beta^4) \\ &\quad - e^6 \frac{\tau^3}{1520} (31\varepsilon^6 - 49\varepsilon^4\beta^2 + 49\varepsilon^2\beta^4 - 31\beta^6) + \dots \end{aligned} \quad (19.99)$$

and obtain the effective Lagrangian the fields generalizing (19.87):

$$\begin{aligned} \mathcal{L}^{\text{eff}} &= \frac{1}{2} \left\{ (\mathbf{E}^2 - \mathbf{B}^2) + \frac{7\alpha^2}{180} \frac{(\hbar c)^3}{(Mc^2)^4} (\mathbf{E}^2 - \mathbf{B}^2)^2 \right. \\ &\quad \left. + \frac{31\pi\alpha^3}{315} \left[\frac{(\hbar c)^3}{(Mc^2)^4} \right]^2 (\mathbf{E}^2 - \mathbf{B}^2) [2(\mathbf{E}^2 - \mathbf{B}^2)^2 - 4(\mathbf{E}\mathbf{B})^2] + \dots \right\}, \end{aligned} \quad (19.100)$$

For strong fields, a saddle point approximation to the generalized version of the integral (19.97) yields the asymptotic form

$$\mathcal{L}^{\text{eff}} \equiv -\frac{e^2}{192\pi^2} (\mathbf{E}^2 - \mathbf{B}^2) \log \left[-4e^2 \frac{(\hbar c)^3}{(Mc^2)^4} (\mathbf{E}^2 - \mathbf{B}^2) \right] + \dots \quad (19.101)$$

Spin-1/2 Particles

We anticipate the small modification which is necessary to obtain the analogous result for spin-1/2 fermions: The tools for this will be developed in Subsections 19.5.1–19.5.3. The relevant formula has actually been derived before in Eq. (7.520). Extending that equation to a constant field tensor that contains both magnetic and

electric fields, and going to imaginary time $\tau = \lambda/c$ and antiperiodic boundary conditions in the interval $t_b - t_a = i\hbar\beta$, we find the functional determinant

$$4 \text{Det}^{1/2} \left(-g_{\mu\nu} \partial_\lambda + i \frac{e}{Mc^2} F_{\mu\nu} \right) = 4 \det^{1/2} \left(\cosh \frac{e}{Mc} F_{\mu\nu} \frac{\hbar\beta}{2} \right), \quad (19.102)$$

with an ordinary determinant of the 4×4 -dimensional matrix of the cosin on the right-hand side. According to Eqs. (7.520) and (7.525), the result is

$$4 \text{Det}^{1/2} \left(-g_{\mu\nu} \partial_\lambda + i \frac{e}{Mc^2} F_{\mu\nu} \right) = 4 \cosh(\mu_B \mathcal{B} \beta / 2) \cos(\mu_B \mathcal{E} \beta / 2). \quad (19.103)$$

where $\mu_B = e\hbar/Mc$ is the Bohr magneton (2.649), and \mathcal{B} and \mathcal{E} are defined in Eq. (7.525)

For a purely electric field, the right-hand side becomes $4 \cos(\mu_B E \beta / 2) = 4 \cos(\omega_L^E \hbar \beta / 2)$ [recall (19.66)]. Multiplying the cos-factor into the expansion (19.81), this is modified to

$$z \frac{\cos z}{\sin z} = 1 + 2 \sum_{n=1}^{\infty} \frac{z^2}{z^2 - n^2 \pi^2} = 2 \sum_{n=1}^{\infty} \frac{\zeta^2}{\zeta^2 - \zeta_n^2}, \quad \zeta_n \equiv n\pi \frac{E_c}{E}. \quad (19.104)$$

Performing now the singular integral over ζ in (19.77), we obtain for the decay rate the same formula as in (19.83), except that the alternating signs are absent. The factor 4 in (19.103) reduces to a factor 2 in the effective action. The resulting effective Lagrangian density for spin-1/2 fermions is therefore

$$\Delta \mathcal{L}_{\text{spin}\frac{1}{2}}^{\text{eff}} = -\hbar c \left(\frac{Mc}{\hbar} \right)^4 \frac{1}{2(2\pi)^2} \int_0^\infty \frac{d\zeta}{\zeta^3} \left(\frac{E\zeta/E_c}{\tan E\zeta/E_c} - 1 + \frac{E^2 \zeta^2}{3E_c^3} \right) e^{-\zeta}, \quad (19.105)$$

a result first derived by Heisenberg and Euler in 1935 [8]. Its imaginary part yields the decay rate of the vacuum due to pair creation

$$\begin{aligned} \frac{\Gamma_{\text{spin}\frac{1}{2}}}{V} &= \frac{2}{\hbar} \text{Im} \Delta \mathcal{L}_{\text{spin}\frac{1}{2}}^{\text{eff}} = c \left(\frac{Mc}{\hbar} \right)^4 \left(\frac{E}{E_c} \right)^2 \frac{1}{4\pi^3} \sum_{n=1}^{\infty} \frac{1}{n^2} e^{-n\pi E_c/E} \\ &= \frac{1}{4\pi^3} \frac{e^2}{\hbar c} E^2 \sum_{n=1}^{\infty} \frac{1}{n^2} e^{-n\pi E_c/E}. \end{aligned} \quad (19.106)$$

The reason for the reduction from 4 to 2 is that the sum over bosonic paths has to be first divided by a factor 2 to remove their orientation, before the fermionic factor 4 is applied. This procedure is not so obvious at this point but will be understood later in Subsection 19.5.2. The remaining factor 2 accounts for the two spin orientations of the charged particles.

The Taylor series

$$\frac{z}{\tan z} = 1 - \frac{z^2}{3} - \frac{1}{45} z^4 - \frac{2}{945} z^6 - \dots \quad (19.107)$$

in the integrand of (19.105) leads to the expansion

$$\Delta\mathcal{L}^{\text{eff}} = \hbar c \left(\frac{Mc}{\hbar}\right)^4 \frac{2}{16\pi^2} \left[\frac{1}{45} \left(\frac{E}{E_c}\right)^4 + \frac{4}{315} \left(\frac{E}{E_c}\right)^6 + \dots \right], \quad (19.108)$$

so that

$$\mathcal{L}^{\text{eff}} = \frac{1}{2} \left\{ E^2 + \frac{4\alpha^2}{45} \frac{(\hbar c)^3}{(Mc^2)^4} E^4 + \frac{64\pi\alpha^3}{315} \left[\frac{(\hbar c)^3}{(Mc^2)^4} \right]^2 E^6 + \dots \right\}. \quad (19.109)$$

The term proportional to α^2 -term implies a small amplitude for photon-photon scattering which can be observed in the laboratory [9].

As in the boson result (19.100), each coefficient is exact to leading order in α , and the virtual creation and annihilation of fermion-antifermion pairs gives the physical vacuum a nontrivial E -dependent dielectric constant

$$\epsilon(E) = \frac{1}{E} \frac{\partial \mathcal{L}^{\text{eff}}}{\partial E} = 1 + \frac{8\alpha^2}{45} \frac{(\hbar c)^3}{(Mc^2)^4} E^2 + \frac{64\pi\alpha^3}{105} \left[\frac{(\hbar c)^3}{(Mc^2)^4} \right]^2 E^4 + \dots \quad (19.110)$$

If we admit also a constant \mathbf{B} -field parallel to \mathbf{E} , the formulas (19.106) and (19.105) for the spin- $\frac{1}{2}$ -particles are modified in the same way as the bosonic formulas (19.83) and (19.84), except that the determinant (19.102) in spinor space introduces a further factor $\cosh(eB/Mc)$. Thus we obtain

$$\Delta\mathcal{L}_{\text{spin}\frac{1}{2}}^{\text{eff}} = -\hbar c \left(\frac{Mc}{\hbar}\right)^4 \frac{1}{2(2\pi)^2} \int_0^\infty \frac{d\zeta}{\zeta^3} \left[\frac{E\zeta/E_c}{\tan E\zeta/E_c} \frac{B\zeta/E_c}{\tanh B\zeta/E_c} - 1 + \frac{(E^2 - B^2)\zeta^2}{3E_c^3} \right] e^{-\zeta}. \quad (19.111)$$

For a general combination of constant electric and magnetic fields, we simply exchange E and B by the Lorentz invariants ε and β . From the imaginary part we obtain the decay rate

$$\frac{\Gamma_{\text{spin}\frac{1}{2}}}{V} = \frac{2}{\hbar} \text{Im} \Delta\mathcal{L}_{\text{spin}\frac{1}{2}}^{\text{eff}} = c \left(\frac{Mc}{\hbar}\right)^4 \left(\frac{\varepsilon}{E_c}\right)^2 \frac{1}{4\pi^3} \sum_{n=1}^\infty \frac{1}{n^2} \frac{n\pi\beta/\varepsilon}{\tanh n\pi\beta/\varepsilon} e^{-n\pi E_c/\varepsilon}. \quad (19.112)$$

For strong fields, a saddle point approximation to the generalized integral (19.105) yields the asymptotic form

$$\mathcal{L}^{\text{eff}} \equiv -\frac{e^2}{48\pi^2} (\mathbf{E}^2 - \mathbf{B}^2) \log \left[-4e^2 \frac{(\hbar c)^3}{(Mc^2)^4} (\mathbf{E}^2 - \mathbf{B}^2) \right] + \dots \quad (19.113)$$

19.2.2 Birth of Universe

A similar tunneling phenomenon could explain the birth of the expanding universe [10].

As an idealization of the observed density of matter, the universe is usually assumed to be isotropic and homogeneous. Then it is convenient to describe it by a coordinate frame in which the metric is rotationally invariant. To account for the expansion, we have to allow for an explicit time dependence of the spatial part of the metric. In the spatial part, we choose coordinates which participate in the expansion. They can be imagined as being attached to the gas particles in a homogenized universe. Then the time passing at each coordinate point is the proper time. In this context it is the so-called *cosmic standard time* to be denoted by t . We imagine being an observer at a coordinate point with $dx^i/dt = 0$, and measure t by counting the number of orbits of an electron around a proton in a hydrogen atom, starting from the moment of the big bang (forgetting the fact that in the early time of the universe, the atom does not yet exist).

Geometry

With this time calibration, the component g_{00} of the metric tensor is identically equal to unity

$$g_{00}(x) \equiv 1, \quad (19.114)$$

such that at a fixed coordinate point, the proper time coincides with the coordinate time, $d\tau = dt$. Moreover, since all clocks in space follow the same prescription, there is no mixing between time and space coordinates, a property called *time orthogonality*, so that

$$g_{0i}(x) \equiv 0. \quad (19.115)$$

As a consequence, the Christoffel symbol $\bar{\Gamma}_{00}^\mu$ [recall (10.7)] vanishes identically:

$$\bar{\Gamma}_{00}^\mu \equiv \frac{1}{2}g^{\mu\nu}(\partial_0 g_{0\nu} + \partial_0 g_{0\nu} - g_{00}) \equiv 0. \quad (19.116)$$

This is the mathematical way of expressing the fact that a particle sitting at a coordinate point, which has $dx^i/dt = 0$, and thus $dx^\mu/dt = u^\mu = (c, 0, 0, 0)$, experiences no acceleration

$$\frac{du^\mu}{d\tau} = -\bar{\Gamma}_{00}^\mu c^2 = 0. \quad (19.117)$$

The coordinates themselves are trivially comoving.

Under the above condition, the invariant distance has the general form

$$ds^2 = c^2 dt^2 - {}^{(3)}g_{ij}(x) dx^i dx^j. \quad (19.118)$$

We now impose the spatial isotropy upon the spatial metric g_{ij} . Denote the spatial length element by dl , so that

$$dl^2 = {}^{(3)}g_{ij}(x) dx^i dx^j. \quad (19.119)$$

The isotropy and homogeneity of space is most easily expressed by considering the spatial curvature ${}^{(3)}R_{ijk}{}^l$ calculated from the spatial metric ${}^{(3)}g_{ij}(x)$. The space corresponds to a spherical surface. If its radius is a , the curvature tensor is, according to Eq. (10.161),

$${}^{(3)}R_{ijkl}(x) = \frac{1}{a^2} \left[{}^{(3)}g_{il}(x){}^{(3)}g_{jk}(x) - {}^{(3)}g_{ik}(x){}^{(3)}g_{jl}(x) \right]. \quad (19.120)$$

The derivation of this expression in Section 10.4 was based on the assumption of a spherical space whose curvature $K \equiv 1/a^2$ is positive. If we allow also for hyperbolic and parabolic spaces with negative and vanishing curvature, and characterize these by a constant

$$k = \left\{ \begin{array}{ll} 1 & \text{spherical} \\ 0 & \text{parabolic} \\ -1 & \text{hyperbolic} \end{array} \right\} \text{ universe}, \quad (19.121)$$

then the prefactor $1/a^2$ in (19.120) is replaced by $K \equiv k/a^2$. For $k = -1$ and 0 , the space has an open topology and an infinite total volume.

The Ricci tensor and curvature scalar are in these three cases [compare (10.163) and (10.156)]

$${}^{(3)}R_{il} = k \frac{2}{a^2} g_{il}(x), \quad {}^{(3)}R = k \frac{6}{a^2}. \quad (19.122)$$

By construction it is obvious that for $k = 1$, the three-dimensional space has a closed topology and a finite spatial volume which is equal to the surface of a sphere of radius a in four dimensions

$${}^4S^a = 2\pi^2 a^3. \quad (19.123)$$

A circle in this space has maximal radius a and a maximal circumference $2\pi a$. A sphere with radius $r_0 < a$ has a volume

$$\begin{aligned} {}^{(3)}V_{r_0}^a &= \int_0^{2\pi} d\varphi \int_0^\pi d\theta \sin \theta \int_0^{r_0} dr \frac{r^2}{\sqrt{1 - r^2/a^2}} \\ &= 4\pi \left(\frac{a^3}{2} \arcsin \frac{r_0}{a} - \frac{a^2 r_0}{2} \sqrt{1 - \frac{r_0^2}{a^2}} \right). \end{aligned} \quad (19.124)$$

For small r_0 , the curvature is irrelevant and the volume depends on r_0 like the usual volume of a sphere in three dimensions:

$${}^{(3)}V_{r_0}^a \approx V_{r_0} = \frac{4\pi}{3} r_0^3. \quad (19.125)$$

For $r_0 \rightarrow a$, however, ${}^{(3)}V_{r_0}^a$ approaches a saturation volume $2\pi a^3$.

The analogous expressions for negative and zero curvature are obvious.

Robertson-Walker Metric

In spherical coordinates, the four-dimensional invariant distance (19.118) defines the *Robertson-Walker metric*.

$$ds^2 = c^2 dt^2 - dl^2 \quad (19.126)$$

$$dl^2 = \frac{dr^2}{1 - kr^2/a^2} + r^2(d\theta^2 + \sin^2 \theta d\varphi^2). \quad (19.127)$$

It will be convenient to introduce, instead of r , the angle α on the surface of the four-sphere, such that

$$r = a \sin \alpha. \quad (19.128)$$

Then the metric has the four-dimensional angular form

$$ds^2 = c^2 dt^2 - a^2(t)[d\alpha^2 + f^2(\alpha)(d\theta^2 + \sin^2 \theta d\varphi^2)], \quad (19.129)$$

where for spherical, parabolic, and hyperbolic spaces, $f(\alpha)$ is equal to

$$f(\alpha) = \begin{cases} \sin \alpha & k = 1, \\ \alpha & k = 0, \\ \sinh \alpha & k = -1. \end{cases} \quad (19.130)$$

In order to have maximal symmetry, it is useful to absorb $a(t)$ into the time and define a new timelike variable η by

$$c dt = a(\eta) d\eta, \quad (19.131)$$

so that the invariant distance is measured by

$$ds^2 = a^2(\eta)[d\eta^2 - d\alpha^2 - f^2(\alpha)(d\theta^2 + \sin^2 \theta d\varphi^2)]. \quad (19.132)$$

Then the metric is simply

$$g_{\mu\nu} = a^2(\eta) \begin{pmatrix} 1 & & & \\ & -1 & & \\ & & -f^2(\alpha) & \\ & & & -f^2(\alpha) \sin^2 \theta, \end{pmatrix} \quad (19.133)$$

and the Christoffel symbols become

$$\Gamma_{00}^0 = \frac{a_\eta}{a}, \quad \Gamma_{00}^i = 0, \quad \Gamma_{0i}^0 = 0, \quad \Gamma_{0i}^j = \frac{a_\eta}{a} \delta_i^j, \quad \Gamma_{ij}^0 = -\frac{a_\eta}{a^3} g_{ij}, \quad \Gamma_{ij}^k = 0, \quad (19.134)$$

where the subscripts denote derivatives with respect to the corresponding variables:

$$a_\eta \equiv \frac{da}{d\eta} = \frac{a}{c} \frac{da}{dt} \equiv \frac{a}{c} a_t. \quad (19.135)$$

We now calculate the 00-component of the Ricci tensor:

$$R_{00} = \partial_\mu \Gamma_{00}^\mu - \partial_0 \Gamma_{\mu 0}^\mu - \Gamma_{\mu 0}^\nu \Gamma_{0\nu}^\mu + \Gamma_{00}^\mu \Gamma_{\nu\mu}^\nu. \quad (19.136)$$

Inserting the Christoffel symbols (19.134) we find

$$\partial_\mu \Gamma_{00}^\mu - \partial_0 \Gamma_{\mu 0}^\mu = -\partial_0 \Gamma_{i0}^i = -3 \frac{d}{d\eta} \frac{a_\eta}{a} = -3 \frac{1}{a^2} (a_\eta a - a_\eta^2), \quad (19.137)$$

$$\Gamma_{\mu 0}^\nu \Gamma_{0\nu}^\mu = \Gamma_{00}^0 \Gamma_{00}^0 + \Gamma_{00}^i \Gamma_{0i}^0 + \Gamma_{i0}^0 \Gamma_{00}^i + \Gamma_{i0}^j \Gamma_{0j}^i = \left(\frac{a_\eta}{a}\right)^2 + 3 \left(\frac{a_\eta}{a}\right)^2, \quad (19.138)$$

$$\Gamma_{00}^\mu \Gamma_{\nu\mu}^\nu = \Gamma_{00}^0 \Gamma_{00}^0 + \Gamma_{00}^0 \Gamma_{i0}^i + \Gamma_{00}^i \Gamma_{0i}^0 + \Gamma_{00}^i \Gamma_{ki}^k = \left(\frac{a_\eta}{a}\right)^2 + 3 \left(\frac{a_\eta}{a}\right)^2, \quad (19.139)$$

so that

$$R_{00} = -\frac{3}{a^2} (aa_\eta - a_\eta^2), \quad R_0^0 = g^{00} R_{00} = -\frac{3}{a^4} (aa_\eta - a_\eta^2). \quad (19.140)$$

The other components can be determined by relating them to the three-dimensional curvature tensor ${}^{(3)}R_{ij}$ which has the simple form (19.120). So we calculate

$$\begin{aligned} R_{ij} = R_{\mu ij}^\mu &= R_{kij}^k + R_{0ij}^0 \\ &= {}^{(3)}R_{ij} - \Gamma_{kj}^0 \Gamma_{i0}^k + \Gamma_{ij}^0 \Gamma_{k0}^k + R_{0ij}^0. \end{aligned} \quad (19.141)$$

Inserting

$$R_{0ij}^0 = \partial_0 \Gamma_{ij}^0 - \partial_i \Gamma_{0j}^0 - \Gamma_{0j}^l \Gamma_{il}^0 - \Gamma_{0j}^0 \Gamma_{i0}^0 + \Gamma_{ij}^l \Gamma_{0l}^0 + \Gamma_{ij}^0 \Gamma_{00}^0, \quad (19.142)$$

$${}^{(3)}R_{ij} = k \frac{2}{a^2} g_{ij} \quad (19.143)$$

and the above Christoffel symbols (19.134) gives

$$R_{ij} = -\frac{1}{a^4} (2ka^2 + a_\eta^2 + aa_\eta) g_{ij} \quad (19.144)$$

and thus a curvature scalar

$$\begin{aligned} R &= g^{00} R_{00} + g^{ij} R_{ij} = -\frac{1}{a^2} \left[\frac{3}{a^2} (aa_\eta - a_\eta^2) \right] - \frac{3}{a^4} (2ka^2 + a_\eta^2 + aa_\eta) \\ &= -\frac{6}{a^3} (a_\eta + ka). \end{aligned} \quad (19.145)$$

Action and Field Equation

In the absence of matter, the *Einstein-Hilbert action* of the gravitational field is

$$\mathcal{A} = \int d^4x \sqrt{-g} \mathcal{L} = -\frac{1}{2\kappa} \int d^4x \sqrt{-g} (R + 2\lambda), \quad (19.146)$$

were κ is related to Newton's gravitational constant

$$G_N \approx 6.673 \cdot 10^{-8} \text{ cm}^3 \text{ g}^{-1} \text{ s}^{-2} \quad (19.147)$$

by

$$\frac{1}{\kappa} = \frac{c^3}{8\pi G_N}. \quad (19.148)$$

A natural length scale of gravitational physics is the *Planck length*, which can be formed from a combination of Newton's gravitational constant (19.147), the light velocity $c \approx 3 \times 10^{10}$ cm/s, and Planck's constant $\hbar \approx 1.05459 \times 10^{-27}$:

$$l_P = \left(\frac{c^3}{G_N \hbar} \right)^{-1/2} \approx 1.615 \times 10^{-33} \text{ cm}. \quad (19.149)$$

It is the Compton wavelength $l_P \equiv \hbar/m_P c$ associated with the Planck mass

$$m_P = \left(\frac{c\hbar}{G_N} \right)^{1/2} \approx 2.177 \times 10^{-5} \text{ g} = 1.22 \times 10^{22} \text{ MeV}/c^2. \quad (19.150)$$

The constant $1/\kappa$ in the action (19.146) can be expressed in terms of the Planck length as

$$\frac{1}{\kappa} = \frac{\hbar}{8\pi l_P^2}. \quad (19.151)$$

If we add to (19.146) a matter action and vary to combined action with respect to the metric $g_{\mu\nu}$, we obtain the *Einstein equation*

$$\frac{1}{\kappa} \left(R_{\mu\nu} - \frac{1}{2} g_{\mu\nu} R - \lambda g_{\mu\nu} \right) = T_{\mu\nu}, \quad (19.152)$$

where $T_{\mu\nu}$ is the energy-momentum tensor of matter. The constant λ is called the *cosmological constant*. It is believed to arise from the zero-point oscillations of all quantum fields in the universe.

A single field contributes to the Lagrangian density $\overset{f}{\mathcal{L}}$ in (19.146) a term $-\Lambda \equiv -\lambda/\kappa$ which is typically of the order of \hbar/l_P^4 . For bosons, the sign is positive, for fermions negative, reflecting the filling of all negative-energy in the vacuum. A constant of this size is much larger than the present experimental estimate. In the literature one usually finds estimates for the dimensionless quantity

$$\Omega_{\lambda 0} \equiv \frac{\lambda c^2}{3H_0^2}. \quad (19.153)$$

where H_0 is the *Hubble constant*, whose inverse is roughly the lifetime of the universe

$$H_0^{-1} \approx 14 \times 10^9 \text{ years}. \quad (19.154)$$

Present fits to distant supernovae and other cosmological data yield the estimate [11]

$$\Omega_{\lambda 0} \approx 0.68 \pm 0.10. \quad (19.155)$$

The associated cosmological constant λ has the value

$$\lambda = \Omega_{\lambda 0} \frac{3H_0^2}{c^2} \approx \frac{\Omega_{\lambda 0}}{(6.55 \times 10^{27} \text{ cm})^2} \approx \frac{\Omega_{\lambda 0}}{(6.93 \times 10^9 \text{ ly})^2} \approx \frac{\Omega_{\lambda 0}}{(2.14 R_{\text{universe}})^2}. \quad (19.156)$$

Note that in the presence of λ , the Schwarzschild solution around a mass M has the metric

$$ds^2 = B(r)c^2 dt^2 - B^{-1} dr^2 - r^2 d\theta^2 - r^2 \sin^2 \theta d\phi^2, \quad (19.157)$$

with

$$B(r) = 1 - \frac{2MG_N}{c^2 r} - \frac{2}{3} \lambda r^2 = 1 - \frac{M}{m_{\text{P}}} \frac{l_{\text{P}}}{r} - \frac{2}{3} \Omega_{\lambda 0} \frac{r^2}{(2.14 R_{\text{universe}})^2}. \quad (19.158)$$

The λ -term adds a small repulsion to Newton's force between mass points. if the distances are the order of the radius of the universe.

The value of the constant Λ associated with (19.155) is

$$\Lambda = \frac{\lambda}{\kappa} = \Omega_{\lambda 0} \frac{3H_0^2}{c^2} \frac{l_{\text{P}}^2}{8\pi} \approx 10^{-122} \frac{\hbar}{l_{\text{P}}^4}. \quad (19.159)$$

Such a small prefactor can only arise from an almost perfect cancellation of the contributions of boson and fermion fields. This cancellation is the main reason for postulating a broken supersymmetry in the universe, in which every boson has a fermionic counterpart. So far, the known particle spectra show no trace of such a symmetry. Thus there is need to explain it by some other not yet understood mechanism.

The simplest model of the universe governed by the action (19.146) is called *Friedmann model* or *Friedmann universe*.

19.2.3 Friedmann Model

Inserting (19.140) and (19.145) into the 00-component of the Einstein equation (19.152), we obtain the equation for the energy

$$\frac{3}{a^4} (a_{\eta}^2 + ka^2) - \lambda = \kappa T_0^0. \quad (19.160)$$

In terms of the cosmic standard time t , the general equation reads

$$3 \left[\left(\frac{a_t}{a} \right)^2 + k \frac{c^2}{a^2} \right] - \lambda c^2 = c^2 \kappa T_0^0. \quad (19.161)$$

The simplest Friedmann model is based on an energy-momentum tensor T_0^0 of an ideal pressure-less gas of mass density ρ :

$$T_\mu^\nu = c\rho u_\mu u^\nu, \quad (19.162)$$

where u^μ are the velocity four-vectors $u^\mu = (\gamma, \gamma\mathbf{v}/c)$ of the particles whose components are $u^\mu = (\gamma, \gamma\mathbf{v}/c)$ with $\gamma \equiv 1/\sqrt{1 - v^2/c^2}$ if the four components transform like $(dx^0 = cdt, d\mathbf{x})$. The gas is assumed to be at rest in our comoving coordinates. so that only the T_0^0 -component is nonzero:

$$T_0^0 = c\rho. \quad (19.163)$$

This component is invariant under the time transformation (19.131).

As a fortunate accident, this component of the Einstein equation has no $a_{\eta\eta}a$ term. Thus we may simply study the first-order differential equation

$$\frac{3}{a^4} (a_\eta^2 + ka^2) - \lambda = c\kappa\rho. \quad (19.164)$$

Since the total volume of the universe is $2\pi a^3$, we can express ρ in terms of the total mass M as follows

$$\rho = \frac{M}{2\pi^2 a^3}. \quad (19.165)$$

In this way we arrive at the differential equation

$$\frac{3}{a^4} (a_\eta^2 + ka^2) - \lambda = \frac{\kappa M c}{2\pi^2 a^3} = \frac{4G_N M}{\pi c^2 a^3}. \quad (19.166)$$

This equation of motion can also be obtained in another way. We express the action (19.146) in terms of $a(\eta)$ using the equation (19.180) for R . We use the volume (19.123) and the relation (19.131) to rewrite the integration measure as

$$\int d^4x \sqrt{-g} = \int dt {}^{(4)}S^a = 2\pi^2 \int d\eta a^4(\eta), \quad (19.167)$$

so that

$$\overset{f}{\mathcal{A}} = \frac{2\pi^2}{2\kappa} \int d\eta [6a(a_{\eta\eta} + ka) - 2\lambda a^4] \hat{=} \frac{2\pi^2}{\kappa} \int d\eta [-3a_\eta^2 + 3ka^2 - \lambda a^4]. \quad (19.168)$$

The second expression arises from the first by a partial integration and ignoring the boundary terms which do not influence the equation of motion. The above matter is described by the action

$$\overset{m}{\mathcal{A}} = - \int d^4x \sqrt{-g} c\rho = -2\pi^2 \int d\eta \frac{Mc}{2\pi^2} a(\eta). \quad (19.169)$$

Variation with respect to a yields the Euler-Lagrange equation

$$6(a_{\eta\eta} + ka) - 4\lambda a^3 - \frac{\kappa M c}{2\pi^2} = 0. \quad (19.170)$$

Note that in terms of the Robertson-Walker time t [recall (19.131)], the equation of motion reads

$$\ddot{a} = \frac{\lambda}{3}a - \frac{1}{6} \frac{\kappa Mc}{2\pi^2 a^2}. \quad (19.171)$$

As one should expect, the cosmological expansion is slowed down by matter, due to the gravitational attraction. A positive cosmological constant, on the other hand, accelerates the expansion. At the special value

$$\lambda = \lambda_{\text{Einstein}} \equiv \frac{\kappa Mc}{2\pi^2 a^3} = \frac{4G_{\text{N}}M}{\pi c^2 a^3} = \frac{4\pi G_{\text{N}}\rho}{c}, \quad (19.172)$$

the two effects cancel each other and there exist a time-independent solution at a radius a and a density ρ . This is the cosmological constant which Einstein chose before Hubble's discovery of the expanding universe to agree with Hoyle's steady-state model of the universe (a choice which he later called the biggest blunder of his life).

Multiplying (19.170) by a_η and integration over η yields the pseudo-energy conservation law

$$3(a_\eta^2 + ka^2) - \lambda a^4 - \frac{\kappa Mc}{2\pi^2}a = \text{const}, \quad (19.173)$$

in agreement with (19.166) for a vanishing pseudo-energy.

This equation may also be written as

$$a_\eta^2 + ka^2 - a_{\text{max}}a - \frac{\lambda}{3}a^4 = 0, \quad (19.174)$$

where

$$a_{\text{max}} \equiv \frac{\kappa Mc}{6\pi^2} = \frac{4G_{\text{N}}M}{3\pi c^2}. \quad (19.175)$$

This looks like the energy conservation law for a point particle of mass 2 in an effective potential of the universe

$$V^{\text{univ}}(a) = ka^2 - a_{\text{max}}a - \frac{\lambda}{3}a^4, \quad (19.176)$$

at zero total energy. The potential is plotted for the spherical case $k = 1$ in Fig. 19.2.

Friedmann neglects the cosmological constant and considers the equation

$$a_\eta^2 + ka^2 - a_{\text{max}}a = 0. \quad (19.177)$$

The solution of the differential equation for this trajectory is found by direct integration. Assuming $k = 1$ we obtain

$$\eta = \int \frac{da}{\sqrt{-V^{\text{univ}}(a)}} = \int \frac{da}{\sqrt{-(a - a_{\text{max}}/2)^2 + a_{\text{max}}^2/4}} = -\arccos \frac{2a}{a_{\text{max}}}. \quad (19.178)$$

Figure 19.2 Potential of closed Friedman universe as a function of the reduced radius a/a_{\max} for $\lambda a_{\max}^2 = 0.1$. Note the metastable minimum which leads to a possible solution $a \equiv a_0$. A tunneling process to the right leads to an expanding universe.

With the initial condition $a(0) = 0$, this implies

$$a(\eta) = \frac{a_{\max}}{2} (1 - \cos \eta). \tag{19.179}$$

Integrating Eq. (19.131), we find the relation between η and the physical (=proper) time

$$t = \frac{1}{c} \int d\eta a(\eta) = \frac{a_{\max}}{2c} \int d\eta (1 - \cos \eta) = \frac{a_{\max}}{2c} (\eta - \sin \eta). \tag{19.180}$$

The solution $a(t)$ is the cycloid pictured in Fig. 19.3. The radius of the universe bounces periodically with period $t_0 = \pi a_{\max}/c$ from zero to a_{\max} . Thus it emerges from a big bang, expands with a decreasing expansion velocity due to the gravitational attraction, and recontracts to a point.

Figure 19.3 Radius of universe as a function of time in Friedman universe, measured in terms of the period $t_0 \equiv \pi a_{\max}/c$. (solid curve=closed, dashed curve=hyperbolic, dotted curve =parabolic). The curve for the closed universe is a cycloid.

Certainly, for high densities the solution is inapplicable since the pressure-less ideal gas approximation (19.163) breaks down.

Consider now the case of negative curvature with $k = -1$. Then the differential equation (19.177) reads

$$a_\eta^2 - a^2 - a_{\max}a - \frac{\lambda}{3}a^4 = 0. \quad (19.181)$$

In order to compare the curves we shall again introduce a mass parameter M and rewrite the density as in (19.165), although M has no longer the meaning of the total mass of the universe (which is now infinite). The solution for $\lambda = 0$ is now

$$a(\eta) = \frac{a_{\max}}{2}(\cosh \eta - 1), \quad (19.182)$$

$$t = \frac{a_{\max}}{2c}(\sinh \eta - \eta). \quad (19.183)$$

The solution is again depicted in Fig. 19.3. After a big bang, the universe expands forever, although with decreasing speed, due to the gravitational pull. The quantity a_{\max} is no longer the maximal radius nor is t_0 the period.

Consider finally the parabolic case $k = 0$, where the equation of motion (19.177) reads

$$a_\eta^2 - a_{\max}a - \frac{\lambda}{3}a^4 = 0, \quad (19.184)$$

where M is a mass parameter defined as before in the negative curvature case. Now the solution for $\lambda = 0$ is simply

$$\eta = 2\sqrt{\frac{a}{a_{\max}}}, \quad (19.185)$$

which is inverted to

$$a(\eta) = a_{\max}\frac{\eta^2}{4}. \quad (19.186)$$

Now we solve (19.131) with

$$t = \frac{a_{\max}}{12c}\eta^3, \quad (19.187)$$

so that

$$a(t) = \left(\frac{9}{4}a_{\max}\right)^{1/3} (ct)^{2/3}. \quad (19.188)$$

This solution is simply the continuation of leading term in the previous two solutions to large t .

19.2.4 Tunneling of Expanding Universe

It is now interesting to observe that the potential for the spherical universe in Fig. 19.2 allows for a time-independent solution in which the radius lies at the metastable minimum which we may call a_0 . The solution $a \equiv a_0$ is a time-independent universe. We may now imagine that the expanding universe arises from this by a tunneling process towards the abyss on the right of the potential [10]. Its rate can be calculated from the Euclidean action of the associated classical solution in imaginary time corresponding to the motion from a_0 towards the right in the inverted potential $-V^{\text{univ}}(a)$.

Observe that this birth can only lead to universe of positive curvature. For a negative curvature, where the a^2 -term in (19.176) has the opposite sign, the metastable minimum is absent.

19.3 Relativistic Coulomb System

An external time-independent potential $V(\mathbf{x})$ is introduced into the path integral (19.48) by substituting the energy E by $E - V(\mathbf{x})$. In the case of an attractive Coulomb potential, the second term in the action (19.49) becomes

$$\mathcal{A}^{\text{int}} = - \int_{\lambda_a}^{\lambda_b} d\lambda h(\lambda) \frac{(E + e^2/r)^2}{2Mc^3}, \tag{19.189}$$

where $r = |\mathbf{x}|$. The associated path integral is calculated via a Duru-Kleinert transformation as follows [12].

Consider the three-dimensional Coulomb system where the spacetime dimension is $D = 4$. Then we increase the three-dimensional space in a trivial way by a dummy fourth component x^4 , just as in the nonrelativistic treatment in Section 13.4. The additional variable x^4 is eliminated at the end by an integral $\int dx_a^4/r_a = \int d\gamma_a$, as in (13.120) and (13.127). Then we perform a Kustaanheimo-Stiefel transformation (13.106) $dx^\mu = 2A(u)^\mu{}_\nu du^\nu$. This changes $x'^{\mu 2}$ into $4\vec{u}^2 \vec{u}'^2$, with the vector symbol indicating the four-vector nature. The transformed action reads:

$$\tilde{\mathcal{A}}_{e,E} = \int_{\lambda_a}^{\lambda_b} d\lambda \left\{ \frac{4Mc\vec{u}^2}{2h(\lambda)} \vec{u}'^2(\lambda) + \frac{h(\lambda)}{2Mc^3\vec{u}^2} \left[(M^2c^4 - E^2)\vec{u}^2 - 2Ee^2 - \frac{e^4}{\vec{u}^2} \right] \right\}. \tag{19.190}$$

We now choose the gauge $h(\lambda) = 1$, and go from λ to a new dimensionless parameter s via the path-dependent time transformation $d\lambda = f ds$ with $f = \vec{u}^2$. Result is the DK-transformed action

$$\bar{\mathcal{A}}_{e,E}^{\text{DK}} = \int_{s_a}^{s_b} \frac{ds}{c} \left\{ \frac{4Mc^2}{2} \vec{u}'^2(s) + \frac{1}{2Mc^2} \left[(M^2c^4 - E^2) \vec{u}^2 - 2Ee^2 - \frac{e^4}{\vec{u}^2} \right] \right\}. \tag{19.191}$$

It describes a particle of mass $\mu = 4M$ moving as a function of the ‘‘pseudotime’’ s in a harmonic oscillator potential of dimensionless ‘‘frequency’’

$$\omega = \frac{1}{2Mc^2} \sqrt{M^2c^4 - E^2}. \tag{19.192}$$

The oscillator possesses an additional attractive potential $-e^4/2Mc^2\vec{u}^2$, which is conveniently parametrized in the form of a centrifugal barrier

$$V_{\text{extra}} = \hbar^2 \frac{l_{\text{extra}}^2}{2\mu\vec{u}^2}, \quad (19.193)$$

whose squared angular momentum has the negative value

$$l_{\text{extra}}^2 \equiv -4\alpha^2. \quad (19.194)$$

Here α denotes the fine-structure constant $\alpha \equiv e^2/\hbar c \approx 1/137$. In addition, there is also a trivial constant potential

$$V_{\text{const}} = -\frac{E}{Mc^2}e^2. \quad (19.195)$$

If we ignore, for the moment, the centrifugal barrier V_{extra} , the solution of the path integral can immediately be written down [see (13.127)]:

lab(13.3d)
est(13.121)

$$(\mathbf{x}_b|\mathbf{x}_a)_E = -i\frac{\hbar}{2Mc} \frac{1}{16} \int_0^\infty dS e^{\epsilon^2 ES/Mc^2\hbar} \int_0^{4\pi} d\gamma_a (\vec{u}_b S|\vec{u}_a 0), \quad (19.196)$$

where $(\vec{u}_b S|\vec{u}_a 0)$ is the pseudotime evolution amplitude of the four-dimensional harmonic oscillator.

There are no time slicing corrections for the same reason as in the three-dimensional case. This is ensured by the affine connection of the Kustaanheimo-Stiefel transformation satisfying

$$\Gamma_\mu^{\mu\lambda} = g^{\mu\nu} e_i^\lambda \partial_\mu e^i_\nu = 0 \quad (19.197)$$

(see the discussion in Section 13.6).

Performing the integral over γ_a in (19.196), we obtain

$$\begin{aligned} (\mathbf{x}_b|\mathbf{x}_a)_E &= -i\frac{\hbar}{2Mc} \frac{M\kappa}{\pi\hbar} \int_0^1 d\varrho \frac{\varrho^{-\nu}}{(1-\varrho)^2} I_0 \left(2\kappa \frac{2\sqrt{\varrho}}{1-\varrho} \sqrt{(r_b r_a + \mathbf{x}_b \mathbf{x}_a)/2} \right) \\ &\quad \times \exp \left[-\kappa \frac{1+\varrho}{1-\varrho} (r_b + r_a) \right], \end{aligned} \quad (19.198)$$

with the variable

$$h \equiv e^{-2\omega S}, \quad (19.199)$$

and the parameters

$$\nu = \frac{e^2}{2\omega\hbar} \frac{E}{Mc^2} = \frac{\alpha}{\sqrt{M^2 c^4/E^2 - 1}}, \quad (19.200)$$

$$\kappa = \frac{\mu\omega}{2\hbar} = \frac{1}{\hbar c} \sqrt{M^2 c^4 - E^2} = \frac{E}{\hbar c} \frac{\alpha}{\nu}. \quad (19.201)$$

ref(13.203)As in the further treatment of (13.203), the use of formula (13.207)

lab(13.n1)

est(13.192)

ref(13.207)

lab(13.n5)

est(13.197)

provides us with a partial wave decomposition

$$I_0(z \cos(\theta/2)) = \frac{2}{z} \sum_{l=0}^{\infty} (2l+1) P_l(\cos \theta) I_{2l+1}(z) \quad (19.202)$$

$$\begin{aligned} (\mathbf{x}_b | \mathbf{x}_a)_E &= \frac{1}{r_b r_a} \sum_{l=0}^{\infty} (r_b | r_a)_{E,l} \frac{2l+1}{4\pi} P_l(\cos \theta) \\ &= \frac{1}{r_b r_a} \sum_{l=0}^{\infty} (r_b | r_a)_{E,l} \sum_{m=-l}^l Y_{lm}(\hat{\mathbf{x}}_b) Y_{lm}^*(\hat{\mathbf{x}}_a). \end{aligned} \quad (19.203)$$

The radial amplitude is normalized slightly differently from (13.210):

ref(13.210)

lab(13.n9)

est(13.201)

$$\begin{aligned} (r_b | r_a)_{E,l} &= -i \frac{\hbar}{2Mc} \sqrt{r_b r_a} \frac{2M}{\hbar} \int_0^{\infty} dy \frac{1}{\sinh y} e^{2\nu y} \\ &\quad \times \exp[-\kappa \coth y (r_b + r_a)] I_{2l+1} \left(2\kappa \sqrt{r_b r_a} \frac{1}{\sinh y} \right). \end{aligned} \quad (19.204)$$

At this place, we incorporate the additional centrifugal barrier via the replacement

$$2l+1 \rightarrow 2\tilde{l}+1 \equiv \sqrt{(2l+1)^2 + l_{\text{extra}}^2} \quad (19.205)$$

as in Eqs. (8.146) and (14.223). The integration over y according to (9.29) yields

ref(8.146)

lab(x8.146)

est(19@8.146)

ref(14.223)

lab(14.239)

est(14.239)

$$(r_b | r_a)_{E,l} = -i \frac{\hbar}{2Mc} \frac{M}{\hbar \kappa} \frac{\Gamma(-\nu + \tilde{l} + 1)}{(2\tilde{l} + 1)!} W_{\nu, \tilde{l}+1/2}(2\kappa r_b) M_{\nu, \tilde{l}+1/2}(2\kappa r_a). \quad (19.206)$$

This expression possesses poles in the Gamma function whose positions satisfy the equations $\nu - \tilde{l} - 1 = 0, 1, 2, \dots$. These determine the bound states of the Coulomb system. To simplify subsequent expressions, we introduce the small positive l -dependent parameter

ref(9.29)

lab(intf3)

est(9.52)

$$\delta_l \equiv l - \tilde{l} = l + 1/2 - \sqrt{(l + 1/2)^2 - \alpha^2} \approx \frac{\alpha^2}{2l+1} + \mathcal{O}(\alpha^4). \quad (19.207)$$

Then the pole positions satisfy $\nu = \tilde{n}_l \equiv n - \delta_l$, with $n = l + 1, l + 2, l + 3, \dots$. Using the relation (19.200), we obtain the bound-state energies:

$$\begin{aligned} E_{nl} &= \pm Mc^2 \left[1 + \frac{\alpha^2}{(n - \delta_l)^2} \right]^{-1/2} \\ &\approx \pm Mc^2 \left[1 - \frac{\alpha^2}{2n^2} - \frac{\alpha^4}{n^3} \left(\frac{1}{2l+1} - \frac{3}{8n} \right) + \mathcal{O}(\alpha^6) \right]. \end{aligned} \quad (19.208)$$

Note the appearance of the plus-minus sign as a characteristic property of energies in relativistic quantum mechanics. A correct interpretation of the negative energies as

positive energies of antiparticles is straightforward only within quantum field theory, and will not be discussed here. Even if we ignore the negative energies, there is poor agreement with the experimental spectrum of the hydrogen atom. The spin of the electron must be included to get more satisfactory results.

To find the wave functions, we approximate near the poles $\nu \approx \tilde{n}_l$:

$$\begin{aligned}\Gamma(-\nu + \tilde{l} + 1) &\approx -\frac{(-)^{n_r}}{n_r!} \frac{1}{\nu - \tilde{n}_l}, \\ \frac{1}{\nu - \tilde{n}_l} &\approx \frac{2}{\tilde{n}_l} \frac{\hbar^2 \kappa^2}{2M} \left(\frac{E}{Mc^2}\right)^2 \frac{2Mc^2}{E^2 - E_{nl}^2}, \\ \kappa &\approx \frac{E}{Mc^2} \frac{1}{a_H} \frac{1}{\tilde{n}_l},\end{aligned}\quad (19.209)$$

with the radial quantum number $n_r = n - l - 1$. By analogy with the nonrelativistic equation (13.213), the last equation can be rewritten as

ref(13.213)
lab(13.n11)
est(13.203)

$$\kappa = \frac{1}{\tilde{a}_H} \frac{1}{\nu}, \quad (19.210)$$

where

$$\tilde{a}_H \equiv a_H \frac{Mc^2}{E} \quad (19.211)$$

denotes a modified energy-dependent Bohr radius [compare (4.376)]. It sets the length scale of relativistic bound states in terms of the energy E . Instead of being $1/\alpha \approx 137$ times the Compton wavelength of the electron \hbar/Mc , the modified Bohr radius is equal to $1/\alpha$ times $\hbar c/E$.

Near the positive-energy poles, we now approximate

$$-i\Gamma(-\nu + \tilde{l} + 1) \frac{M}{\hbar\kappa} \approx \frac{(-)^{n_r}}{\tilde{n}_l^2 n_r!} \frac{1}{\tilde{a}_H} \left(\frac{E}{Mc^2}\right)^2 \frac{2Mc^2 i\hbar}{E^2 - E_{nl}^2}. \quad (19.212)$$

Using this behavior and formula (9.48) for the Whittaker functions [together with (9.50)] we write the contribution of the bound states to the spectral representation of the fixed-energy amplitude as

ref(9.48)
lab(9.for)
est(9.73)
ref(9.50)
lab(x9.75)
est(9.75)

$$(r_b|r_a)_{E,l} = \frac{\hbar}{Mc} \sum_{n=l+1}^{\infty} \left(\frac{E}{Mc^2}\right)^2 \frac{2Mc^2 i\hbar}{E^2 - E_{nl}^2} R_{nl}(r_b) R_{nl}(r_a) + \dots \quad (19.213)$$

A comparison between the pole terms in (19.206) and (19.213) renders the radial wave functions

$$\begin{aligned}R_{nl}(r) &= \frac{1}{\tilde{a}_H^{1/2} \tilde{n}_l} \frac{1}{(2\tilde{l} + 1)!} \sqrt{\frac{(\tilde{n}_l + \tilde{l})!}{(n - l - 1)!}} \\ &\quad \times (2r/\tilde{n}_l \tilde{a}_H)^{\tilde{l}+1} e^{-r/\tilde{n}_l \tilde{a}_H} M(-n + l + 1, 2\tilde{l} + 2, 2r/\tilde{n}_l \tilde{a}_H) \quad (19.214) \\ &= \frac{1}{\tilde{a}_H^{1/2} \tilde{n}_l} \sqrt{\frac{(n - l - 1)!}{(\tilde{n} + \tilde{l})!}} e^{-r/\tilde{n} \tilde{a}_H} (2r/\tilde{n}_l \tilde{a}_H)^{\tilde{l}+1} L_{\tilde{n}_l - l - 1}^{2\tilde{l}+1}(2r/\tilde{n}_l \tilde{a}_H).\end{aligned}$$

The properly normalized total wave functions are

$$\psi_{nlm}(\mathbf{x}) = \frac{1}{r} R_{nl}(r) Y_{lm}(\hat{\mathbf{x}}). \quad (19.215)$$

The continuous wave functions are obtained in the same way as from the non-relativistic amplitude in formulas (13.221)–(13.229).

19.4 Relativistic Particle in Electromagnetic Field

Consider now the relativistic particle in a general spacetime-dependent electromagnetic vector field $A^\mu(x)$.

19.4.1 Action and Partition Function

An electromagnetic field $A^\mu(x)$ is included into the canonical action (19.14) in the usual way by the minimal substitution (2.644):

$$\bar{\mathcal{A}}_e[p, x] = \int_{\lambda_a}^{\lambda_b} d\lambda \left\{ -ip\dot{x} + \frac{\hbar(\lambda)}{2Mc} \left[\left(p - \frac{e}{c} A \right)^2 + M^2 c^2 \right] \right\}, \quad (19.216)$$

and the amplitude (19.22):

$$(x_b|x_a) = \frac{\hbar}{2Mc} \int_0^\infty dS \int \mathcal{D}h \Phi[h] \int \mathcal{D}^D x e^{-\bar{\mathcal{A}}_e/\hbar}, \quad (19.217)$$

with the minimally coupled action [compare (2.706)]

$$\bar{\mathcal{A}}_e = \int_{\lambda_a}^{\lambda_b} d\lambda \left[\frac{Mc}{2\hbar(\lambda)} \dot{x}^2(\lambda) + i \frac{e}{c} \dot{x}(\lambda) A(x(\lambda)) + \hbar(\lambda) \frac{Mc}{2} \right], \quad (19.218)$$

which reduces in the simplest gauge (19.23) to the obvious extension of (19.26):

$$(x_b|x_a) = \frac{\hbar^2}{2M} \int_0^\infty d\beta e^{-\beta Mc^2/2} \int \mathcal{D}^4 x e^{-\mathcal{A}_e}, \quad (19.219)$$

with the action

$$\mathcal{A}_e = \mathcal{A}_{e,0} + \mathcal{A}_{e,\text{int}} \equiv \int_0^{\hbar\beta} d\tau \left[\frac{M}{2} \dot{x}^2(\tau) + i \frac{e}{c} \dot{x}(\tau) A(x(\tau)) \right]. \quad (19.220)$$

The partition function of a single closed particle loop of all shapes and lengths in an external electromagnetic field is from (19.37)

$$Z_1 = \int_0^\infty \frac{d\beta}{\beta} e^{-\beta Mc^2/2} \int \mathcal{D}^D x e^{-\mathcal{A}_e/\hbar}. \quad (19.221)$$

As in (19.45) and (19.46) this yields, up to a factor $1/\hbar$ the effective action of an ensemble of closed particle loops in an external electromagnetic field.

19.4.2 Perturbation Expansion

Since the electromagnetic coupling is rather small, we can split the exponent $e^{-\mathcal{A}/\hbar}$ into $e^{-\mathcal{A}_0/\hbar}e^{-\mathcal{A}_{\text{int}}/\hbar}$ and expand the second factor in powers of \mathcal{A}_{int} :

$$e^{-\mathcal{A}_{\text{int}}/\hbar} = \sum_{n=0}^{\infty} \frac{(-ie/\hbar c)^n}{n!} \prod_{i=1}^n \left[\int_0^{\hbar\beta} d\tau_i \dot{x}(\tau_i) A(x(\tau_i)) \right]. \quad (19.222)$$

If the noninteracting effective action implied by Eqs. (19.39), (19.37), and (19.46) is denoted by

$$\frac{\Gamma_{e,0}}{\hbar} \equiv -Z_1 = - \int_0^{\infty} \frac{d\beta}{\beta} e^{-\beta M c^2/2} \frac{V_D}{\sqrt{2\pi\hbar^2\beta/M}^D} = - \frac{V_D}{\lambda_M^C{}^D} \frac{1}{(4\pi)^{D/2}} \Gamma(1-D/2), \quad (19.223)$$

with the Compton wavelength λ_M^C of Eq. (19.31), we obtain the perturbation expansion

$$\frac{\Gamma_e}{\hbar} = \frac{\Gamma_{e,0}}{\hbar} - \int_0^{\infty} \frac{d\beta}{\beta} e^{-\beta M c^2/2} \frac{V_D}{\sqrt{2\pi\hbar^2\beta/M}^D} \sum_{n=1}^{\infty} \frac{(-ie/c)^n}{n!} \left\langle \prod_{i=1}^n \left[\int_0^{\hbar\beta} d\tau_i \dot{x}(\tau_i) A(x(\tau_i)) \right] \right\rangle_0, \quad (19.224)$$

where $\langle \dots \rangle_0$ denotes the free-particle expectation values [compare (3.483)–(3.486)] taken in the free path integral with periodic paths with a fixed β [compare (19.38) and (19.41)]:

$$\langle \mathcal{O}[x] \rangle_0 \equiv \frac{\int \mathcal{D}^D x \mathcal{O}[x] e^{-\mathcal{A}_{e,0}/\hbar}}{\int \mathcal{D}^D x e^{-\mathcal{A}_{e,0}/\hbar}}. \quad (19.225)$$

The denominator is equal to $V_D/\sqrt{2\pi\hbar^2\beta/M}^D$.

The free effective action in the expansion (19.224) can be omitted by letting the sum start with $n = 0$.

The evaluation of the cumulants proceeds by Fourier decomposing the vector fields as

$$A(x) = \int \frac{d^D k}{(2\pi)^D} e^{ikx} A(k), \quad (19.226)$$

and rewriting (19.224) as

$$\begin{aligned} \frac{\Gamma_e}{\hbar} &= \frac{\Gamma_{e,0}}{\hbar} - \int_0^{\infty} \frac{d\beta}{\beta} e^{-\beta M c^2/2} \frac{V_D}{\sqrt{2\pi\hbar^2\beta/M}^D} \\ &\times \sum_{n=1}^{\infty} \frac{(-ie/\hbar c)^n}{n!} \prod_{i=1}^n \left[\int \frac{d^D k_i}{(2\pi)^D} A^{\mu_i}(k_i) \right] \left\langle \prod_{i=1}^n \left[\int_0^{\hbar\beta} d\tau_i \dot{x}^{\mu_i}(\tau_i) e^{ik_i x(\tau_i)} \right] \right\rangle_0. \end{aligned} \quad (19.227)$$

First we evaluate the expectation values

$$\left\langle \dot{x}(\tau_1) e^{ik_1 x(\tau_1)} \dots \dot{x}(\tau_n) e^{ik_n x(\tau_n)} \right\rangle_0. \quad (19.228)$$

Due to the periodic boundary conditions, we separate, as in Section 3.25, the path average $x_0 = \bar{x}(\tau)$ [recall (3.807)], writing

$$x(\tau) = x_0 + \delta x(\tau), \quad (19.229)$$

and factorize (19.228) as

$$\left\langle e^{i(k_1 + \dots + k_n)x_0} \right\rangle_0 \left\langle \delta \dot{x}(\tau_1) e^{ik_1 \delta x(\tau_1)} \dots \delta \dot{x}(\tau_n) e^{ik_n \delta x(\tau_n)} \right\rangle_0. \quad (19.230)$$

The first average can be found as an average with respect to the x_0 -part of the path integral whose measure was given in Eq. (3.811). It yields a δ function ensuring the conservation of the total energy and momenta of the n photons involved:

$$\left\langle e^{i(k_1 + \dots + k_n)x_0} \right\rangle_0 = \frac{1}{V_D} (2\pi)^D \delta^{(D)}(k_1 + \dots + k_n). \quad (19.231)$$

The denominator comes from the normalization of the expectation value which has an integral $\int d^D x_0$ in the denominator.

The second average is obtained using Wick's theorem. The correlation function $\langle \delta x^\mu(\tau_1) \delta x^\nu(\tau_2) \rangle_0$, is obtained from Eq. (3.842) in the limit $\Omega \rightarrow 0$ for $\tau_1, \tau_2 \in (0, \beta)$. It is the periodic propagator with subtracted zero mode:

$$\langle \delta x^\mu(\tau_1) \delta x^\nu(\tau_2) \rangle_0 = \delta^{\mu\nu} G(\tau_1, \tau_2) = \delta^{\mu\nu} \frac{\hbar}{M} \bar{\Delta}(\tau_1, \tau_2), \quad (19.232)$$

where $\bar{\Delta}(\tau_1 - \tau_2)$ is the subtracted periodic Green function $G_{\omega, e}^a(\tau - \tau')$ of the differential operator $-\partial_\tau^2$ calculated in Eq. (3.254) in the short notation of Subsection 10.12.1 [see Eq. (10.565)]. In the presently used physical units it reads:

$$\bar{\Delta}(\tau, \tau') \equiv \bar{\Delta}(\tau - \tau') = \frac{(\tau - \tau')^2}{2\hbar\beta} - \frac{\tau - \tau'}{2} + \frac{\hbar\beta}{12}, \quad \tau \in [0, \hbar\beta]. \quad (19.233)$$

The time derivatives of (19.233) are from (10.566):

$$\dot{\bar{\Delta}}(\tau, \tau') = -\dot{\bar{\Delta}}(\tau, \tau') \equiv \frac{\tau - \tau'}{\hbar\beta} - \frac{\epsilon(\tau - \tau')}{2}, \quad \tau, \tau' \in [0, \hbar\beta]. \quad (19.234)$$

With these functions it is straightforward to calculate the expectation value using the Wick rule (3.310) for $j(\tau) = \sum_i^n k_i \delta(\tau - \tau_i)$:

$$\left\langle e^{ik_1 \delta x(\tau_1)} \dots e^{ik_n \delta x(\tau_n)} \right\rangle_0 = e^{-\frac{1}{2} \sum_{i,j=1}^n k_i k_j G(\tau_i, \tau_j)}. \quad (19.235)$$

By rewriting the right-hand side as

$$e^{-\frac{1}{2} \sum_{i,j=1}^n k_i k_j G(\tau_i, \tau_j)} = e^{-\frac{1}{2} \sum_{i,j=1}^n k_i k_j [G(\tau_i, \tau_j) - G(\tau_i, \tau_i)] - \frac{1}{2} (\sum_{i=1}^n k_i)^2 G(\tau_i, \tau_i)}, \quad (19.236)$$

we see that if the momenta k_i add up to zero, $\sum_{i=1}^n k_i = 0$, we can replace (19.235) by

$$\left\langle e^{ik_1 \delta x(\tau_1)} \dots e^{ik_n \delta x(\tau_n)} \right\rangle_0 = \exp \left\{ - \sum_{i < j}^n k_i k_j [G(\tau_i, \tau_j) - G(\tau_i, \tau_i)] \right\}. \quad (19.237)$$

It is therefore useful to introduce the subtracted Green function

$$G'(\tau_i, \tau_j) \equiv G(\tau_i, \tau_j) - G(\tau_i, \tau_i). \quad (19.238)$$

Recall the similar situation in the evaluation (5.377).

An obvious extension of (19.235) is

$$\begin{aligned} & \left\langle e^{i[k_1 \delta x(\tau_1) + q_1 \dot{x}(\tau_1)]} \dots e^{i[k_n \delta x(\tau_n) + q_n \dot{x}(\tau_n)]} \right\rangle_0 \\ &= e^{-\frac{1}{2} \sum_{i,j=1}^n k_i k_j G(\tau_i, \tau_j) - \frac{1}{2} \sum_{i,j=1}^n q_i q_j G'(\tau_i, \tau_j) - \frac{1}{2} \sum_{i,j=1}^n k_i q_j G'(\tau_i, \tau_j)}, \end{aligned} \quad (19.239)$$

where the dots have the same meaning as in (10.395).

19.4.3 Lowest-Order Vacuum Polarization

Consider the lowest nontrivial case $n = 2$. By differentiating (19.237) with respect to iq_1 and iq_2 , and setting $q_i = 0$, we obtain for $k_2 = -k_1 = -k$:

$$\left\langle \dot{x}(\tau_1) e^{ik\delta x(\tau_1)} \dot{x}(\tau_2) e^{-ik\delta x(\tau_2)} \right\rangle_0 = \left[G'(\tau_1, \tau_2) + k^2 G(\tau_1, \tau_2) G'(\tau_1, \tau_2) \right] e^{k^2 [G(\tau_1, \tau_2) - G(\tau_1, \tau_1)]}. \quad (19.240)$$

Inserting this into (19.227) after factorization according to (19.230), we obtain the lowest correction to the effective action

$$\begin{aligned} \Delta \Gamma_e &= -\frac{e^2}{2\hbar c^2} \int_0^\infty \frac{d\beta}{\beta} e^{-\beta M c^2/2} \frac{1}{\sqrt{2\pi \hbar^2 \beta / M}} \prod_{i=1}^2 \left[\int \frac{d^D k_i}{(2\pi)^D} \right] (2\pi)^D \delta^{(D)}(k_1 + k_2) A^\mu(k_1) A^\nu(k_2) \\ &\times \int_0^{\hbar\beta} d\tau_1 \int_0^{\hbar\beta} d\tau_2 \left[G'(\tau_1, \tau_2) \delta^{\mu\nu} + k_1^\mu k_1^\nu G(\tau_1, \tau_2) G'(\tau_1, \tau_2) \right] e^{k_1^2 G'(\tau_1, \tau_2)}, \end{aligned} \quad (19.241)$$

where we have displayed the proper vector indices. A partial integration over τ_1 brings the second line to the form

$$-\int_0^{\hbar\beta} d\tau_1 \int_0^{\hbar\beta} d\tau_2 \left(k_1^2 \delta^{\mu\nu} - k_1^\mu k_1^\nu \right) G(\tau_1, \tau_2) G'(\tau_1, \tau_2) e^{k_1^2 G'(\tau_1, \tau_2)}. \quad (19.242)$$

Expressing $G'(\tau_1, \tau_2)$ as $(\hbar/M) \left[\bar{\Delta}(\tau_1 - \tau_2) - \bar{\Delta}(0) \right]$ and using the periodicity in τ_2 , we calculate the integral

$$\frac{\hbar^2}{M^2} \left(k_1^2 \delta^{\mu\nu} - k_1^\mu k_1^\nu \right) \hbar\beta \int_0^{\hbar\beta} d\tau \dot{\Delta}'^2(\tau) e^{\hbar k_1^2 M [\Delta'_p(\tau) - \Delta'_p(0)]}. \quad (19.243)$$

We now introduce reduced times $u \equiv \tau/\hbar\beta$ and rewrite the Green functions for $\tau \in (0, \hbar\beta)$, $u \in (0, 1)$ as

$$\bar{\Delta}(\tau_1 - \tau_2) = -\frac{\hbar\beta}{2} \left[u(1-u) - \frac{1}{6} \right], \quad (19.244)$$

$$\dot{\Delta}(\tau_1 - \tau_2) = u - \frac{1}{2}, \quad (19.245)$$

such that the integral in (19.243) becomes

$$\frac{1}{4} \int_0^1 du (2u-1)^2 e^{-\beta \hbar^2 k_1^2 u(1-u)/2M}. \quad (19.246)$$

Inserting this into (19.241) and dropping the irrelevant subscript of k_1 we arrive at

$$\begin{aligned} \Delta\Gamma_e = & \frac{e^2}{2\hbar c^2} \int_0^\infty \frac{d\beta}{\beta} e^{-\beta M c^2/2} \frac{1}{\sqrt{2\pi \hbar^2 \beta/M}^D} \int \frac{d^D k}{(2\pi)^D} A^\mu(k) A^\nu(-k) \\ & \times (k^2 \delta^{\mu\nu} - k^\mu k^\nu) \frac{\hbar^4 \beta^2}{4M^2} \int_0^1 du (2u-1)^2 e^{-\beta \hbar^2 k^2 2Mu(1-u)/2M}. \end{aligned} \quad (19.247)$$

After replacing $\hbar^2 \beta/2M \rightarrow \beta$, the integral over β can easily be performed using the formula (2.498) with the result

$$\begin{aligned} \Delta\Gamma_e = & \frac{e^2 \hbar}{c^2} \frac{1}{(4\pi)^{D/2}} \frac{1}{2c} \int \frac{d^D k}{(2\pi)^D} A^\mu(k) A^\nu(-k) (k^2 \delta^{\mu\nu} - k^\mu k^\nu) \\ & \times \Gamma(2-D/2) \int_0^1 du (2u-1)^2 [u(1-u)k^2 + M^2 c^2/\hbar^2]^{D/2-2}. \end{aligned} \quad (19.248)$$

In the prefactor we recognize the fine structure constant $\alpha = e^2/\hbar c$ [recall (1.505)]. The momentum integral can be rewritten as

$$\frac{1}{2} \int \frac{d^D k}{(2\pi)^D} A^\mu(k) A^\nu(-k) (k^2 \delta^{\mu\nu} - k^\mu k^\nu) = \frac{1}{4} \int \frac{d^D k}{(2\pi)^D} F_{\mu\nu}(-k) F_{\mu\nu}(k), \quad (19.249)$$

where

$$F_{\mu\nu}(x) = \partial_\mu A_\nu(x) - \partial_\nu A_\mu(x) \quad (19.250)$$

is the tensor of electromagnetic field strengths. We now abbreviate the integral over u as follows:

$$\Pi(k^2) \equiv \alpha \frac{4\pi}{(4\pi)^{D/2}} \Gamma(2-D/2) \int_0^1 du (2u-1)^2 [u(1-u)k^2 + M^2 c^2/\hbar^2]^{D/2-2}. \quad (19.251)$$

This allows us to re-express (19.248) in configuration space:

$$\Delta\Gamma_e = \frac{1}{16\pi c} \int d^4 x F_{\mu\nu}(x) \Pi(-\partial^2) F_{\mu\nu}(x), \quad (19.252)$$

where $F_{\mu\nu}(x)$ is the Euclidean version of the gauge-invariant 4-dimensional curl of the vector potential:

$$F_{\mu\nu}(x) = \partial_\mu A_\nu(x) - \partial_\nu A_\mu(x). \quad (19.253)$$

In Minkowski space, the components of $F_{\mu\nu}$ are the electric and magnetic fields:

$$F_{0i} = -F^{0i} = -\partial^0 A^i + \partial^i A^0 = -\partial_0 A^i - \partial_i A^0 = -E^i, \quad (19.254)$$

$$F_{ij} = F^{ij} = \partial^i A^j - \partial^j A^i = -\partial_i A^j + \partial_j A^i = -\epsilon_{ijk} B^k. \quad (19.255)$$

This is in accordance with the electrodynamic definitions

$$\mathbf{E} \equiv -\frac{1}{c}\dot{\mathbf{A}} - \nabla\phi, \quad \mathbf{B} \equiv \nabla \times \mathbf{A}, \quad (19.256)$$

where $A^0(x)$ is identified with the electric potential $\phi(x)$.

In terms of $F_{\mu\nu}(x)$, the Maxwell action in the presence of a charge density $\rho(x)$ and a electric current density $\mathbf{j}(x)$

$$\mathcal{A}^{\text{em}} = \int dt d^3x \left\{ \frac{1}{4\pi} [\mathbf{E}^2(x) - \mathbf{B}^2(x)] - \left[\rho(x)\phi(x) - \frac{1}{c}\mathbf{j}(x) \cdot \mathbf{A}(x) \right] \right\}, \quad (19.257)$$

can be written covariantly as

$$\mathcal{A}^{\text{em}} = - \int d^4x \left[\frac{1}{8\pi c} F_{\mu\nu}^2(x) + \frac{1}{c^2} j^\mu(x) A_\mu(x) \right], \quad (19.258)$$

where

$$j_\mu(x) = (c\rho(x), \mathbf{j}(x)) \quad (19.259)$$

is the four-vector formed by charge density and electric current.

By extremizing the action (19.258) in the vector field $A^\mu(x)$ we find the Maxwell equations in the covariant form

$$\partial_\nu F^{\nu\mu}(x) = \frac{1}{c} j^\mu(x), \quad (19.260)$$

whose zeroth and spatial components reduce to the time-honored laws of Gauss and Ampère:

$$\nabla \cdot \mathbf{E} = 4\pi\rho \quad (\text{Gauss's law}), \quad (19.261)$$

$$\nabla \times \mathbf{B} = \frac{4\pi}{c} \mathbf{j} \quad (\text{Ampère's law}). \quad (19.262)$$

Expressing $\mathbf{E}(x)$ in terms of the potential using Eq. (19.256) and inserting this into Gauss's law, we obtain for a static point charge e at the origin the Poisson equation

$$-\nabla^2\phi(\mathbf{x}) = 4\pi e\delta^{(3)}(\mathbf{x}). \quad (19.263)$$

An electron of charge $-e$ experiences an attractive mechanical potential $V(\mathbf{x}) = -e\phi(\mathbf{x})$. In momentum space this satisfies the equation reads

$$\mathbf{k}^2 V(\mathbf{k}) = -4\pi e^2. \quad (19.264)$$

From this we find directly the Coulomb potential of a hydrogen atom

$$V(\mathbf{x}) = (\nabla^2)^{-1} 4\pi e\delta^{(3)}(\mathbf{x}) = - \int \frac{d^3k}{(2\pi)^3} \frac{4\pi e^2}{\mathbf{k}^2} = -\frac{e^2}{r}, \quad r \equiv |\mathbf{x}|, \quad (19.265)$$

where e^2 can be expressed in terms of the fine-structure constant α as $e^2 = \hbar c \alpha$. (1.505).

The Euclidean result (19.252) implies that a fluctuating closed particle orbit changes the first term in the Maxwell action (19.258) to

$$\mathcal{A}_{\text{em}}^{\text{eff}} = - \int d^D x \frac{1}{16\pi c} F_{\mu\nu}(x) [1 + \Pi(-\partial^2)] F_{\mu\nu}(x). \quad (19.266)$$

The quantity $\Pi(-\partial^2)$ is the *self-energy* of the electromagnetic field caused by the fluctuating closed particle orbit.

The self-energy changes the Maxwell equations (19.261) and (19.262) into

$$\begin{aligned} [1 + \Pi(-\partial^2)] \nabla \cdot \mathbf{E} &= 4\pi\rho, \\ [1 + \Pi(-\partial^2)] \nabla \times \mathbf{B} &= \frac{4\pi}{c} \mathbf{j}. \end{aligned} \quad (19.267)$$

The static equation (19.264) for the atomic potential changes therefore into

$$[1 + \Pi(\mathbf{k}^2)] \mathbf{k}^2 V(\mathbf{k}) = -4\pi e^2. \quad (19.268)$$

Since $\Pi(\mathbf{k}^2)$ is of order $\alpha \approx 1/137$, this can be solved approximately by

$$V(\mathbf{k}) \equiv -4\pi e^2 [1 - \Pi(\mathbf{k}^2)] \frac{1}{\mathbf{k}^2}. \quad (19.269)$$

In real space, the attractive atomic potential is changed to lowest order in α as

$$-\frac{\alpha}{r} \rightarrow - [1 - \Pi(\nabla^2)] \frac{\alpha}{r}. \quad (19.270)$$

Set us calculate this change explicitly. For small ϵ and k^2 , we expand the self-energy (19.251) in $D = 4 - \epsilon$ dimensions as

$$\Pi(k^2) = \frac{\alpha}{24\pi} \left[-\frac{2}{\epsilon} + \log \frac{M^2 c^2 e^\gamma}{4\pi \hbar^2} \right] - \frac{\alpha \hbar^2 k^2}{160\pi M^2 c^2} + \mathcal{O} \left(\epsilon, \frac{k^2}{M^2 c^2 / \hbar^2} \right). \quad (19.271)$$

Inserting this into (19.269), or into (19.269) and using the Poisson equation $-\nabla^2 \times 1/r = 4\pi \delta^{(3)}(\mathbf{x})$, we see that the self energy changes the Coulomb potential as follows:

$$-\frac{\alpha}{r} \rightarrow - [1 - \Pi(\nabla^2)] \frac{\alpha}{r} \approx - \left\{ 1 - \frac{\alpha}{24\pi^2} \left[-\frac{2}{\epsilon} + \log \frac{M^2 c^2 e^\gamma}{4\pi \hbar^2} \right] \right\} \frac{\alpha}{r} - \frac{\alpha^2 \hbar^2}{40M^2 c^2} \delta^{(3)}(\mathbf{x}). \quad (19.272)$$

The first term amounts to a small renormalization of the electromagnetic coupling by the factor in curly brackets, which is close to unity for finite ϵ since α is small. We are, however, interested in the result in $D = 4$ spacetime dimensions where $\epsilon \rightarrow 0$ and (19.272) diverges. The physical resolution of this divergence problem is to assume

the initial point charge e_0 in the electromagnetic interaction to be different from the experimentally observed e to precisely compensate the renormalization factor, i.e.,

$$e_0^2 = e^2 \left\{ 1 + \frac{\alpha}{24\pi^2} \left[-\frac{2}{\epsilon} + \log \frac{M^2 c^2 e^\gamma}{4\pi\hbar^2} \right] \right\}. \quad (19.273)$$

Thus, the result Eq. (19.272) is really obtained in terms of e_0 , i.e., with α replaced by α_0 . Then, using (19.273), we find that up to order α^2 , the atomic potential is

$$V^{\text{eff}}(\mathbf{x}) = -\frac{\alpha}{r} - \frac{\alpha^2 \hbar^2}{40M^2 c^2} \delta^{(3)}(\mathbf{x}). \quad (19.274)$$

The second is an additional attractive contact interaction. It shifts the energies of the s -wave bound states in Eq. (19.208) slightly downwards.

19.5 Path Integral for Spin-1/2 Particle

For particles of spin 1/2 the path integral formulation becomes algebraically more involved. Let us first recall a few facts from Dirac's theory of the electron.

19.5.1 Dirac Theory

In the Dirac theory, electrons are described by a four-component field $\psi_\alpha(x)$ in spacetime parametrized by $x^\mu = (ct, \mathbf{x})$ with $\mu = 0, 1, 2, 3$. The field satisfies the wave equation

$$(i\hbar\rlap{-}\not{\partial} - Mc)\psi(x) = 0, \quad (19.275)$$

where $\rlap{-}\not{\partial}$ is a short notation for $\gamma^\mu \partial_\mu$ and γ^μ are 4×4 Dirac matrices satisfying the anticommutation rules

$$\{\gamma^\mu, \gamma^\nu\} = 2g^{\mu\nu}, \quad (19.276)$$

where $g_{\mu\nu}$ is now the Minkowski metric

$$g_{\mu\nu} = \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & -1 & 0 & 0 \\ 0 & 0 & -1 & 0 \\ 0 & 0 & 0 & -1 \end{pmatrix}. \quad (19.277)$$

An explicit representation of these rules is most easily written in terms of the Pauli matrices (1.448):

$$\gamma^0 = \begin{pmatrix} \sigma^0 & 0 \\ 0 & -\sigma^0 \end{pmatrix}, \quad \gamma^i = \begin{pmatrix} 0 & \sigma^i \\ -\sigma^i & 0 \end{pmatrix}, \quad (19.278)$$

where σ^0 is a 2×2 unit matrix. The anticommutation rules (19.276) follow directly from the multiplication rules for the Pauli matrices:

$$\sigma^i \sigma^j = \delta^{ij} + i\epsilon^{ijk} \sigma^k. \quad (19.279)$$

The action of the Dirac field is

$$\mathcal{A} = \int d^4x \bar{\psi}(x) (i\hbar\partial - Mc) \psi(x), \quad (19.280)$$

where the conjugate field $\bar{\psi}(x)$ is defined as

$$\bar{\psi}(x) \equiv \psi^\dagger(x)\gamma^0. \quad (19.281)$$

It can be shown that this makes $\bar{\psi}(x)\psi(x)$ a scalar field under Lorentz transformations, $\bar{\psi}(x)\gamma^\mu\psi(x)$ a vector field, and \mathcal{A} an invariant. If we decompose $\psi(x)$ into its Fourier components

$$\psi(x) = \sum_{\mathbf{k}} \frac{1}{\sqrt{V}} e^{i\mathbf{k}\mathbf{x}} \psi_{\mathbf{k}}(t), \quad (19.282)$$

where V is the spatial volume, the action reads

$$\mathcal{A} = \int_{t_a}^{t_b} dt \sum_{\mathbf{k}} \psi_{\mathbf{k}}^\dagger(t) [i\hbar\partial_t - H(\hbar\mathbf{k})] \psi_{\mathbf{k}}(t), \quad (19.283)$$

with the 4×4 Hamiltonian matrix

$$H(\mathbf{p}) \equiv \gamma^0 \boldsymbol{\gamma} \mathbf{p} c + \gamma^0 M c^2. \quad (19.284)$$

This can be rewritten in terms of 2×2 -submatrices as

$$H(\mathbf{p}) = \begin{pmatrix} Mc & \mathbf{p}\boldsymbol{\sigma} \\ -\mathbf{p}\boldsymbol{\sigma} & -Mc \end{pmatrix} c. \quad (19.285)$$

Since the matrix is Hermitian, it can be diagonalized by a unitary transformation to

$$H^d(\mathbf{p}) = \begin{pmatrix} \varepsilon_{\mathbf{k}} & 0 \\ 0 & -\varepsilon_{\mathbf{k}} \end{pmatrix}, \quad (19.286)$$

where

$$\varepsilon_{\mathbf{k}} \equiv c\sqrt{\mathbf{p}^2 + M^2c^2} \quad (19.287)$$

are energies of the relativistic particles of mass M and momentum \mathbf{p} . Each entry in (19.286) is a 2×2 -submatrix.

This is achieved by the *Foldy-Wouthuysen transformation*

$$H^d = e^{iS} H e^{-iS}, \quad (19.288)$$

where

$$S = -i\boldsymbol{\gamma} \cdot \boldsymbol{\zeta}/2, \quad \boldsymbol{\zeta} \equiv \arctan(\mathbf{v}/c), \quad \mathbf{v} \equiv \mathbf{p}/M = \text{velocity}. \quad (19.289)$$

The vector ζ points in the direction of the velocity \mathbf{v} and has the length $\zeta = \arctan(v/c)$, such that

$$\cos \zeta = \frac{Mc}{\sqrt{\mathbf{p}^2 + M^2c^2}}, \quad \sin \zeta = \frac{|\mathbf{p}|}{\sqrt{\mathbf{p}^2 + M^2c^2}}. \quad (19.290)$$

A function of a vector \mathbf{v} is defined by its Taylor series where even powers of \mathbf{v} are scalars $\mathbf{v}^{2n} = v^{2n}$ and odd powers are vectors $\mathbf{v}^{2n+1} = v^{2n}\mathbf{v}$. If $\hat{\mathbf{v}}$ denotes as usual the direction vector $\hat{\mathbf{v}} \equiv \mathbf{v}/|\mathbf{v}|$, the matrix $\boldsymbol{\gamma} \cdot \hat{\mathbf{v}}$ has the property that all even powers of it are equal to a 4×4 unity matrix up to an alternating sign: $(\boldsymbol{\gamma} \cdot \hat{\mathbf{v}})^{2n} = (-1)^n$. Thus $S = -i\boldsymbol{\gamma} \cdot \hat{\mathbf{v}}\zeta$ and the Taylor series of e^{iS} reads explicitly

$$e^{iS} = \sum_{n=0,2,4,\dots} \frac{(-1)^n}{n!} \left(\frac{\zeta}{2}\right)^n + (\boldsymbol{\gamma} \cdot \hat{\mathbf{v}}) \sum_{n=1,3,5,\dots} \frac{(-1)^{n-1}}{n!} \left(\frac{\zeta}{2}\right)^n = \cos \frac{\zeta}{2} + \boldsymbol{\gamma} \cdot \hat{\mathbf{v}} \sin \frac{\zeta}{2}. \quad (19.291)$$

Now, S commutes trivially with $\boldsymbol{\gamma} \cdot \mathbf{p} = \boldsymbol{\gamma} \cdot \hat{\zeta} |\mathbf{p}|$, while anticommuting with γ^0 due to the anticommutation rules (19.276). Hence we can move the right-hand transformation in (19.288) simply to the left-hand side with a sign change of S , and obtain

$$H^d = e^{2iS} H. \quad (19.292)$$

It is easy to calculate e^{2iS} : we merely have to double the rapidity in (19.291) and obtain

$$e^{2iS} = \cos \zeta + \boldsymbol{\gamma} \cdot \hat{\mathbf{v}} \sin \zeta = \frac{Mc}{\sqrt{\mathbf{p}^2 + M^2c^2}} (1 + \boldsymbol{\gamma} \cdot \mathbf{p}/Mc). \quad (19.293)$$

Hence we obtain

$$H^d = e^{2iS} H = \frac{Mc}{\sqrt{\mathbf{p}^2 + M^2c^2}} (1 + \boldsymbol{\gamma} \cdot \mathbf{p}/Mc) Mc^2 \gamma^0 (1 + \boldsymbol{\gamma} \cdot \mathbf{p}/Mc). \quad (19.294)$$

Taking the right-hand parentheses to the left of γ^0 changes the sign of $\boldsymbol{\gamma}$. The product $(1 + \boldsymbol{\gamma} \cdot \mathbf{p}/Mc)(1 - \boldsymbol{\gamma} \cdot \mathbf{p}/Mc)$ is simply $1 + \mathbf{p}^2/M^2c^2$, such that

$$H^d = c\sqrt{\mathbf{p}^2 + M^2c^2} \gamma^0 = \varepsilon_{\mathbf{k}} \gamma^0 = \hbar\omega_{\mathbf{k}} \gamma^0. \quad (19.295)$$

Remembering γ^0 from Eq. (19.278) shows that H^d has indeed the diagonal form (19.286).

Going to the diagonal fields $\psi_{\mathbf{k}}^d(t) = e^{iS} \psi_{\mathbf{k}}(t)$, the action becomes

$$\mathcal{A} = \int_{t_a}^{t_b} dt \sum_{\mathbf{k}} \psi_{\mathbf{k}}^{d\dagger}(t) [i\hbar\partial_t - H^d(\hbar\mathbf{k})] \psi_{\mathbf{k}}^d(t). \quad (19.296)$$

Thus a Dirac field is equivalent to a sum of infinitely many momentum states, each being associated with four harmonic oscillators of the Fermi type. The path integral is a product of independent harmonic path integrals of frequencies $\pm\omega_{\mathbf{k}}$.

It is then easy to calculate the quantum-mechanical partition function using the result (7.419) for each oscillator, continued to real times:

$$Z_{\text{QM}} = \prod_{\mathbf{k}} \left\{ 2 \cosh^4[\omega_{\mathbf{k}}(t_b - t_a)/2] \right\}. \quad (19.297)$$

This can also be written as

$$Z_{\text{QM}} = \exp \left(4 \sum_{\mathbf{k}} \log \{ 2 \cosh[\omega_{\mathbf{k}}(t_b - t_a)/2] \} \right), \quad (19.298)$$

or as

$$Z_{\text{QM}} = \exp \left[4 \sum_{\mathbf{k}} \text{Tr} \log (i\hbar\partial_t - \hbar\omega_{\mathbf{k}}) \right] = \exp \left\{ \sum_{\mathbf{k}} \text{Tr} \log [i\hbar\partial_t - H^{\text{d}}(\hbar\mathbf{k})] \right\}. \quad (19.299)$$

Since the trace is invariant under unitary transformations, we can rewrite this as

$$Z_{\text{QM}} = \exp \left\{ \sum_{\mathbf{k}} \text{Tr} \log [i\hbar\partial_t - H(\hbar\mathbf{k})] \right\}, \quad (19.300)$$

or, since the determinant of γ^0 is unity, as

$$Z_{\text{QM}} = \exp \left\{ \sum_{\mathbf{k}} \text{Tr} \log [i\hbar\gamma^0\partial_t - \gamma^0 H^{\text{d}}(\hbar\mathbf{k})] \right\} = \exp \left\{ \sum_{\mathbf{k}} \text{Tr} \log [i\hbar\gamma^0\partial_t - \hbar c\boldsymbol{\gamma}\mathbf{k} - Mc^2] \right\}.$$

If we include the spatial coordinates into the functional trace, this can also be written as

$$Z_{\text{QM}} = \exp \left[\text{Tr} \log (i\hbar\gamma^0\partial_t - i\hbar c\boldsymbol{\gamma}\boldsymbol{\nabla} - Mc^2) \right] = \exp \{ \text{Tr} \log [c(i\hbar\boldsymbol{\not{\partial}} - Mc)] \}.$$

In analytic regularization of Section 2.15, the factor c in the tracelog can be dropped. Moreover, there exists a simple algebraic identity

$$(i\hbar\boldsymbol{\not{\partial}} + Mc)(i\hbar\boldsymbol{\not{\partial}} - Mc) = -\hbar^2\partial^2 - M^2c^2. \quad (19.301)$$

The factors on the left-hand side have the same functional determinant since [compare (7.338) and (7.420)]

$$\begin{aligned} \text{Det}(i\hbar\boldsymbol{\not{\partial}} - Mc) &= e^{\text{Tr} \log(i\hbar\boldsymbol{\not{\partial}} - Mc)} = e^{V_4 \int \frac{d^4 p}{(2\pi)^4} \text{Tr} \log(\hbar\not{p} - Mc)} = e^{V_4 \int \frac{d^4 p}{(2\pi)^4} \text{Tr} \log(-\hbar\not{p} - Mc)} \\ &= \text{Det}(-i\hbar\boldsymbol{\not{\partial}} - Mc). \end{aligned} \quad (19.302)$$

This allows us, as a generalization of (7.420), to write

$$\text{Det}(i\hbar\boldsymbol{\not{\partial}} - Mc) = \text{Det}(i\hbar\boldsymbol{\not{\partial}} + Mc) = \sqrt{\text{Det}(-\hbar^2\partial^2 - M^2c^2)_{1_{4 \times 4}}}, \quad (19.303)$$

where $1_{4 \times 4}$ is a 4×4 unit matrix. In this way we arrive at the quantum-mechanical partition function

$$Z_{\text{QM}} = \exp \left[4 \times \frac{1}{2} \text{Tr} \log(-\hbar^2\partial^2 - M^2c^2) \right] \equiv e^{i\Gamma_0^{\text{f}}/\hbar}. \quad (19.304)$$

The factor 4 comes from the trace in the 4×4 matrix space, whose indices have disappeared in the formula. The exponent determines the effective action Γ of the quantum system by analogy with the Euclidean relation Eq. (19.46).

The Green function of the Dirac equation (19.275) is a 4×4 -matrix defined by

$$(i\hbar\cancel{\partial} - Mc)_{\alpha\beta}(x|x_a)_{\beta\gamma} = i\hbar\delta^{(D)}(x - x_a)\delta_{\alpha\gamma}. \quad (19.305)$$

Suppressing the Dirac indices, it has the spectral representation

$$(x_b|x_a) = \int \frac{d^4p}{(2\pi\hbar)^4} \frac{i\hbar}{\cancel{p} - Mc + i\eta} e^{-ip(x_b-x_a)/\hbar}. \quad (19.306)$$

This can be written more formally as a functional matrix

$$(x_b|x_a) = \langle x_b | \frac{i\hbar}{i\hbar\cancel{\partial} - Mc} | x_a \rangle, \quad (19.307)$$

which obviously satisfies the differential equation (19.305).

19.5.2 Path Integral

It is straightforward to write down a path integral representation for the amplitude (19.307):

$$(x_b|x_a) = \int_0^\infty dS \int_{x_a=x(\lambda_a)}^{x_b=x(\lambda_b)} \mathcal{D}^4x \int \frac{\mathcal{D}^4p}{(2\pi\hbar)^4} e^{iA/\hbar}, \quad (19.308)$$

with the action

$$\mathcal{A}[x, p] = \int_0^S d\lambda [-p\dot{x} + (\cancel{p} - Mc)]. \quad (19.309)$$

As in Section 19.1, the parameter λ is a length along the orbits, but in contrast to that section we shall work here with real time t , and λ is related t by $\lambda = ct$. and S is the total reparametrization-invariant length. The dot denotes the derivative $\dot{x} \equiv dx(\lambda)/d\lambda$. The path integral over $x(\lambda)$ ensures that the momentum is λ -independent, so that the path integral over $p(\lambda)$ reduces to an ordinary Fourier integral [compare Eq. (2.41)]:

$$\int_{x_a=x(\lambda_a)}^{x_b=x(\lambda_b)} \mathcal{D}^4x \int \frac{\mathcal{D}^4p}{(2\pi\hbar)^4} = \int \frac{d^4p}{(2\pi\hbar)^4} e^{ip(x_b-x_a) + iS(\cancel{p}-Mc)/\hbar} \quad (19.310)$$

Performing the integral over S in (19.308) leads to

$$(x_b|x_a) = \int \frac{d^4p}{(2\pi\hbar)^4} e^{ip(x_b-x_a)} \frac{i\hbar}{\cancel{p} - Mc}, \quad (19.311)$$

in agreement with the amplitude (19.307). The minus sign in front of $p\dot{x}$ is necessary to have the positive sign for the spatial part $\mathbf{p}\dot{\mathbf{x}}$ in the Minkowski metric (19.277).

The action (19.309) can immediately be generalized to

$$\bar{\mathcal{A}}[x, p] = \int_0^S d\lambda [-p\dot{x} + h(\lambda)(\not{p} - Mc)], \quad (19.312)$$

with any function $h(\lambda) > 0$. This makes it invariant under the reparametrization

$$\lambda \rightarrow f(\lambda), \quad h(\lambda) \rightarrow h(\lambda)/f(\lambda). \quad (19.313)$$

The path integral (19.308) contains then an extra functional integration over $h(\lambda)$ with some gauge-fixing functional $\Phi[h]$, as in (19.22), which has been chosen in (19.309) as $\Phi[h] = \delta[h - 1]$.

The path integral alone yields an amplitude

$$\langle x | e^{iS(i\hbar\not{\partial} - Mc)/\hbar} | x_a \rangle, \quad (19.314)$$

and the integral over S in (19.308) produces indeed the propagator (19.307). In evaluating this we must assume, as usual, that the mass carries an infinitesimal negative imaginary part $i\eta$. This is also necessary to guarantee the convergence of the path integral (19.308).

Electromagnetism is introduced as usual by the minimal substitution (2.644). In the operator version, we have to substitute

$$\partial_\mu \longrightarrow \partial_\mu + i\frac{e}{\hbar c}A_\mu. \quad (19.315)$$

Thus we obtain the gauge-invariant action

$$\bar{\mathcal{A}}[x, p] = \int_0^S d\lambda \left[-p\dot{x} + h(\lambda) \left(\not{p} - \frac{e\hbar}{c}\not{A} - Mc \right) \right]. \quad (19.316)$$

Another path integral representation which is closer to the spinless case is obtained by rewriting (19.307) as

$$(x|x_a) = (i\hbar\not{\partial} + Mc) \langle x | \frac{i\hbar}{-\hbar^2\partial^2 - M^2c^2} | x_a \rangle, \quad (19.317)$$

where we have omitted the negative infinitesimal imaginary part $-i\hbar$ of the mass, for brevity, and used the fact that

$$(i\hbar\not{\partial} + Mc)(i\hbar\not{\partial} - Mc) = -\hbar^2\partial^2 - M^2c^2, \quad (19.318)$$

on account of the anticommutation relation (19.276). By rewriting (19.317) as a proper-time integral

$$(x|x_a) = \frac{1}{2Mc} (i\hbar\not{\partial} + Mc) \int_0^\infty dS \langle x | e^{iS(-\hbar^2\partial^2 - M^2c^2)/2Mc\hbar} | x_a \rangle, \quad (19.319)$$

we find immediately the canonical path integral

$$(x|x_a) = \frac{1}{2Mc} (i\hbar\not{\partial} + Mc) \int_0^\infty dS \int_{x_a=x(\lambda_a)}^{x=x(\lambda_b)} \mathcal{D}^4x \int \frac{\mathcal{D}^4p}{(2\pi\hbar)^4} e^{i\mathcal{A}/\hbar}, \quad (19.320)$$

with the action

$$\mathcal{A}[x, p] = \int_0^S d\lambda \left[-p\dot{x} + \frac{1}{2Mc} (p^2 - M^2c^2) \right]. \quad (19.321)$$

The suppressed Dirac indices of the 4×4 -amplitude on the left-hand side, $(x|x_a)_{\alpha\beta}$, are entirely due to the prefactor $(i\hbar\partial + Mc)_{\alpha\beta}$ on the right-hand side.

As in the generalization of (19.309) to (19.309), this action can be generalized to

$$\bar{\mathcal{A}}[x, p] = \int_0^S d\lambda \left[-p\dot{x} + \frac{h(\lambda)}{2Mc} (p^2 - M^2c^2) \right], \quad (19.322)$$

with any function $h(\lambda) > 0$, thus becoming invariant under the reparametrization (19.313), and the path integral (19.308) contains then an extra functional integration $\int \mathcal{D}h(\lambda) \Phi[h]$. The action (19.322), is precisely the Minkowski version of the path integral of a spinless particle of the previous section [see Eq. (19.14)].

Introducing here electromagnetism by the minimal substitution (19.315) in the prefactor of (19.317) and on the left-hand side of (19.318), the latter becomes then

$$\left(i\hbar\partial - \frac{e}{c}\mathcal{A} + Mc \right) \left(i\hbar\partial - \frac{e}{c}\mathcal{A} - Mc \right) = \hbar^2 \left[\left(i\partial - \frac{e}{\hbar c}A \right)^2 - \frac{e}{\hbar c} \Sigma^{\mu\nu} F_{\mu\nu} \right] - M^2c^2, \quad (19.323)$$

where

$$\Sigma^{\mu\nu} \equiv \frac{i}{4} [\gamma^\mu, \gamma^\nu] = -\Sigma^{\nu\mu} \quad (19.324)$$

are the generators of Lorentz transformations in the space of Dirac spinors. For any fixed index μ , they satisfy the commutation rules:

$$[\Sigma^{\mu\nu}, \Sigma^{\mu\kappa}] = ig^{\mu\mu} \Sigma^{\nu\kappa}. \quad (19.325)$$

Due to the antisymmetry in the two indices, this determines all nonzero commutators of the Lorentz group.

Using Eqs. (19.254), we can write the last interaction term in (19.323) as

$$\Sigma^{\mu\nu} F_{\mu\nu} = -2\Sigma^i B^i + 2\Sigma^{0i} E^i, \quad (19.326)$$

where Σ^i are the generators of rotation

$$\Sigma^i \equiv \frac{1}{2} \epsilon_{ijk} \Sigma^{jk} = \frac{1}{2} \begin{pmatrix} \sigma^i & 0 \\ 0 & \sigma^i \end{pmatrix}, \quad (19.327)$$

and

$$\Sigma^{0i} \equiv i\alpha^i \equiv i\gamma^0\gamma^i = i \begin{pmatrix} -\sigma^i & 0 \\ 0 & \sigma^i \end{pmatrix} \quad (19.328)$$

are the generators of rotation-free Lorentz transformations. Thus

$$\Sigma^{\mu\nu} F_{\mu\nu} = - \begin{pmatrix} \boldsymbol{\sigma}(\mathbf{B} + i\mathbf{E}) & 0 \\ 0 & \boldsymbol{\sigma}(\mathbf{B} - i\mathbf{E}) \end{pmatrix}. \quad (19.329)$$

19.5.3 Amplitude with Electromagnetic Interaction

The obvious generalization of the path integral (19.320) which includes minimal electromagnetic interactions is then

$$(x|x_a) = \frac{1}{2M} \left[\left(i\hbar\dot{\phi} - \frac{e}{c}\mathcal{A} \right) + Mc \right] \int_0^\infty dS \int \mathcal{D}h(\lambda) \Phi[h] \int_{x_a=x(\lambda_a)}^{x=x(\lambda_b)} \mathcal{D}^4x \int \frac{\mathcal{D}^4p}{(2\pi\hbar)^4} \hat{T} e^{iA/\hbar}, \quad (19.330)$$

with the action

$$\bar{\mathcal{A}}[x, p] = \int_0^S d\lambda \left\{ -p\dot{x} + \frac{h(\lambda)}{2Mc} \left[\left(p - \frac{e}{c}A \right)^2 - \frac{\hbar e}{c} \Sigma^{\mu\nu} F_{\mu\nu} - M^2 c^2 \right] \right\}. \quad (19.331)$$

The symbol \hat{T} is the time-ordering operator defined in (1.241), now with respect to the proper time λ , which has to be present to account for the possible noncommutativity of $F_{\mu\nu}\Sigma^{\mu\nu}/2$ at different λ . Integrating out the momentum variables yields the configuration-space path integral

$$(x|x_a) = \frac{1}{2M} \left[\left(i\hbar\dot{\phi} - \frac{e}{c}\mathcal{A} \right) + Mc \right] \int_0^\infty dS \int \mathcal{D}h(\lambda) \Phi[h] \int_{x_a=x(\lambda_a)}^{x=x(\lambda_b)} \mathcal{D}^4x \hat{T} e^{iA/\hbar}, \quad (19.332)$$

with the action

$$\bar{\mathcal{A}}[x] = \int_0^S d\lambda \left[-\frac{Mc}{2h(\lambda)} \dot{x}^2 - \frac{e}{c} \dot{x}A - h(\lambda) \frac{\hbar e}{2Mc^2} \Sigma^{\mu\nu} F_{\mu\nu} - h(\lambda) \frac{Mc}{2} \right]. \quad (19.333)$$

The coupling to the magnetic field adds to the rest energy Mc^2 an interaction energy

$$H_{\text{int}} = -\frac{\hbar e}{Mc} \boldsymbol{\sigma} \cdot \mathbf{B}. \quad (19.334)$$

From this we extract the magnetic moment of the electron. We compare (19.334) with the general interaction energy (8.316), and identify the magnetic moment as

$$\boldsymbol{\mu} = \frac{\hbar e}{Mc} \boldsymbol{\sigma}. \quad (19.335)$$

Recall that in 1926, Uhlenbeck and Goudsmit explained the observed Zeeman splitting of atomic levels by attributing to an electron a half-integer spin. However, the magnetic moment of the electron turned out to be roughly twice as large as what one would expect from a charged rotating sphere of angular momentum \mathbf{L} , whose magnetic moment is

$$\boldsymbol{\mu} = \mu_B \frac{\mathbf{L}}{\hbar}, \quad (19.336)$$

where $\mu_B \equiv \hbar e/Mc$ is the Bohr magneton (2.649). On account of this relation, it is customary to parametrize the magnetic moment of an elementary particle of spin \mathbf{S} as follows:

$$\boldsymbol{\mu} = g\mu_B \frac{\mathbf{S}}{\hbar}. \quad (19.337)$$

The dimensionless ratio g with respect to (19.336) is called the *gyromagnetic ratio* or *Landé factor*. For a spin-1/2 particle, \mathbf{S} is equal to $\boldsymbol{\sigma}/2$, and comparison with (19.335) yields the gyromagnetic ratio

$$g = 2, \quad (19.338)$$

the famous result found first by Dirac, predicting the intrinsic magnetic moment μ of an electron to be equal to the Bohr magneton μ_B , thus being twice as large as expected from the relation (19.336), if we insert there the spin 1/2 for the orbital angular momentum.

In quantum electrodynamics one can calculate further corrections to this Dirac result as a perturbation expansion in powers of the fine-structure constant α [recall (1.505)]. The first correction to g due to one-loop Feynman diagrams was found by Schwinger:

$$g = 2 \times \left(1 + \frac{\alpha}{2\pi}\right) \approx 2 \times 1.001161, \quad (19.339)$$

where α is the fine-structure constant (1.505). Experimentally, the gyromagnetic ratio has been measured to an incredible accuracy:

$$g = 2 \times 1.001\,159\,652\,193(10), \quad (19.340)$$

in excellent agreement with (19.339). If the perturbation expansion is carried to higher orders, one is able to reach agreement up to the last experimentally known digits [14].

In the literature, there exist other representations of path integrals for Dirac particles involving Grassmann variables. For this we recall the discussion in Subsection 7.11.3 that a path integral over four real Grassmann fields θ^μ , $\mu = 0, 1, 2, 3$

$$\int \mathcal{D}^4\theta \exp \left[\frac{i}{\hbar} \int dt \left(-\frac{i\hbar}{4} \theta_\mu \dot{\theta}^\mu \right) \right], \quad (19.341)$$

generates a matrix space corresponding to operators $\hat{\theta}^\mu$ with the anticommutation rules

$$\{\hat{\theta}^\mu, \hat{\theta}^\nu\} = 2g^{\mu\nu}, \quad (19.342)$$

and the matrix elements

$$\langle \beta | \hat{\theta}^\mu | \alpha \rangle = (\gamma_5 \gamma^\mu)_{\beta\alpha}, \quad \beta, \alpha = 1, 2, 3, 4. \quad (19.343)$$

It is then possible to replace path integral (19.332) by

$$\begin{aligned} (x|x_a) &= \frac{1}{2M} \int_0^\infty dS \int \mathcal{D}h \Phi[h] \\ &\times \int \mathcal{D}\chi \Phi[\chi] \int \mathcal{D}^4\theta \int \mathcal{D}x \int \frac{\mathcal{D}p}{(2\pi\hbar)^4} e^{i(\bar{A}[x] + \mathcal{A}_G[\theta^\mu, A])/\hbar}, \end{aligned} \quad (19.344)$$

with the action of a relativistic spinless particle [the action (19.333) without the spin coupling]

$$\bar{\mathcal{A}}[x, p] = \int_0^S d\lambda \left\{ -p\dot{x} + \frac{h(\lambda)}{2Mc} \left[\left(p - \frac{e}{c}A \right)^2 - M^2c^2 \right] \right\}, \quad (19.345)$$

and an action involving the Grassmann fields θ^μ :

$$\mathcal{A}_G[\theta^\mu, A] = \int_0^S d\lambda \left\{ -\frac{i\hbar}{4}\theta_\mu(\lambda)\dot{\theta}^\mu(\lambda) + h(\lambda)\frac{i\hbar e}{4Mc^2}F_{\mu\nu}(x(\lambda))\theta^\mu(\lambda)\theta^\nu(\lambda) \right\}. \quad (19.346)$$

This follows directly from Eq. (7.513). The function $h(\lambda)$ is the same as in the bosonic actions (19.14) and the path integral (19.22) guaranteeing the reparametrization invariance (19.13).

After integrating out the momentum variables in the path integral (19.344), the canonical action is of course replaced by the configuration space action (19.218). In the simplest gauge (19.23), the total action reads

$$\bar{\mathcal{A}}[x, \theta^\mu] = \int_0^S d\lambda \left[-\frac{Mc}{2}\dot{x}^2 - \frac{e}{c} \left(\dot{x}A - i\frac{\hbar}{4Mc}F_{\mu\nu}\theta^\mu\theta^\nu \right) - \frac{Mc}{2} + \frac{i\hbar}{4}\theta_\mu(\tau)\dot{\theta}^\mu(\tau) \right]. \quad (19.347)$$

The Grassmann variables can be integrated out using formula (19.103), which reads here [compare (7.501)]:

$$\int \mathcal{D}^4\theta e^{\frac{i}{4}\int dt [-i\theta_\mu(t)\dot{\theta}^\mu(t) + (ie/4Mc)F_{\mu\nu}\theta^\mu\theta^\nu]} = 4 \text{Det}^{1/2} \left[-i\delta_{\mu\nu}\partial_t + \frac{ie}{Mc}F_{\mu\nu}(x(\lambda)) \right]. \quad (19.348)$$

For a constant field tensor $F_{\mu\nu}$ and with the usual antiperiodic boundary conditions in the interval $ct = \lambda \in (0, S)$, the right-hand side has been given before in Eq. (19.103). In the present case it reads:

$$4 \text{Det}^{1/2} \left(-ig_{\mu\nu}\partial_\lambda + i\frac{e}{Mc^2}F_{\mu\nu} \right) = 4 \cos \left(\frac{e}{Mc^2}\mathcal{B}\frac{S}{2} \right) \cosh \left(\frac{e}{Mc^2}\mathcal{E}\frac{S}{2} \right). \quad (19.349)$$

19.5.4 Effective Action in Electromagnetic Field

In the absence of electromagnetism, the effective action of the fermion orbits is given by (19.304). Its Euclidean version differs from the Klein-Gordon expression in (19.38) only by a factor -2 :

$$\frac{\Gamma_{e,0}^f}{\hbar} = -2 \text{Tr} \log \left[-\hbar^2\partial^2 + M^2c^2 \right]. \quad (19.350)$$

Explicitly we have from (19.39), (19.41), and (19.46):

$$\frac{\Gamma_{e,0}^f}{\hbar} = 2V_D \int_0^\infty \frac{d\beta}{\beta} e^{-\beta Mc^2/2} \frac{1}{\sqrt{2\pi\hbar^2\beta/M}^D} = 2\frac{V_D}{\lambda_M^C} \frac{1}{(4\pi)^{D/2}} \Gamma(1 - D/2). \quad (19.351)$$

The factor 2 may be thought of as $4 \times 1/2$ where the factor 4 comes from the free path integral over the Grassmann field,

$$\int \mathcal{D}^D \theta e^{-\mathcal{A}_{e,0}[\theta]/\hbar} = 4. \quad (19.352)$$

counts the four components of the Dirac field. Recall that by (19.286), the Dirac field carries four modes, one of energy $\hbar\omega_{\mathbf{k}}$, with two spin degrees of freedom, the other of energy $-\hbar\omega_{\mathbf{k}}$ with two spin degrees. The latter are shown in quantum field theory to correspond to an antiparticle with spin 1/2. The path integral over $x(\lambda)$ which counts paths in opposite directions with the ground state energy (19.39) describes particles and antiparticles [recall the remarks after Eq. 19.45]. This explains why only the spin factor 2 remains in (19.351).

By including the vector potential via the minimal substitution $\hat{p} \rightarrow \hat{p} - (e/c)A$, we obtain the Euclidean effective action from Eq. (19.221), and thus obtain immediately the path integral representation

$$\frac{\tilde{\Gamma}_e^f}{\hbar} = 2 \int_0^\infty \frac{d\beta}{\beta} e^{-\beta M c^2/2} \int \mathcal{D}^D x e^{-\mathcal{A}_e/\hbar}, \quad (19.353)$$

with the Euclidean action (19.220).

This is not yet the true partition function Γ_e of the spin-1/2 particle, since the proper path integral contains the additional Grassmann terms of the action (19.347). In the Euclidean version, the full interaction is

$$\mathcal{A}_{e,\text{int}}[x, \theta] = \int_0^{\hbar\beta} d\lambda \frac{e}{c} \left[i \dot{x}_\mu(\lambda) A_\mu(x(\lambda)) - \frac{i}{4M} F_{\mu\nu}(x(\lambda)) \theta^\mu(\lambda) \theta^\nu(\lambda) \right]. \quad (19.354)$$

Thus we obtain the path integral representation

$$\frac{\Gamma_e^f}{\hbar} = 2 \int_0^\infty \frac{d\beta}{\beta} e^{-\beta M c^2/2} \int \mathcal{D}^D x \int \mathcal{D}^D \theta e^{-\{\mathcal{A}_{e,0}[x,\theta] + \mathcal{A}_{e,\text{int}}[x,\theta]\}/\hbar}, \quad (19.355)$$

where the free part of the Euclidean action is

$$\mathcal{A}_{e,0}[x, \theta] = \mathcal{A}_{e,0}[x] + \mathcal{A}_{e,0}[\theta] \equiv \int_0^{\hbar\beta} d\tau \frac{M}{2} \dot{x}^2(\tau) + \int_0^{\hbar\beta} d\tau \frac{\hbar}{4} \theta^\mu(\tau) \dot{\theta}^\mu(\tau). \quad (19.356)$$

19.5.5 Perturbation Expansion

The perturbation expansion is a straightforward generalization of the expansion (19.224):

$$\begin{aligned} \frac{\Gamma_e^f}{\hbar} &= \frac{\Gamma_{e,0}^f}{\hbar} + \int_0^\infty \frac{d\beta}{\beta} e^{-\beta M c^2/2} \frac{2V_D}{\sqrt{2\pi\hbar^2\beta/M}^D} \sum_{n=1}^\infty \frac{(-ie/c)^n}{n!} \\ &\times \left\langle \prod_{i=1}^n \left\{ \int_0^{\hbar\beta} d\tau_i \left[\dot{x}_\mu(\tau_i) A_\mu(x(\tau_i)) - \frac{\hbar}{4Mc} F_{\mu\nu}(x(\tau_i)) \theta^\mu(\tau_i) \theta^\nu(\tau_i) \right] \right\} \right\rangle_0. \end{aligned} \quad (19.357)$$

The leading free effective action coincides, of course, with the $n = 0$ -term of the sum [compare (19.351)].

The expectation values are now defined by the Grassmann extension of the Gaussian path integral (19.225):

$$\langle \mathcal{O}[x, \theta] \rangle_0 \equiv \frac{\int \mathcal{D}^D x \int \mathcal{D}^D \theta \mathcal{O}[x, \theta] e^{-\mathcal{A}_{e,0}[x, \theta]/\hbar}}{\int \mathcal{D}^D x e^{-\mathcal{A}_{e,0}[x]/\hbar} \int \mathcal{D}^D \theta e^{-\mathcal{A}_{e,0}[\theta]/\hbar}}. \quad (19.358)$$

where the denominator is equal to $(1/2)V_D/\sqrt{2\pi\hbar^2\beta/M}^D \times 4$.

There exists also an expansion analogous to (19.227), where the vector potentials have been Fourier decomposed according to (19.226). Then we obtain an expansion just like (19.227), except for a factor -2 and with the expectation values replaced as follows:

$$\begin{aligned} & \left\langle \prod_{i=1}^n \left[\int_0^{\hbar\beta} d\tau_i \dot{x}^{\mu_i}(\tau_i) e^{ik_i x(\tau_i)} \right] \right\rangle_0 \\ & \rightarrow \left\langle \prod_{i=1}^n \left\{ \int_0^{\hbar\beta} d\tau_i \left[\dot{x}^{\mu_i}(\tau_i) + \frac{i\hbar}{2Mc} k_i^{\nu_i} \theta^{\nu_i}(\tau_i) \theta^{\mu_i}(\tau_i) \right] e^{ik_i x(\tau_i)} \right\} \right\rangle_0. \end{aligned} \quad (19.359)$$

The evaluation of these expectation values proceeds as in Eqs. (19.228)–(19.239), except that we also have to form Wick contractions of Grassmann variables which have the free correlation functions

$$\langle \theta^\mu(\tau) \theta^\nu(\tau') \rangle = 2\delta^{\mu\nu} G_{\omega,e}^a(\tau - \tau'), \quad (19.360)$$

where

$$G_{\omega,e}^a(\tau - \tau') = \frac{1}{2}\epsilon(\tau), \quad \tau \in [-\hbar\beta, \hbar\beta] \quad (19.361)$$

is the Euclidean version of the antiperiodic Green function (3.109) solving the inhomogeneous equation

$$\partial_\tau G_{\omega,e}^a(\tau) = \delta(\tau). \quad (19.362)$$

Outside the basic interval $[-\hbar\beta, \hbar\beta]$ the function is to be continued antiperiodically, in accordance with the fermionic nature of the Grassmann variables.

In operator language, the correlation function (19.360) is the time-ordered expectation value $\langle \hat{T} \hat{\theta}(\tau) \hat{\theta}(\tau') \rangle_0$ [recall (3.299)]. By letting $\tau \rightarrow \tau'$ once from above and once from below, the correlation function shows agreement with the anticommutation rule (19.342). In verifying this we must use the fact that the time ordered product of fermion operators is defined by the following modification of the bosonic definition in Eq. (1.241):

$$\hat{T}(\hat{O}_n(t_n) \cdots \hat{O}_1(t_1)) \equiv \epsilon_P \hat{O}_{i_n}(t_{i_n}) \cdots \hat{O}_{i_1}(t_{i_1}), \quad (19.363)$$

where t_{i_n}, \dots, t_{i_1} are the times t_n, \dots, t_1 relabeled in the causal order, so that

$$t_{i_n} > t_{i_{n-1}} > \dots > t_{i_1}. \quad (19.364)$$

The difference lies in the sign factor ϵ_P which is equal to 1 for an even and -1 for an odd number of permutations of fermion variables.

19.5.6 Vacuum Polarization

Let us see how the fluctuations of an electron loop change the electromagnetic field action. To lowest order, we must form the expectation value (19.359) for $n = 0$ and $k_1 = -k_2 \equiv k$:

$$\left\langle \left[\dot{x}^{\mu_1}(\tau_1) + \frac{i\hbar}{2Mc} k^{\nu_1} \theta^{\nu_1}(\tau_1) \theta^{\mu_1}(\tau_1) \right] e^{ik\delta x(\tau_1)} \left[\dot{x}^{\mu_2}(\tau_2) - \frac{i\hbar}{2Mc} k^{\nu_2} \theta^{\nu_2}(\tau_2) \theta^{\mu_2}(\tau_2) \right] e^{-ik\delta x(\tau_2)} \right\rangle_0. \quad (19.365)$$

From the contraction of the velocities $\dot{x}^{\mu_1}(\tau_1)$ and $\dot{x}^{\mu_2}(\tau_2)$ we obtain again the spinless result (19.240) leading in (19.242) to the integrand

$$\left(k_1^2 \delta^{\mu_1 \nu_2} - k_1^{\mu_1} k_1^{\nu_2} \right) G^2(\tau_1, \tau_2) = \left(k_1^2 \delta^{\mu_1 \nu_2} - k_1^{\mu_1} k_1^{\nu_2} \right) \frac{\hbar^2}{M^2 c^2} (u - 1/2)^2. \quad (19.366)$$

In addition, there are the Wick contractions of the Grassmann variables:

$$\begin{aligned} & \left\langle \left[\frac{\hbar}{2Mc} k^{\nu_1} \theta^{\nu_1}(\tau_1) \theta^{\mu_1}(\tau_1) \right] e^{ik\delta x(\tau_1)} \left[\frac{i\hbar}{2Mc} k^{\nu_2} \theta^{\nu_2}(\tau_2) \theta^{\mu_2}(\tau_2) \right] e^{-ik\delta x(\tau_2)} \right\rangle_0 \\ &= - \left(k_1^2 \delta^{\mu_1 \nu_2} - k_1^{\mu_1} k_1^{\nu_2} \right) \frac{\hbar^2}{M^2 c^2} \frac{1}{4} \epsilon^2(\tau_1 - \tau_2). \end{aligned} \quad (19.367)$$

Since $\epsilon^2(\tau_1 - \tau_2) = 1$, this changes the spinless result (19.366) to

$$\left(k_1^2 \delta^{\mu_1 \nu_2} - k_1^{\mu_1} k_1^{\nu_2} \right) G^2(\tau_1, \tau_2) = \left(k_1^2 \delta^{\mu_1 \nu_2} - k_1^{\mu_1} k_1^{\nu_2} \right) \frac{\hbar^2}{M^2 c^2} [(u - 1/2)^2 - 1/4]. \quad (19.368)$$

Remembering the factor -2 in the expansion (19.358) with respect to the spinless one, we find that the vacuum polarization due to fluctuating spin-1/2 orbits is obtained from the spinless result (19.251) by changing the factor $4(u - 1/2)^2 = (2u - 1)^2$ in the integrand to $-2 \times 4u(u - 1) = 8u(1 - u)$. The resulting function $\Pi(k^2)$ has the expansion

$$\Pi(k^2) = \frac{1}{3\pi} \left[\frac{2}{\epsilon} - \log \frac{M^2 c^2 e^\gamma}{4\pi \hbar^2} \right] - \frac{\hbar^2 k^2}{15\pi M^2 c^2} + \mathcal{O} \left(\epsilon, \frac{k^2}{M^2 c^2 / \hbar^2} \right). \quad (19.369)$$

The first term produces a renormalization of the charge which is treated as in the bosonic case [recall (19.271)–(19.274)], which causes an additional contact interaction

$$-\frac{\alpha}{r} \rightarrow -\frac{\alpha}{r} - \frac{4\alpha^2 \hbar^2}{15M^2 c^2} \delta^{(3)}(\mathbf{x}). \quad (19.370)$$

There, the vacuum polarization has the effect of lowering the state $2S_{1/2}$, which is the s-state of principal quantum number $n = 2$, against the p-state $2P_{1/2}$ by 27.3 MHz. The experimental frequency shift is positive ≈ 1057 MHz [recall Eq. (18.600)],

and is mainly due to the effect of the electron moving through a bath of photons as calculated in Eq. (18.599).

The effect of vacuum polarization was first calculated by Uehling [13], who assumed it to be the main cause for the Lamb shift. He was disappointed to find only 3% of the experimental result, and a wrong sign.

The situation in muonic atoms is different. There the vacuum polarization *does* produce the dominant contribution to the Lamb shift for a simple reason: The other effects contain in a factor M/M_μ^2 , where M_μ^2 is the mass of the muon, whereas the vacuum polarization still involves an electron loop containing only the electron mass M , thus being enhanced by a factor $(M_\mu/M)^2 \approx 210^2$ over the others.

The calculations for the electron in an atom have been performed to quite high orders [14] within quantum electrodynamics. We have gone through the above calculation only to show that it is possible to re-obtain quantum field-theoretic result within the path integral formalism. More details are given in the review article [5],

As mentioned in the beginning, the above calculations are greatly simplified version of analogous calculations within superstring theory, which so far have not produced any physical results. If this ever happens, one should expect that also in this field a second-quantized field theory would be extremely useful to extract efficiently observable consequences. Such a theory still need development [15].

19.6 Supersymmetry

It is noteworthy that the various actions for a spin-1/2 particle is invariant under certain supersymmetry transformations.

19.6.1 Global Invariance

Consider first the fixed-gauge action (19.347). Its appearance can be made somewhat more symmetric by absorbing a factor $\sqrt{\hbar/2M}$ into the Grassmann variables $\theta^\mu(\tau)$, so that it reads

$$\bar{\mathcal{A}}[x, \theta^\mu] = \int d\tau \left[-\frac{M}{2} \dot{x}^2 - \frac{e}{c} \left(\dot{x}A + \frac{i}{2} F_{\mu\nu} \theta^\mu \theta^\nu \right) - \frac{Mc^2}{2} + \frac{M}{2} i\theta_\mu(\tau) \dot{\theta}^\mu(\tau) \right]. \quad (19.371)$$

The correlation functions (19.360) of the θ -variables are now

$$\langle \theta^\mu(\tau) \theta^\nu(\tau') \rangle = \delta^{\mu\nu} G^f(\tau, \tau') \equiv \delta^{\mu\nu} \frac{\hbar}{M} \Delta_0^f(\tau - \tau'), \quad (19.372)$$

with $\Delta_0^f(\tau - \tau') = \epsilon(\tau - \tau')/2$. In this normalization, $G^f(\tau, \tau')$ coincides, up to a sign, with the first term in the derivative $G(\tau, \tau')$ of the bosonic correlation function [recall (19.232) and the first term in (19.234)].

Let us apply to the variables the infinitesimal transformations

$$\delta x^\mu(\tau) = i\alpha \theta^\mu(\tau), \quad \delta \theta^\mu(\tau) = \alpha \dot{x}^\mu(\tau). \quad (19.373)$$

where α is an arbitrary Grassmann parameter. For the free terms this is obvious. The interacting terms change by

$$-i\alpha \int d^4x \frac{e}{c} (\dot{\theta}^\mu A_\mu + F_{\mu\nu} \dot{x}^\mu \theta^\nu). \quad (19.374)$$

Inserting $F_{\mu\nu} \dot{x}^\mu(\tau) = dA_\nu(x(\tau))/d\tau - \partial_\nu[A^\mu(x(\tau))\dot{x}^\mu(\tau)]$, the first term cancels and the second is a pure surface term, such that the action is indeed invariant.

Supersymmetric theories have a compact representation in an extended space called *superspace*. This space is formed by pairs (τ, ζ) , where ζ is a Grassmann variable playing the role of a supersymmetric partner of the time parameter τ . The coordinates $x^\mu(\tau)$ are extended likewise by defining

$$X^\mu(\tau) \equiv x^\mu(\tau) + i\zeta\theta^\mu(\tau). \quad (19.375)$$

A supersymmetric derivative is defined by

$$DX^\mu(\tau) \equiv \left(\frac{\partial}{\partial\zeta} + i\zeta \frac{\partial}{\partial\tau} \right) X^\mu(\tau) = i\theta^\mu(\tau) + i\zeta\dot{x}^\mu(\tau). \quad (19.376)$$

If we now form the integral, using the Grassmann formula (7.379),

$$\int d\tau \frac{d\zeta}{2\pi} i \dot{X}_\mu(\tau) DX^\mu(\tau) = \int d\tau \frac{d\zeta}{2\pi} i [\dot{x}(\tau) + i\zeta\dot{\theta}^\mu(\tau)] [i\theta^\mu(\tau) + i\zeta\dot{x}^\mu(\tau)], \quad (19.377)$$

we find

$$\int d\tau (-\dot{x}^2 + i\theta_\mu \dot{\theta}^\mu), \quad (19.378)$$

which proportional to the free part of the action (19.347). As a curious property of differentiations in superspace we note that

$$D^2 X^\mu(\tau) = i\dot{x}^\mu(\tau) - \zeta\dot{\theta}^\mu(\tau), \quad D^3 X^\mu(\tau) = -\dot{\theta}^\mu(\tau) - \zeta\ddot{x}(\tau), \quad (19.379)$$

such that the kinetic term (19.377) can also be written as

$$- \int d\tau \frac{d\zeta}{2\pi} X_\mu(\tau) D^3 X^\mu(\tau). \quad (19.380)$$

The interaction is found from the integral in superspace

$$\begin{aligned} & i \int d\tau \frac{d\zeta}{2\pi} A^\mu(X(\tau)) DX(\tau) \\ &= i \int d\tau \frac{d\zeta}{2\pi} [A^\mu(x(\tau)) + i\partial_\nu A^\mu(x(\tau))\theta^\nu(\tau)] [i\theta^\mu(\tau) + i\zeta\dot{x}^\mu(\tau)], \end{aligned} \quad (19.381)$$

which is equal to

$$- \int d\tau \left[A^\mu(\tau) \dot{x}(\tau) + \frac{i}{2} F_{\mu\nu} \theta^\mu(\tau) \theta^\nu(\tau) \right],$$

thus reproducing the interaction in (19.347). The action in superspace can therefore be written in the simple form

$$\mathcal{A}[X] = i \int d\tau \frac{d\zeta}{2\pi} \left[-\frac{M}{2} X_\mu(\tau) D^3 X^\mu(\tau) + \frac{e}{c} A^\mu(X(\tau)) DX(\tau) \right]. \quad (19.382)$$

19.6.2 Local Invariance

A larger class of supersymmetry transformations exists for the action without gauge fixing which is the sum of the free part (19.345) and the interacting part (19.346). Absorbing again the factor $\sqrt{\hbar/2M}$ into the Grassmann variable $\theta^\mu(\tau)$, and rescaling in addition $h(\tau)$ by a factor $1/c$, the reparametrization-invariant action reads

$$\bar{\mathcal{A}}[x, p, \theta, h] = \int d\tau \left\{ -p\dot{x} + \frac{h(\tau)}{2M} \left[\left(p - \frac{e}{c}A \right)^2 - M^2c^2 \right] + \frac{M}{2} i\theta_\mu(\tau)\dot{\theta}^\mu(\tau) - ih(\tau)\frac{e}{c}F_{\mu\nu}(x(\tau))\theta^\mu(\tau)\theta^\nu(\tau) \right\}. \quad (19.383)$$

Let us now compose the action from invariant building blocks. For simplicity, we ignore the electromagnetic interaction. In a first step we also omit the mass term. The extra variable $h(\tau)$ requires an extra Grassmann partner $\chi(\tau)$ for symmetry, and we form the action

$$\bar{\mathcal{A}}_1[x, p, \theta, h, \chi] = \int d\tau \left\{ -p\dot{x} + \frac{h(\tau)}{2M}p^2 + \frac{M}{2}i\theta_\mu(\tau)\dot{\theta}^\mu(\tau) + \frac{i}{2}\chi(\tau)\theta^\mu(\tau)p_\mu(\tau) \right\}. \quad (19.384)$$

This action possesses a *local supersymmetry*. If we now perform τ -dependent versions of the supersymmetry transformations (19.373)

$$\begin{aligned} \delta x^\mu &= i\alpha(\tau)\theta^\mu, & \delta\theta^\mu &= \alpha(\tau)p, & \delta p &= 0, \\ \delta h &= i\alpha(\tau)\chi, & \delta\chi &= 2\dot{\alpha}(\tau). \end{aligned} \quad (19.385)$$

If we integrate out the momenta in the path integral, the action (19.384) goes over into

$$\bar{\mathcal{A}}_1[x, \theta, h, \chi] = \int d\tau \left\{ -\frac{\dot{x}^2}{2h(\tau)} + \frac{M}{2}i\theta_\mu(\tau)\dot{\theta}^\mu(\tau) + \frac{i}{2h(\tau)}\chi(\tau)\theta^\mu(\tau)\dot{x}_\mu(\tau) \right\}, \quad (19.386)$$

where a term proportional to $\chi^2(\tau)$ has been omitted since it vanishes due to the nilpotency (7.375). This action is locally supersymmetric under the transformations

$$\begin{aligned} \delta x^\mu &= i\alpha(\tau)\theta^\mu, & \delta\theta^\mu &= \frac{\alpha(\tau)}{h(\tau)} \left[\dot{x} - \frac{i}{2}\chi\theta^\mu \right], \\ \delta h &= i\alpha(\tau)\chi, & \delta\chi &= 2\dot{\alpha}(\tau). \end{aligned} \quad (19.387)$$

We now add the mass term

$$\mathcal{A}_M = -\frac{1}{2} \int d\tau h(\tau)Mc^2. \quad (19.388)$$

This needs a supersymmetric partner to compensate the variation of \mathcal{A}_m under (19.387).

$$\mathcal{A}_5 = \frac{i}{2} \int d\tau \left[\theta_5(\tau)\dot{\theta}_5(\tau) + Mc\chi(\tau)\theta_5(\tau) \right]. \quad (19.389)$$

Indeed, add to (19.387) the transformation

$$\delta\theta_5 = Mc\alpha(\tau), \quad (19.390)$$

we see that the sum $\mathcal{A}_M + \mathcal{A}_5$ is invariant. Adding this to (19.384), we obtain the locally invariant canonical action

$$\begin{aligned} \bar{\mathcal{A}}[x, p, \theta, \theta_5, h, \chi] = \int d\tau \left\{ -p\dot{x} + \frac{h(\tau)}{2M}p^2 - \frac{h(\tau)}{2}Mc + \frac{M}{2}i \left[\theta_\mu(\tau)\dot{\theta}^\mu(\tau) + \theta_5(\tau)\dot{\theta}_5(\tau) \right] \right. \\ \left. + \frac{i}{2}\chi(\tau) \left[\theta^\mu(\tau)p_\mu(\tau) + Mc\theta_5(\tau) \right] \right\}. \end{aligned} \quad (19.391)$$

Appendix 19A Proof of Same Quantum Physics of Modified Action

Consider the sliced path integral for a relativistic point particle associated with the original action (19.12). If we set the initial and final parameters λ_a and λ_b equal to λ_0 and λ_{N+1} , and slice the λ -axis at the places λ_n ($n = 1, 2, \dots, N$), the action becomes

$$\mathcal{A}_{\text{cl,e}} = Mc \sum_{n=1}^{N+1} |x_n - x_{n-1}|, \quad (19A.1)$$

where $|x_n - x_{n-1}| = \sqrt{(x_n - x_{n-1})^2}$ are the Euclidean distances [recall (19.2)]. The Euclidean amplitude for the particle to run from $x_a = x_0$ to $x_b = x_{N+1}$ is therefore given by the product of integrals in D spacetime dimensions

$$(x_b|x_a) = \mathcal{N} \prod_{n=1}^N \left[\int d^D x_n \right] e^{-Mc \sum_{n=1}^{N+1} |x_n - x_{n-1}|/\hbar}. \quad (19A.2)$$

As a consequence of the reparameterization invariance of (19.12), this expression is independent of the thickness $\lambda_n - \lambda_{n-1}$ of the slices, which we shall denote by rename as $\equiv h_n\epsilon$, where ϵ is some fixed small number.

We now factorize the exponential of the sum into a product of $N+1$ exponentials and represent each factor as an integral [using Formulas (1.347) and (1.349)]

$$e^{-Mc|x_n - x_{n-1}|/\hbar} = \sqrt{\frac{\epsilon Mc}{2\pi\hbar}} \int_0^\infty dh_n h_n^{-1/2} e^{-\epsilon h_n Mc/2\hbar - Mc(x_n - x_{n-1})^2/2h_n\epsilon\hbar}. \quad (19A.3)$$

Absorbing constants in the normalization factor \mathcal{N} , we arrive at

$$\begin{aligned} (x_b|x_a) = \mathcal{N} \prod_{n=1}^{N+1} \left[\int_0^\infty dh_n h_n^{(D-1)/2} \right] e^{-Mc\epsilon \sum_{n=1}^{N+1} h_n/2} \\ \times \frac{1}{\sqrt{2\pi\epsilon h_{N+1}/Mc}^D} \prod_{n=1}^N \left[\int \frac{d^D x_n}{\sqrt{2\pi\epsilon h_n/Mc}^D} \right] e^{-Mc\epsilon \sum_{n=1}^{N+1} (x_n - x_{n-1})^2/2h_n\epsilon}, \end{aligned} \quad (19A.4)$$

The second line contains only harmonic integrals over x_n , which can all be done with the help of the formulas of Appendix 2B, with the result

$$(x_b|S|x_a0) = \frac{1}{\sqrt{2\pi S\hbar/Mc}^D} e^{-Mc(x_b - x_a)^2/2S\hbar}, \quad (19A.5)$$

where S is the total parameter length

$$S \equiv \sum_{n=1}^{N+1} \epsilon h_n, \tag{19A.6}$$

Replacing (19A.5) by its Fourier representation [compare with (1.333) and (1.341)], we can rewrite (19A.4) as

$$(x_b|x_a) = \mathcal{N} \prod_{n=1}^{N+1} \left[\int_0^\infty dh_n h_n^{(D-1)/2} \right] e^{-McS/2\hbar} \int \frac{d^D p}{(2\pi\hbar)^D} e^{-Sp^2/2Mc+ip(x_b-x_a)/\hbar}. \tag{19A.7}$$

Thus we are left with the product of integrals over h_n . Before we can perform these, we must make sure to respect the sum (19A.6). This is done by inserting an auxiliary unit integral that separates out an integral over the total length S :

$$1 = \int_0^\infty dS \delta(\sum_{n=1}^{N+1} \epsilon h_n - S) = \int_0^\infty \frac{dS}{2\lambda_C} \int_{-i\infty}^\infty \frac{d\sigma}{2\pi i} e^{-\sigma(\sum_{n=1}^{N+1} \epsilon h_n - S)/2\lambda_C}, \tag{19A.8}$$

where λ_C is the Compton wavelength (19.31). Then the product of integrals over h_n in the brackets of (19A.7) can be rewritten as follows:

$$\int_0^\infty \frac{dS}{2\lambda_C} \left\{ \int_{-i\infty}^\infty \frac{d\sigma}{2\pi i} e^{\sigma S/2\lambda_C} \prod_{n=1}^{N+1} \left[\int_0^\infty dh_n h_n^{(D-1)/2} e^{-\sigma \epsilon h_n/2\lambda_C} \right] \right\} e^{-S/2\lambda_C} \tag{19A.9}$$

Setting $h_n = r_n^2$, we treat the curly brackets as

$$\begin{aligned} & \int_{-i\infty}^\infty \frac{d\sigma}{2\pi i} e^{\sigma S/2\lambda_C} \prod_{n=1}^{N+1} \left[\int_{-\infty}^\infty dr_n r_n^D e^{-\sigma \epsilon r_n^2/2\lambda_C} \right] \\ &= \left[\frac{2\pi\lambda_C}{\Gamma(D+1)\epsilon} \right]^{N+1} \int_{-i\infty}^\infty \frac{d\sigma}{2\pi i} e^{\sigma S/2\lambda_C} \sigma^{-(N+1)(D+1)/2}. \end{aligned} \tag{19A.10}$$

For large N , the integral over σ can be approximated by the Gaussian integral around the neighborhood of the saddle point at $\sigma = (N + 1)(D + 1)\lambda_C/S$:

$$\int_{-i\infty}^\infty \frac{d\sigma}{2\pi i} e^{\sigma S/2\lambda_C} \sigma^{-(N+1)(D+1)/2} \underset{\text{large } N}{\approx} \frac{1}{\sqrt{2\pi}} \left[\frac{S}{(N + 1)(D + 1)\lambda_C} \right]^{(N+1)(D+1)/2}. \tag{19A.11}$$

While letting N tend to infinity, we keep $S/(N + 1) \equiv \bar{\epsilon}$ fixed. Then we may write the right-hand side as an exponential

$$\frac{1}{\sqrt{2\pi}} \left[\frac{(D + 1)\lambda_C}{\bar{\epsilon}} \right]^{-S(D+1)/2\bar{\epsilon}} = \frac{1}{\sqrt{2\pi}} e^{-zS/2\lambda_C}, \tag{19A.12}$$

where

$$z \equiv \nu \log \nu \quad \text{with} \quad \nu \equiv (D + 1)\lambda_C/\bar{\epsilon} \tag{19A.13}$$

is a large number. Inserting (20.246) back into the curly brackets of (19A.9), the constant z can be absorbed into the mass of the particle by replacing M by the renormalized quantity $M_1 = M(1+z)$. With this, (19A.9) becomes

$$\int_0^\infty \frac{dS}{2\lambda_C} e^{-SM_1c/2\hbar}, \tag{19A.14}$$

and the path integral (19A.4) reduces to

$$(x_b|x_a) = \mathcal{N}'' \int_0^\infty \frac{dS}{2\lambda_C} e^{-M_1 c S/2\hbar} \int \frac{d^D p}{(2\pi\hbar)^D} e^{-S p^2/2Mc + ip(x_b - x_a)/\hbar}, \quad (19A.15)$$

where all irrelevant factors are contained in the normalization factor \mathcal{N}'' . The remaining integral over S can now be done and yields

$$(x_b|x_a) = \mathcal{N}'' \int \frac{d^D k}{(2\pi)^D} \frac{1}{k^2 + M_R^2 c^2/\hbar^2} e^{ik(x_b - x_a)},$$

where M_R is the renormalized mass

$$M_R = M(1+z)^{1/2}. \quad (19A.16)$$

If we choose the normalization factor $\mathcal{N}'' = 1$, this is exactly the same result as that obtained before in Eq. (19.30) from the modified action (19.10), if we use in the original action (19.12) the mass $M/(1+z)^{1/2}$ rather than M for the calculation.

Path Integrals and Financial Markets

An important field of applications for path integrals are financial markets. The prices of assets fluctuate as a function of time and, if the number of participants in the market is large, the fluctuations are pretty much random. Then the time dependence of prices can be modeled by fluctuating paths.

20.1 Fluctuation Properties of Financial Assets

Let $S(t)$ denote the price of a stock or another financial asset. Over long time spans, i.e., if data recording frequency is low, the average over many stock prices has a time behavior that can be approximated by pieces of exponentials. This is why they are usually plotted on a logarithmic scale. This is best illustrated by a plot of the Dow-Jones industrial index over 60 years in Fig. 20.1. The fluctuations of the index have a certain average width called the *volatility* of the market. Over

Figure 20.1 Logarithmic plot of Dow Jones industrial index over 80 years. There are four roughly linear regimes, two of exponential growth, two of stagnation [1].

Figure 20.2 (a) Index S&P 500 for 13-year period Jan. 1, 1984 — Dec. 14, 1996, recorded every minute, and (b) volatility in time intervals 30 min (from Ref. [2]).

long times, the volatility is not constant but changes stochastically, as illustrated by the data of the S&P 500 index over the years 1984-1997, as shown in Fig. 20.2 [3]. In particular, there are strong increases shortly before a market crash.

The theory to be developed will at first ignore these fluctuations and assume a constant volatility. Attempts to include them have been made in the literature [3]–[79] and a promising version will be described in Section 20.4.

The volatilities follow approximately a Gamma distribution, as illustrated in Fig. 20.3.

Figure 20.3 Comparison of best Gaussian, log-normal, and Gamma distribution fits to volatilities over 300 min (from Ref. [80]). The normalized log-normal distribution has the form $D^{\text{log-normal}}(z) = (2\pi\sigma^2 z^2)^{-1/2} e^{-(\log z - \mu)^2 / 2\sigma^2}$. The Gamma distribution will be discussed further in Subsection 20.1.5.

An individual stock will in general be more volatile than an average market index, especially when the associated company is small and only few shares are traded per day.

20.1.1 Harmonic Approximation to Fluctuations

To lowest approximation, the stock price $S(t)$ satisfies a stochastic differential equation for exponential growth

$$\frac{\dot{S}(t)}{S(t)} = r_S + \eta(t), \quad (20.1)$$

where r_S is the growth rate, and $\eta(t)$ is a white noise variable defined by the correlation functions

$$\langle \eta(t) \rangle = 0, \quad \langle \eta(t)\eta(t') \rangle = \sigma^2 \delta(t - t'). \quad (20.2)$$

The standard deviation σ is a precise measure for the volatility of the stock price. The squared volatility $v \equiv \sigma^2$ is called the *variance*.

The quantity $dS(t)/S(t)$ is called the *return* of the asset. From financial data, the return is usually extracted for finite time intervals Δt rather than the infinitesimal dt since prices $S(t)$ are listed for certain discrete times $t_n = t_0 + n\Delta t$. There are, for instance, abundant tables of daily closing prices of the market $S(t_n)$, from which one obtains the *daily returns* $\Delta S(t_n)/S(t_n) = [S(t_{n+1}) - S(t_n)]/S(t_n)$. The set of available $S(t_n)$ is called the *time series* of prices.

For a suitable choice of the time scales to be studied, the assumption of a white noise is fulfilled quite well by actual fluctuations of asset prices, as illustrated in Fig. 20.4.

Figure 20.4 Fluctuation spectrum of exchange rate DM/US\$ as function of frequency in units 1/sec, showing that the noise driving the stochastic differential equation (20.1) is approximately white (from [13]).

For the logarithm of the stock or asset price¹

$$x(t) \equiv \log S(t) \quad (20.3)$$

this implies a stochastic differential equation for linear growth [14, 15, 16, 17]

$$\dot{x}(t) = \frac{\dot{S}}{S} - \frac{1}{2}\sigma^2 = r_x + \eta(t), \quad (20.4)$$

where

$$r_x \equiv r_S - \frac{1}{2}\sigma^2 \quad (20.5)$$

is the drift of the process [compare (18.405)]. A typical set of solutions of (20.4) is shown in Fig. 20.5.

Figure 20.5 Behavior of logarithmic stock price following the stochastic differential equation (20.3).

The finite differences $\Delta x(t_n) = x(t_{n+1}) - x(t_n)$ and the corresponding differentials dx are called *log-returns*.

The extra term $\sigma^2/2$ in (20.5) is due to Itô's Lemma (18.413) for functions of a stochastic variable $x(t)$. Recall that the formal expansion in powers of dt :

$$\begin{aligned} dx(t) &= \frac{dx}{dS}dS(t) + \frac{1}{2} \frac{d^2x}{dS^2}dS^2(t) + \dots \\ &= \frac{\dot{S}(t)}{S(t)}dt - \frac{1}{2} \left[\frac{\dot{S}(t)}{S(t)} \right]^2 dt^2 + \dots \end{aligned} \quad (20.6)$$

may be treated in the same way as the expansion (18.426) using the mnemonic rule (18.429), according to which we may substitute $\dot{x}^2 dt \rightarrow \langle \dot{x}^2 \rangle dt = \sigma^2$, and thus

$$\left[\frac{\dot{S}(t)}{S(t)} \right]^2 dt \rightarrow \dot{x}^2(t) dt = \sigma^2. \quad (20.7)$$

The higher powers in dt do not contribute for Gaussian fluctuations since they carry higher powers of dt . For the same reason the constant rates r_S and r_x in $\dot{S}(t)/S(t)$ and $\dot{x}(t)$ do not show up in $[\dot{S}(t)/S(t)]^2 dt = \dot{x}^2(t) dt$.

¹To form the logarithm, the stock or asset price $S(t)$ is assumed to be dimensionless, i.e. the numeric value of the price in the relevant currency.

In charts of stock prices, relation (20.5) implies that if we fit a straight line through a plot of the logarithms of the prices with slope r_x , the stock price itself grows on the average like

$$\langle S(t) \rangle = S(0) e^{r_x t} = S(0) \langle e^{r_x t + \int_0^t dt' \eta(t')} \rangle = S(0) e^{(r_x + \sigma^2/2)t}. \quad (20.8)$$

This result is, of course, a direct consequence of Eq. (18.425).

The description of the logarithms of the stock prices by Gaussian fluctuations around a linear trend is only a rough approximation to the real stock prices. The volatilities depend on time. If observed at small time intervals, for instance every minute or hour, they have distributions in which frequent events have an exponential distribution [see Subsection 20.1.6]. Rare events, on the other hand, have a much higher probability than in Gaussian distributions. The observed probability distributions possess *heavy tails* in comparison with the extremely light tails of Gaussian distributions. This was first noted by Pareto in the 19th century [18], reemphasized by Mandelbrot in the 1960s [19], and investigated recently by several authors [20, 22]. The theory needs therefore considerable refinement. As an intermediate generalization we shall introduce, beside the heavy power-like tails, also the so-called *semi-heavy tails*, which drop off faster than any power, such as $e^{-x^a} x^b$ with arbitrarily small $a > 0$ and any $b > 0$. We shall see later in Section 20.4 that semi-heavy tails of financial distribution may be viewed as a consequence of Gaussian fluctuations with fluctuating volatilities. Before we come to these we may fit the data phenomenologically with various non-Gaussian distributions and explore the consequences.

20.1.2 Lévy Distributions

Following Pareto and Mandelbrot we may attempt to approximately fit the distributions of the price changes $\Delta S_n = S(t_{n+1}) - S(t_n)$, the returns $\Delta S_n/S(t_n)$, and the log-returns $\Delta x_n = x(t_{n+1}) - x(t_n)$ for a certain time difference $\Delta t = t_{n+1} - t_n$ with the help of Lévy distributions [19, 22, 24, 23]. For brevity we shall, from now on, use the generic variable z to denote any of the above differences. The Lévy distributions are defined by the Fourier transform

$$\tilde{L}_{\sigma^2}^\lambda(z) \equiv \int_{-\infty}^{\infty} \frac{dp}{2\pi} e^{ipz} L_{\sigma^2}^\lambda(p), \quad (20.9)$$

with

$$L_{\sigma^2}^\lambda(p) \equiv \exp \left[-(\sigma^2 p^2)^{\lambda/2} / 2 \right]. \quad (20.10)$$

For an arbitrary distribution $\tilde{D}(z)$, we shall write the Fourier decomposition as

$$\tilde{D}(z) = \int \frac{dp}{2\pi} e^{ipz} D(p) \quad (20.11)$$

and the Fourier components $D(p)$ as an exponential

$$D(p) \equiv e^{-H(p)}, \tag{20.12}$$

where $H(p)$ plays a similar role as the Hamiltonian in quantum statistical path integrals. By analogy with this we shall also define $\tilde{H}(z)$ so that

$$\tilde{D}(z) = e^{-\tilde{H}(z)}. \tag{20.13}$$

An equivalent definition of the Hamiltonian is

Figure 20.6 Left: Lévy tails of the S&P 500 index (1 minute log-returns) plotted against z/δ . Right: Double-logarithmic plot exhibiting power-like tail regions of the S&P 500 index (1 minute log-returns) (after Ref. [23])

$$e^{-H(p)} \equiv \langle e^{-ipz} \rangle. \tag{20.14}$$

For the Lévy distributions (20.9), the Hamiltonian is

$$H(p) = \frac{1}{2}(\sigma^2 p^2)^{\lambda/2}. \tag{20.15}$$

The Gaussian distribution is recovered in the limit $\lambda \rightarrow 2$ where the Hamiltonian simply becomes $\sigma^2 p^2/2$.

For large z , the Lévy distribution (20.9) falls off with the characteristic power-law

$$\tilde{L}_{\sigma^2}^{\lambda}(z) \rightarrow A_{\sigma^2}^{\lambda} \frac{\lambda}{|z|^{1+\lambda}}. \tag{20.16}$$

This power falloff is the heavy tail of the distribution discussed above. It is also called *power tail*, *Paretian tail*, or *Lévy tail*). The size of the tails is found by approximating the integral (20.9) for large z , where only small momenta contribute, as follows:

$$\tilde{L}_{\sigma^2}^{\lambda}(z) \approx \int_{-\infty}^{\infty} \frac{dp}{2\pi} e^{ipz} \left[1 - \frac{1}{2}(\sigma^2 p^2)^{\lambda/2} \right] \xrightarrow{z \rightarrow \infty} A_{\sigma^2}^{\lambda} \frac{\lambda}{|z|^{1+\lambda}}, \tag{20.17}$$

with

$$A_{\sigma^2}^\lambda = -\frac{\sigma^\lambda}{2\lambda} \int_0^\infty \frac{dp'}{\pi} p'^\lambda \cos p' = \frac{\sigma^\lambda}{2\pi\lambda} \sin(\pi\lambda/2) \Gamma(1 + \lambda). \tag{20.18}$$

The stock market data are fitted best with λ between 1.2 and 1.5 [13], and we shall use $\lambda = 3/2$ most of the time, for simplicity, where one has

$$A_{\sigma^2}^{3/2} = \frac{1}{4} \frac{\sigma^{3/2}}{\sqrt{2\pi}}. \tag{20.19}$$

The full Taylor expansion of the Fourier transform (20.10) yields the asymptotic series

$$\tilde{L}_{\sigma^2}^\lambda(z) = \sum_{n=0}^\infty \frac{(-1)^n}{n!} \int_0^\infty \frac{dp}{\pi} \frac{\sigma^{\lambda n} p^{\lambda n}}{2^n} \cos pz = \sum_{n=0}^\infty \frac{(-1)^{n+1}}{n!} \frac{\sigma^{\lambda n}}{2^n \pi} \Gamma(1 + n\lambda) \frac{\sin \frac{\pi\lambda}{2}}{|z|^{1+\lambda}}. \tag{20.20}$$

This series is not useful for practical calculations since it diverges. In particular, it is unable to reproduce the pure Gaussian distribution in the limit $\lambda \rightarrow 2$.

There also exists an asymmetric Lévy distribution whose Hamiltonian is

$$H_{\lambda,\sigma,\beta}(p) = \frac{1}{2} |\sigma p|^\lambda [1 - i\beta\epsilon(p)F_{\lambda,\sigma}(p)], \tag{20.21}$$

where $\epsilon(p)$ is the step function (1.316), and

$$F_{\lambda,\sigma}(p) = \begin{cases} \tan(\pi\lambda/2) & \text{for } \lambda \neq 1, \\ -(1/\pi) \log p^2 & \text{for } \lambda = 1. \end{cases} \tag{20.22}$$

The large- $|z|$ behavior of this distribution is again given by (20.17), except that the prefactor (20.18) is multiplied by a factor $(1 + \beta)$.

20.1.3 Truncated Lévy Distributions

Mathematically, an undesirable property of the Lévy distributions is that their fluctuation width diverges for $\lambda < 2$, since the second moment

$$\sigma^2 = \langle z^2 \rangle \equiv \int_{-\infty}^\infty dz z^2 \tilde{L}_{\sigma^2}^\lambda(z) = -\frac{d^2}{dp^2} L_{\sigma^2}^\lambda(p) \Big|_{p=0} \tag{20.23}$$

is infinite. If one wants to describe data which show heavy tails for large log-returns but have finite widths one must make them fall off at least with semi-heavy tails at very large returns. Examples are the so-called *truncated Lévy distributions* [22]. They are defined by

$$\tilde{L}_{\sigma^2}^{(\lambda,\alpha)}(z) \equiv \int_{-\infty}^\infty \frac{dp}{2\pi} e^{ipz} L_{\sigma^2}^{(\lambda,\alpha)}(p) = \int_{-\infty}^\infty \frac{dp}{2\pi} e^{ipz-H(p)}, \tag{20.24}$$

with a Hamiltonian which generalizes the Lévy Hamiltonian (20.15) to

$$\begin{aligned}
 H(p) &\equiv \frac{\sigma^2}{2} \frac{\alpha^{2-\lambda}}{\lambda(1-\lambda)} \left[(\alpha + ip)^\lambda + (\alpha - ip)^\lambda - 2\alpha^\lambda \right] \\
 &= \sigma^2 \frac{(\alpha^2 + p^2)^{\lambda/2} \cos[\lambda \arctan(p/\alpha)] - \alpha^\lambda}{\alpha^{\lambda-2}\lambda(1-\lambda)}. \tag{20.25}
 \end{aligned}$$

The asymptotic behavior of the truncated Lévy distributions differs from the power behavior of the Lévy distribution in Eq. (20.17) by an exponential factor $e^{-\alpha z}$ which guarantees the finiteness of the width σ and of all higher moments. A rough estimate of the leading term is again obtained from the Fourier transform of the lowest expansion term of the exponential function $e^{-H(p)}$:

$$\begin{aligned}
 \tilde{L}_{\sigma^2}^{(\lambda,\alpha)}(z) &\approx e^{2s\alpha^\lambda} \int_{-\infty}^{\infty} \frac{dp}{2\pi} e^{ipz} \left\{ 1 - s \left[(\alpha + ip)^\lambda + (\alpha - ip)^\lambda \right] \right\} \\
 &\xrightarrow{z \rightarrow \infty} e^{2s\alpha^\lambda} \Gamma(1 + \lambda) \frac{\sin(\pi\lambda)}{\pi} s \frac{e^{-\alpha|z|}}{|z|^{1+\lambda}}, \tag{20.26}
 \end{aligned}$$

where

$$s \equiv \frac{\sigma^2}{2} \frac{\alpha^{2-\lambda}}{\lambda(1-\lambda)}. \tag{20.27}$$

The integral follows directly from the formulas [25]

$$\int_{-\infty}^{\infty} \frac{dp}{2\pi} e^{ipz} (\alpha + ip)^\lambda = \frac{\Theta(z)}{\Gamma(-\lambda)} \frac{e^{-\alpha z}}{z^{1+\lambda}}, \quad \int_{-\infty}^{\infty} \frac{dp}{2\pi} e^{ipz} (\alpha - ip)^\lambda = \frac{\Theta(-z)}{\Gamma(-\lambda)} \frac{e^{-\alpha|z|}}{|z|^{1+\lambda}}, \tag{20.28}$$

and the identity for Gamma functions²

$$\frac{1}{\Gamma(-z)} = -\Gamma(1 + z) \sin(\pi z) / \pi. \tag{20.29}$$

The full expansion is integrated with the help of the formula [26]

$$\begin{aligned}
 &\int_{-\infty}^{\infty} \frac{dp}{2\pi} e^{ipz} (\alpha + ip)^\lambda (\alpha - ip)^\nu \\
 &= (2\alpha)^{\lambda/2+\nu/2} \frac{1}{|z|^{1+\lambda/2+\nu/2}} \begin{cases} \frac{1}{\Gamma(-\lambda)} W_{(\nu-\lambda)/2, (1+\lambda+\nu)/2}(2\alpha z) & z > 0, \\ \frac{1}{\Gamma(-\nu)} W_{(\lambda-\nu)/2, (1+\lambda+\nu)/2}(2\alpha z) & z < 0, \end{cases} \tag{20.30}
 \end{aligned}$$

where the Whittaker functions $W_{(\nu-\lambda)/2, (1+\lambda+\nu)/2}(2\alpha z)$ can be expressed in terms of Kummer's confluent hypergeometric function ${}_1F_1(a; b; x)$ of Eq. (9.45) as

$$\begin{aligned}
 W_{\delta,\kappa}(x) &= \frac{\Gamma(-2\kappa)}{\Gamma(1/2 - \kappa - \delta)} x^{\kappa+1/2} e^{-x/2} {}_1F_1(1/2 + \kappa - \delta; 2\kappa + 1; x) \\
 &+ \frac{\Gamma(2\kappa)}{\Gamma(1/2 + \kappa - \delta)} x^{-\kappa+1/2} e^{-x/2} {}_1F_1(1/2 - \kappa - \delta; -2\kappa + 1; x), \tag{20.31}
 \end{aligned}$$

²M. Abramowitz and I. Stegun, op. cit., Formula 6.1.17.

as can be seen from (9.39), (9.46) and Ref. [27]. For $\nu = 0$, only $z > 0$ gives a nonzero integral (20.30), which reduces, with $W_{-\lambda/2, 1/2+\lambda/2}(z) = z^{-\lambda/2}e^{-z/2}$, to the left equation in (20.28). Setting $\lambda = \nu$ we find

$$\int_{-\infty}^{\infty} \frac{dp}{2\pi} e^{ipz} (\alpha^2 + p^2)^\nu = (2\alpha)^{\nu/2} \frac{1}{|z|^{1+\nu}} \frac{1}{\Gamma(-\nu)} W_{0, 1/2+\nu}(2\alpha|z|). \tag{20.32}$$

Inserting

$$W_{0, 1/2+\nu}(x) = \sqrt{\frac{2z}{\pi}} K_{1/2+\nu}(x/2), \tag{20.33}$$

we may write

$$\int_{-\infty}^{\infty} \frac{dp}{2\pi} e^{ipz} (\alpha^2 + p^2)^\nu = \left(\frac{2\alpha}{|z|}\right)^{1/2+\nu} \frac{1}{\sqrt{\pi}\Gamma(-\nu)} K_{1/2+\nu}(\alpha|z|). \tag{20.34}$$

For $\nu = -1$ where $K_{-1/2}(x) = K_{1/2}(x) = \sqrt{\pi/2x}e^{-x}$, this reduces to

$$\int_{-\infty}^{\infty} \frac{dp}{2\pi} e^{ipz} \frac{1}{\alpha^2 + p^2} = \frac{1}{2\alpha} e^{-\alpha|z|}. \tag{20.35}$$

Summing up all terms in the expansion of the exponential function $e^{-H(p)}$:

$$\tilde{L}_{\sigma^2}^{(\lambda, \alpha)}(z) \approx e^{2s\alpha^\lambda} \int_{-\infty}^{\infty} \frac{dp}{2\pi} \left\{ 1 + \sum_{n=1}^{\infty} \frac{(-s)^n}{n!} [(\alpha + ip)^\lambda + (\alpha - ip)^\lambda]^n \right\} e^{ipz} \tag{20.36}$$

yields the true asymptotic behavior

$$\tilde{L}_{\sigma^2}^{(\lambda, \alpha)}(z) \xrightarrow{z \rightarrow \infty} e^{(2-2^\lambda)s\alpha^\lambda} \Gamma(1 + \lambda) \frac{\sin(\pi\lambda)}{\pi} s \frac{e^{-\alpha|z|}}{|z|^{1+\lambda}}, \tag{20.37}$$

which differs from the estimate (20.26) by a constant factor (see Appendix 20A for details) [28]. Hence the tails are semi-heavy.

In contrast to Gaussian distributions which are characterized completely by their width σ , the truncated Lévy distributions contain three parameters σ , λ , and α . Best fits to two sets of fluctuating market prices are shown in Fig. 20.7. For the S&P 500 index we plot the cumulative distributions

$$P_{<}(z) = \int_{-\infty}^z dz' \tilde{L}_{\sigma^2}^{(\lambda, \alpha)}(z'), \quad P_{>}(z) = \int_z^{\infty} dz' \tilde{L}_{\sigma^2}^{(\lambda, \alpha)}(z') = 1 - P_{<}(z), \tag{20.38}$$

for the price differences $z = \Delta S$ over $\Delta t = 15$ minutes. For the ratios of the changes of the currency rates DM/\$ we plot the returns $z = \Delta S/S$ with the same Δt . The plot shows the negative and positive branches $P_{<}(-z)$, and $P_{>}(z)$ both plotted on the positive z axis. By definition:

$$\begin{aligned} P_{<}(-\infty) &= 0, & P_{<}(0) &= 1/2, & P_{<}(\infty) &= 1, \\ P_{>}(-\infty) &= 1, & P_{>}(0) &= 1/2, & P_{>}(\infty) &= 0. \end{aligned} \tag{20.39}$$

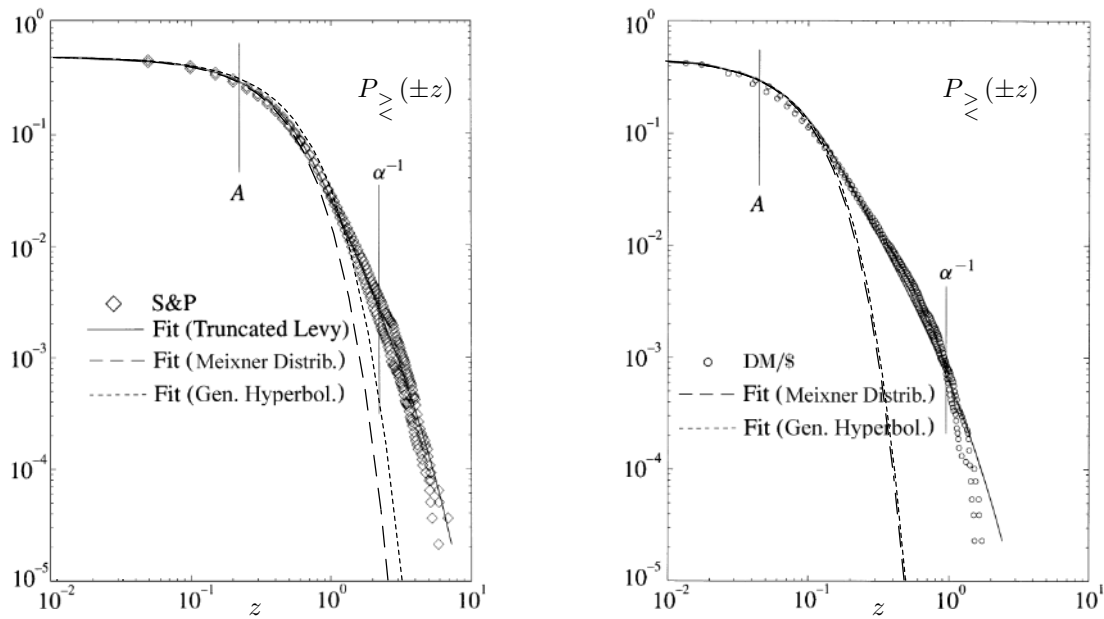

Figure 20.7 Best fit of cumulative versions (20.38) of truncated Lévy distribution to financial data. For the S&P 500 index, the fluctuating variable z is directly the index change ΔS every $\Delta t=15$ minutes (fit with $\sigma^2 = 0.280$ and $\kappa = 12.7$). For the DM/US\$ exchange ratio, the variable z is equal to $100\Delta S/S$ every fifteen minutes (fit with $\sigma^2 = 0.0163$ and $\kappa = 20.5$). The negative fluctuations lie on a slightly higher curve than the positive ones. The difference is often neglected. The parameters A and α are the size and truncation parameters of the distribution. The best value of λ is $3/2$ (from [13]). The dashed curves show the best fits of generalized hyperbolic functions (20.117) (l.h.s. $\lambda = 1.46$, $\alpha = 4.93$, $\beta = 0$, $\delta = 0.52$; r.h.s. $\lambda = 1.59$, $\alpha = 32.1$, $\beta = 0$, $\delta = 0.221$).

The fits are also compared with those by other distributions explained in the figure captions. A fit to most data sequences is possible with a rather universal parameter λ close to $\lambda = 3/2$. The remaining two parameters fix all expansion coefficients of Hamiltonian (20.25):

$$H(p) = \frac{1}{2}c_2 p^2 - \frac{1}{4!}c_4 p^4 + \frac{1}{6!}c_6 p^6 - \frac{1}{8!}c_8 p^8 + \dots \tag{20.40}$$

The numbers $c_{2n} = -(-1)^n H^{(2n)}(0)$ are the *cumulants* of the truncated Lévy distribution [compare (3.587)], also denoted by $\langle z^n \rangle_c$. Here they are equal to

$$\begin{aligned} \langle z^2 \rangle_c &= c_2 = \sigma^2, \\ \langle z^4 \rangle_c &= c_4 = \sigma^2(2 - \lambda)(3 - \lambda)\alpha^{-2}, \\ \langle z^6 \rangle_c &= c_6 = \sigma^2(2 - \lambda)(3 - \lambda)(4 - \lambda)(5 - \lambda)\alpha^{-4}, \\ &\vdots \\ \langle z^{2n} \rangle_c &= c_{2n} = \sigma^2 \frac{\Gamma(2n - \lambda)}{\Gamma(2 - \lambda)} \alpha^{2-2n}. \end{aligned} \tag{20.41}$$

The first cumulant c_2 determines the quadratic fluctuation width

$$\langle z^2 \rangle \equiv \int_{-\infty}^{\infty} dz z^2 \tilde{L}_{\sigma^2}^{(\lambda, \alpha)}(z) = -\left. \frac{d^2}{dp^2} e^{-H(p)} \right|_{p=0} = c_2 = \sigma^2, \tag{20.42}$$

the second the expectation of the fourth power of z

$$\langle z^4 \rangle \equiv \int_{-\infty}^{\infty} dz z^4 \tilde{L}_{\sigma^2}^{(\lambda, \alpha)}(z) = \left. \frac{d^4}{dp^4} e^{-H(p)} \right|_{p=0} = c_4 + 3c_2^2, \tag{20.43}$$

and so on:

$$\langle z^6 \rangle = c_6 + 15c_4c_2 + 15c_2^3, \quad \langle z^8 \rangle = c_8 + 28c_6c_2 + 35c_4^2 + 210c_4c_2^2 + 105c_2^4, \dots \tag{20.44}$$

In a first analysis of the data, one usually determines the so-called *kurtosis*, which is the normalized fourth-order cumulant

$$\kappa \equiv \bar{c}_4 \equiv \frac{c_4}{c_2^2} = \frac{\langle z^4 \rangle_c}{\langle z^2 \rangle_c^2} = \frac{\langle z^4 \rangle_c}{\sigma^4}. \tag{20.45}$$

It depends on the parameters σ, λ, α as follows

$$\kappa = \frac{(2 - \lambda)(3 - \lambda)}{\sigma^2 \alpha^2}. \tag{20.46}$$

Given the volatility σ and the kurtosis κ , we extract the Lévy parameter α from the equation

$$\alpha = \frac{1}{\sigma} \sqrt{\frac{(2 - \lambda)(3 - \lambda)}{\kappa}}. \tag{20.47}$$

In terms of κ and λ , the normalized expansion coefficients are

Figure 20.8 Change in shape of truncated Lévy distributions of width $\sigma = 1$ with increasing kurtoses $\kappa = 0$ (Gaussian, solid curve), 1, 2, 5, 10.

$$\begin{aligned} \bar{c}_4 &= \kappa, & \bar{c}_6 &= \kappa^2 \frac{(5-\lambda)(4-\lambda)}{(3-\lambda)(2-\lambda)}, & \bar{c}_8 &= \kappa^2 \frac{(7-\lambda)(6-\lambda)(5-\lambda)(4-\lambda)}{(3-\lambda)^2(2-\lambda)^2}, \\ &\vdots & & & & \\ \bar{c}_n &= \kappa^{n/2-1} \frac{\Gamma(n-\lambda)/\Gamma(4-\lambda)}{(3-\lambda)^{n/2-2}(2-\lambda)^{n/2-2}}. \end{aligned} \tag{20.48}$$

For $\lambda = 3/2$, the second equation in (20.47) becomes simply

$$\alpha = \frac{1}{2} \sqrt{\frac{3}{\sigma^2 \kappa}}, \tag{20.49}$$

and the coefficients (20.50):

$$\begin{aligned} \bar{c}_4 &= \kappa, & \bar{c}_6 &= \frac{5 \cdot 7}{3} \kappa^2, & \bar{c}_8 &= 5 \cdot 7 \cdot 11 \kappa^2, \\ &\vdots & & & & \\ \bar{c}_n &= \frac{\Gamma(n-3/2)/\Gamma(5/2)}{3^{n/2-2}/2^{n-4}} \kappa^{n/2-1}. \end{aligned} \tag{20.50}$$

At zero kurtosis, the truncated Lévy distribution reduces to a Gaussian distribution of width σ . The change in shape for a fixed width and increasing kurtosis is shown in Fig. 20.8.

From the S&P and DM/US\$ data with time intervals $\Delta t = 15$ min one extracts $\sigma^2 = 0.280$ and 0.0163 , and the kurtoses $\kappa = 12.7$ and 20.5 , respectively. This implies $\alpha \approx 0.46$ and $\alpha \approx 1.50$, respectively. The other normalized cumulants ($\bar{c}_6, \bar{c}_8, \dots$) are then all determined to be $(1881.72, 788627.46, \dots)$ and $(-4902.92, 3.3168 \times 10^6, \dots)$, respectively. The cumulants increase rapidly showing that the expansion needs resummation.

The higher normalized cumulants are given by the following ratios of expectation values

$$\begin{aligned} \bar{c}_6 &= \frac{\langle z^6 \rangle}{\langle z^2 \rangle^3} - 15 \frac{\langle z^4 \rangle}{\langle z^2 \rangle^2} + 30, \\ \bar{c}_8 &= \frac{\langle z^8 \rangle}{\langle z^2 \rangle^4} - 28 \frac{\langle z^6 \rangle}{\langle z^2 \rangle^3} - 35 \frac{\langle z^4 \rangle^2}{\langle z^2 \rangle^4} + 420 \frac{\langle z^4 \rangle}{\langle z^2 \rangle^2} - 630, \dots \end{aligned} \tag{20.51}$$

In praxis, the high-order cumulants cannot be extracted from the data since they are sensitive to the extremely rare events for which the statistics is too low to fit a distribution function.

20.1.4 Asymmetric Truncated Lévy Distributions

We have seen in the data of Fig. 20.7 that the price fluctuations have a slight asymmetry: Price drops are slightly larger than rises. This is accounted for by an asymmetric truncated Lévy distribution. It has the general form [24]

$$L_{\sigma^2}^{(\lambda, \alpha, \beta)}(p) \equiv e^{-H(p)}, \tag{20.52}$$

with a Hamiltonian function

$$\begin{aligned} H(p) &\equiv \frac{\sigma^2}{2} \frac{\alpha^{2-\lambda}}{\lambda(1-\lambda)} [(\alpha + ip)^\lambda(1 + \beta) + (\alpha - ip)^\lambda(1 - \beta) - 2\alpha^\lambda] \\ &= \sigma^2 \frac{(\alpha^2 + p^2)^{\lambda/2} \{\cos[\lambda \arctan(p/\alpha)] + i\beta \sin[\lambda \arctan(p/\alpha)]\} - \alpha^\lambda}{\alpha^{\lambda-2}\lambda(1-\lambda)}. \end{aligned} \quad (20.53)$$

This has a power series expansion

$$H(p) = ic_1 p + \frac{1}{2}c_2 p^2 - i\frac{1}{3!}c_3 p^3 - \frac{1}{4!}c_4 p^4 + i\frac{1}{5!}c_5 p^5 + \dots \quad (20.54)$$

There are now even and odd cumulants $c_n = -i^n H^{(n)}(0)$ with the values

$$c_n = \sigma^2 \frac{\Gamma(n-\lambda)}{\Gamma(2-\lambda)} \alpha^{2-n} \begin{cases} 1 & n = \text{even}, \\ \beta & n = \text{odd}. \end{cases} \quad (20.55)$$

The even cumulants are the same as before in (20.41). Similarly, the even expectation values (20.42)–(20.44) are extended by the odd expectation values:

$$\begin{aligned} \langle z \rangle &\equiv \int_{-\infty}^{\infty} dz z \tilde{L}_{\sigma^2}^{(\lambda, \alpha, \beta)}(z) = i \frac{d}{dp} e^{-H(p)} \Big|_{p=0} = c_1, \\ \langle z^2 \rangle &\equiv \int_{-\infty}^{\infty} dz z^2 \tilde{L}_{\sigma^2}^{(\lambda, \alpha, \beta)}(z) = -\frac{d^2}{d^2 p} e^{-H(p)} \Big|_{p=0} = c_2 + c_1^2, \\ \langle z^3 \rangle &\equiv \int_{-\infty}^{\infty} dz z^3 \tilde{L}_{\sigma^2}^{(\lambda, \alpha, \beta)}(z) = -i \frac{d^3}{d^3 p} e^{-H(p)} \Big|_{p=0} = c_3 + 3c_2 c_1 + c_1^3, \\ \langle z^4 \rangle &\equiv \int_{-\infty}^{\infty} dz z^4 \tilde{L}_{\sigma^2}^{(\lambda, \alpha, \beta)}(z) = \frac{d^4}{d^4 p} e^{-H(p)} \Big|_{p=0} = c_4 + 4c_3 c_1 + 3c_2^2 + 6c_2 c_1^2 + c_1^4, \\ &\vdots \end{aligned} \quad (20.56)$$

The inverse relations are

$$\begin{aligned} c_1 &= \langle z \rangle_c = \langle z \rangle, \\ c_2 &= \langle z^2 \rangle_c = \langle z^2 \rangle - \langle z \rangle^2 = \langle (z - \langle z \rangle_c)^2 \rangle, \\ c_3 &= \langle z^3 \rangle_c = \langle z^3 \rangle - 3\langle z \rangle \langle z^2 \rangle + 2\langle z \rangle^3 = \langle (z - \langle z \rangle_c)^3 \rangle, \\ c_4 &= \langle z^4 \rangle_c = \langle z^4 \rangle - 3\langle z^2 \rangle^2 - 4\langle z \rangle \langle z^3 \rangle + 12\langle z \rangle^2 \langle z^2 \rangle - 6\langle z \rangle^4 \\ &= \langle (z - \langle z \rangle_c)^4 \rangle - 3\langle z^2 - \langle z \rangle_c^2 \rangle^2 = \langle (z - \langle z \rangle_c)^4 \rangle - 3c_2^2. \end{aligned} \quad (20.57)$$

These are, of course, just simple versions of the cumulant expansions (3.585) and (3.587).

The distribution is now centered around a nonzero average value:

$$\mu \equiv \langle z \rangle = c_1. \quad (20.58)$$

The fluctuation width is given by

$$\sigma^2 \equiv \langle z^2 \rangle - \langle z \rangle^2 = \langle (z - \langle z \rangle)^2 \rangle = c_2. \tag{20.59}$$

For large z , the asymmetric truncated Lévy distributions exhibit semi-heavy tails, obtained by a straightforward modification of (20.28):

$$\begin{aligned} \tilde{L}_{\sigma^2}^{(\lambda, \alpha)}(z) &\approx \int_{-\infty}^{\infty} \frac{dp}{2\pi} e^{ipz} \left\{ 1 - \frac{\sigma^2}{2} \frac{\alpha^{2-\lambda}}{\lambda(1-\lambda)} \left[(\alpha + ip)^\lambda (1+\beta) + (\alpha - ip)^\lambda (1-\beta) - 2\alpha^\lambda \right] \right\} \\ &\xrightarrow{z \rightarrow \infty} \sigma^2 e^{2s\alpha^\lambda} \Gamma(1 + \lambda) \frac{\sin(\pi\lambda)}{\pi} s \frac{e^{-\alpha|z|}}{|z|^{1+\lambda}} [1 + \beta \operatorname{sgn}(z)]. \end{aligned} \tag{20.60}$$

In analyzing the data, one uses the *skewness*

$$s \equiv \frac{\langle (z - \langle z \rangle)^3 \rangle}{\sigma^3} = \bar{c}_3 = \frac{c_3}{c_2^{3/2}}. \tag{20.61}$$

It depends on the parameters σ , λ , β , and α or κ as follows

Figure 20.9 Change in shape of truncated Lévy distributions of width $\sigma = 1$ and kurtosis $\kappa = 1$ with increasing skewness $s = 0$ (solid curve), 0.4, 0.8. The curves are centered around $\langle z \rangle$.

$$s = \frac{(2 - \lambda)\beta}{\sigma\alpha}. \tag{20.62}$$

The kurtosis can also be defined by [compare (20.45)]³

$$\kappa \equiv \bar{c}_4 \equiv \frac{c_4}{c_2^2} = \frac{\langle z^4 \rangle_c}{\langle z^2 \rangle_c^2} = \frac{\langle z^4 \rangle_c}{\sigma^4} = \frac{\langle (z - \langle z \rangle)^4 \rangle}{\sigma^4} - 3. \tag{20.63}$$

From the data one extracts the three parameters volatility σ , skewness s , and kurtosis κ , which completely determine the asymmetric truncated Lévy distribution.

³Some authors call the ratio $\langle (z - \langle z \rangle)^4 \rangle / \sigma^4$ in (20.63) kurtosis and the quantity κ the *excess kurtosis*. Their kurtosis is equal to 3 for a Gaussian distribution, ours vanishes.

The data are then plotted against $z - \langle z \rangle = z - \mu$, so that they are centered at the average position. This centered distribution will be denoted by $\bar{L}_{\sigma^2}^{(\lambda, \alpha, \beta)}(z)$, i.e.

$$\bar{L}_{\sigma^2}^{(\lambda, \alpha, \beta)}(z) \equiv \tilde{L}_{\sigma^2}^{(\lambda, \alpha, \beta)}(z - \mu). \tag{20.64}$$

The Hamiltonian associated with this zero-average distribution is

$$\bar{H}(p) \equiv H(p) - H'(0)p, \tag{20.65}$$

and its expansion in power of the momenta starts out with p^2 , i.e. the first term in (20.54) is subtracted.

In terms of σ , s , and κ , the normalized expansion coefficients are

$$\bar{c}_n = \kappa^{n/2-1} \frac{\Gamma(n - \lambda)/\Gamma(4 - \lambda)}{(3 - \lambda)^{n/2-2}(2 - \lambda)^{n/2-2}} \begin{cases} 1 & n = \text{even,} \\ \sqrt{(3 - \lambda)/(2 - \lambda)\kappa s} & n = \text{odd.} \end{cases} \tag{20.66}$$

The change in shape of the distributions of a fixed width and kurtosis with increasing skewness is shown in Fig. 20.9. We have plotted the distributions centered around the average position $z = \langle c_1 \rangle$ which means that we have removed the linear term ic_1p from $H(p)$ in (20.52), (20.53), and (20.54). This subtracted Hamiltonian whose power series expansion begins with the term $c_2p^2/2$ will be denoted by

$$\bar{H}(p) \equiv H(p) - H'(0)p = \frac{1}{2}c_2p^2 - i\frac{1}{3!}c_3p^3 - \frac{1}{4!}c_4p^4 + i\frac{1}{5!}c_5p^5 + \dots \tag{20.67}$$

20.1.5 Gamma Distribution

For a Hamiltonian

$$H_+(p) = \nu \log(1 - ip/\mu) \tag{20.68}$$

one obtains the normalized *Gamma distribution* of mathematical statistics:

$$\tilde{D}_{\mu, \nu}^{\text{Gamma}}(z) = \frac{1}{\Gamma(\nu)} \mu^\nu z^{\nu-1} e^{-\mu z}, \quad \int_0^\infty dz \tilde{D}_{\mu, \nu}^{\text{Gamma}}(z) = 1, \tag{20.69}$$

which is restricted to positive variables z .

Expanding $H_+(p)$ in a power series $-\sum_{n=1}^\infty i^n \nu \mu^{-n} p^n / n = -\sum_{n=1}^\infty i^n c_n p^n / n!$, we identify the cumulants

$$c_n = (n - 1)! \nu / \mu^n, \tag{20.70}$$

so that the lowest moments are

$$\bar{z} = \nu/\mu, \quad \sigma^2 = \nu/\mu^2, \quad s = 2/\sqrt{\nu}, \quad \kappa = 6/\nu. \tag{20.71}$$

The maximum of the distribution lies slightly below the average value \bar{z} at

$$z_{\text{max}} = (\nu - 1)/\mu = \bar{z} - 1/\mu. \tag{20.72}$$

The Gamma distribution was seen in Fig. 20.3 to yield an optimal fit to the fluctuating volatilities when it is plotted as a distribution of the volatility $\sigma = \sqrt{z}$:

$$\tilde{D}_{\mu,\nu}^{\text{Chi}}(\sigma) \equiv 2\sigma \tilde{D}_{\mu,\nu}^{\text{Gamma}}(\sigma^2), \quad \int_0^\infty d\sigma \tilde{D}_{\mu,\nu}^{\text{Chi}}(\sigma) = 1. \quad (20.73)$$

As a normalized distribution of the volatility σ rather than the variance $v = \sigma^2$, one calls this function a *Chi distribution*.

In the limit $\nu \rightarrow \infty$ at fixed $\bar{z} = \nu/\mu$, the Gamma distribution becomes a Dirac δ -function:

$$\tilde{D}_{\mu,\nu}^{\text{Gamma}}(z) \rightarrow \delta\left(z - \frac{\nu}{\mu}\right). \quad (20.74)$$

If we add to $H_+(p)$ the Hamiltonian

$$H_-(p) = \nu \log(1 + ip/\mu) \quad (20.75)$$

we obtain the distribution of negative z -values:

$$\tilde{D}_{\mu,\nu}^{\text{Gamma}}(z) = \frac{1}{\Gamma(\nu)} \mu^{-\nu} |z|^{\nu-1} e^{-\mu|z|}, \quad z \leq 0. \quad (20.76)$$

By combining the two Hamiltonians with different parameters μ one can set up a skewed two-sided distribution.

20.1.6 Boltzmann Distribution

The highest-frequency returns ΔS of NASDAQ 100 and S&P 500 indices have a special property: they display a purely exponential behavior for positive as well as negative z , as long as the probability is rather large [32]. The data are fitted by the Boltzmann distribution

Figure 20.10 Boltzmann distribution of S&P 500 and NASDAQ 100 high-frequency log-returns recorded by the minute.

$$\tilde{B}(z) = \frac{1}{2T} e^{-|z|/T}. \quad (20.77)$$

We can see in Fig. 20.10, that only a very small set of rare events of large $|z|$ does not follow the Boltzmann law, but displays heavy tails. This allows us to assign a temperature to the stock markets [33]. The temperature depends on the volatility of the selected stocks and changes only very slowly with the general economic and political environment. Near a crash it reaches maximal values, as shown in Fig. 20.11.

It is interesting to observe the historic development of Dow Jones temperature over the last 78 years (1929-2006) in Fig. 20.12. Although the world went through a lot of turmoil and economic development in the 20th century, the temperature remained almost a constant except for short heat bursts. The hottest temperatures occurred in the 1930's, the time of the great depression. These temperatures were never reached again. An especially hot burst occurred during the crash year 1987. Thus, in the long run, the market temperature is not related to the value of the index but indicates the riskiness of the market. Only in bubbles, high temperatures go along with high stock prices. An extraordinary increase in market temperature before a crash may be useful to investors as a signal to go short.

The Fourier transform of the Boltzmann distribution is

$$B(p) = \int_{-\infty}^{\infty} dz e^{ipz} \frac{1}{2T} e^{-|z|/T} = \frac{1}{1 + (Tp)^2} = e^{-H(p)}, \tag{20.78}$$

so that we identify the Hamiltonian as

$$H(p) = \log[1 + (Tp)^2]. \tag{20.79}$$

This has only even cumulants:

$$c_{2n} = -(-1)^n H^{(2n)}(0) = 2(2n - 1)! T^{2n}, \quad n = 1, 2, \dots \tag{20.80}$$

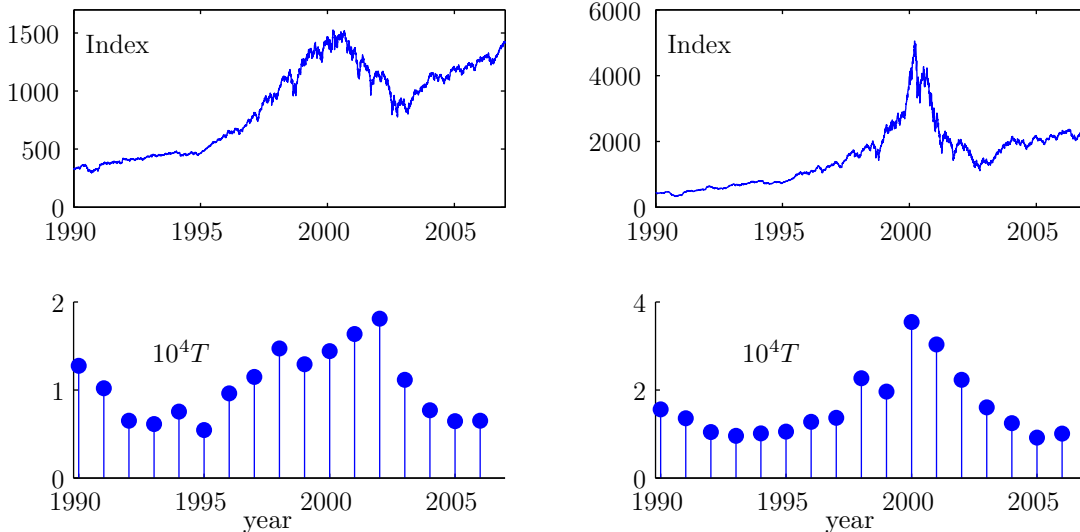

Figure 20.11 Market temperatures of S&P 500 and NASDAQ 100 indices from 1990 to 2006. The crash in the year 2000 occurred at the maximal temperatures $T_{\text{S\&P500}} \approx 2 \times 10^{-4}$ and $T_{\text{NASDAQ}} \approx 4 \times 10^{-4}$.

Figure 20.12 Dow Jones index over 78 years (1929-2006) and the annual market temperature, which is remarkably uniform, except in the 1930's, in the beginning of the great depression. An other high extreme temperature occurred in the crash year 1987.

The Boltzmann distribution is a special case of a two-sided Gamma distribution discussed in the previous subsection. It has semi-heavy tails.

We now observe that the Fourier transform can be rewritten as an integral [recall (2.499)]

$$B(p) = e^{-H(p)} = \frac{1}{1 + (Tp)^2} = \int_0^\infty d\tau e^{-\tau(1+T^2p^2)}. \quad (20.81)$$

This implies that Boltzmann distribution can be obtained from a superposition of Gaussian distributions. Indeed, the prefactor of p^2 is equal to twice the variance $v = \sigma^2$ of the Gaussian distribution. Hence we change the variable of integration from τ to σ^2 , substituting $\tau = \sigma^2/2T^2$, and obtain

$$B(p) = e^{-H(p)} = \frac{1}{2T^2} \int_0^\infty d\sigma^2 e^{-\sigma^2/2T^2} e^{-\sigma^2 p^2/2}. \quad (20.82)$$

The Fourier transform of this is the desired representation of the Boltzmann distribution as a volatility integral over Gaussian distributions of different widths:

$$\tilde{B}(z) = \frac{1}{2T^2} \int_0^\infty d\sigma^2 e^{-\sigma^2/2T^2} \frac{1}{\sqrt{2\pi\sigma^2}} e^{-z^2/2\sigma^2}. \quad (20.83)$$

The volatility distribution function is recognized to be a special case of the Gamma distribution (20.69) for $\mu = 1/2T^2$, $\nu = 1$.

20.1.7 Student or Tsallis Distribution

Recently, another non-Gaussian distribution has become quite popular through work of Tsallis [58, 59, 60]. It has been proposed as a good candidate for describing heavy tails a long time ago under the name Student distribution by Praetz [61] and by Blattberg and Gonedes [62]. This distribution can be written as

$$\tilde{D}_\delta(z) = N_\delta \frac{1}{\sqrt{2\pi\sigma_\delta^2}} e_\delta^{-z^2/2\sigma_\delta^2}, \quad (20.84)$$

where N_δ is a normalization factor

$$N_\delta = \frac{\sqrt{\delta}\Gamma(1/\delta)}{\Gamma(1/\delta - 1/2)}, \quad (20.85)$$

and $\sigma_K \equiv \sigma\sqrt{1 - 3\delta/2}$, where σ is the volatility of the distribution. The function $e_\delta(z)$ is an approximation of the exponential function called δ -exponential:

$$e_\delta^z \equiv (1 - \delta z)^{-1/\delta}. \quad (20.86)$$

In the limit $\delta \rightarrow 0$, this reduces to the ordinary exponential function e^z .

Remarkably, the distribution of a fixed total amount of money W between N persons of equal earning talents follows such a distribution. The partition functions is given by

$$Z_N(W) = \left[\prod_{n=1}^N \int_0^W dw_n \right] \delta(w_1 + \dots + w_N - W). \quad (20.87)$$

After rewriting this as

$$Z_N(W) = \int_{-\infty}^{\infty} \frac{d\lambda}{2\pi} \left[\prod_{n=1}^N \int_0^W dw_n \right] e^{-i\lambda(w_1 + \dots + w_N)} e^{i\lambda W} = \int_{-\infty}^{\infty} \frac{d\lambda}{2\pi} \frac{(e^{-i\lambda W} - 1)^N e^{i\lambda W}}{(-i\lambda + \epsilon)^N}, \quad (20.88)$$

where ϵ is an infinitesimal positive number, and a binomial expansion of $(e^{-i\lambda W} - 1)^N e^{i\lambda W}$, we can perform the integral over λ , using the formula⁴

$$\int_{-\infty}^{\infty} \frac{d\lambda}{2\pi} \frac{1}{(-i\lambda + \epsilon)^\nu} e^{-ipx} = \frac{p^{\nu-1}}{\Gamma(\nu)} e^{-\epsilon p} \Theta(p), \quad (20.89)$$

⁴See I.S. Gradshteyn and I.M. Ryzhik, *op. cit.*, Formula 3.382.7.

where $\Theta(z)$ is the Heaviside function (1.304), we obtain

$$Z_N(W) = \frac{W^{N-1}}{\Gamma(N)} \sum_{k=0}^{N-1} (-1)^k \binom{N}{N-k} (N-k-1)^{N-1} \quad (20.90)$$

The sum over binomial coefficients adds up to unity, due to a well-known identity for binomial coefficients⁵, so that

$$Z_N(W) = \frac{W^{N-1}}{\Gamma(N)}. \quad (20.91)$$

If we replace W by $W - w_n$, this partition function gives us the unnormalized probability that an individual owns the part w_n of total wealth. The normalized probability is then

$$P_N(w_n) = Z_N^{-1} \frac{(W - w_n)^{N-2}}{\Gamma(N-1)} = \frac{N-1}{W} \left(1 - \frac{w_n}{E}\right)^{N-2}. \quad (20.92)$$

Defining $w \equiv W/(N-2)$, which for large N is the average wealth per person, $P_N(w_n)$ can be expressed in terms of the δ -exponential (20.86) as

$$P_N(w_n) = \frac{N-1}{W} \left[1 - \frac{w_n}{(N-2)w}\right]^{N-2} = \frac{N-1}{W} e_{-1/(N-2)}^{-w_n/w}. \quad (20.93)$$

In the limit of infinitely many individuals, this turns into the normalized Boltzmann distribution $w^{-1}e^{-w_n/w}$.

The *Student-Tsallis distribution* (20.84) is simply a normalized δ -exponential. Instead of the parameter δ one often uses the Tsallis parameter $q = \delta + 1$. A plot of these functions for different δ -values is shown on the left hand of Fig. 20.13. From Eq. (20.86) we see that the Student-Tsallis distribution with $\delta > 0$ has heavy tails with a power behavior $1/z^{1/\delta} = 1/z^{1/(q-1)}$. A fit of the log-returns of 10 NYSE top-volume stocks is shown in Fig. 20.13.

Remarkably, the δ -exponential in (20.84) can be written as a superposition of Gaussian distributions. With the help of the integral formula (2.499) we find

$$e_{\delta}^{-z^2/2\sigma_{\delta}^2} = \frac{1}{\Gamma(1/\delta)} \int_0^{\infty} \frac{ds}{s} s^{1/\delta} e^{-s} e^{-s\delta z^2/2\sigma_{\delta}^2}. \quad (20.94)$$

After a change of variables this can be rewritten as

$$e_{\delta}^{-z^2/2\sigma_{\delta}^2} = \frac{\mu^{1/\delta}}{\Gamma(1/\delta)} \int_0^{\infty} \frac{dv}{v} v^{1/\delta} e^{-\mu v} e^{-vz^2/2}, \quad \mu = \sigma_{\delta}^2/\delta. \quad (20.95)$$

This is a superposition of Gaussian functions $e^{-vz^2/2}$ whose *inverse variances* $v = 1/\sigma^2$ occur with a weight that is precisely the Gamma distribution of the variable v with $\nu = 1/\delta$:

$$\tilde{D}_{\mu, 1/\delta}^{\text{Gamma}}(v) = \frac{1}{\Gamma(1/\delta)} \mu^{1/\delta} v^{\nu} e^{-\mu v}. \quad (20.96)$$

⁵See I.S. Gradshteyn and I.M. Ryzhik, *op. cit.*, Formula 0.154.6.

Figure 20.13 Left: Logarithmic plot of the normalized δ -exponential (20.84) (Student-Tsallis distribution) for $\delta = 0$ (Gaussian), 0.2, 0.4, 0.6, all for $\sigma = 1$. Right: Fit of the log-returns of 20 NYSE top-volume stocks over short time scales from 1 to 3 minutes by this distribution (after Ref. [60]). Dotted line is Gaussian distribution.

20.1.8 Tsallis Distribution in Momentum Space

When fitting the volatility distributions of the S&P 500 index in Fig. 20.3, we observed that the best fit was obtained by a Gamma distribution. Inspired by the discussion in the last section we observe that the δ -exponential (20.86) in momentum space

$$e^{-H_{\delta,\beta}(p)} \equiv e_{\delta}^{-\beta p^2/2} = \left(1 + \beta\delta p^2/2\right)^{-1/\delta}, \quad (20.97)$$

has precisely such a decomposition. We simply rewrite it by analogy with (20.94) as

$$e_{\delta}^{-\beta p^2/2} = \frac{1}{\Gamma(1/\delta)} \int_0^{\infty} \frac{ds}{s} s^{1/\delta} e^{-s} e^{-s\beta\delta p^2/2}, \quad \beta \equiv \nu/\mu = 1/\mu\delta, \quad (20.98)$$

and change the variable of integration to obtain

$$e_{\delta}^{-\beta p^2/2} = \frac{\mu^{\nu}}{\Gamma(\nu)} \int_0^{\infty} \frac{dv}{v} v^{\nu} e^{-\mu v} e^{-\nu p^2/2}, \quad \nu = 1/\delta, \quad \mu = \nu/\beta = 1/\beta\delta. \quad (20.99)$$

This is a superposition of Gaussian distributions whose variances $v = \sigma^2$ are weighted by the Gamma distribution (20.69):

$$e_{\delta}^{-\beta p^2/2} = \int_0^{\infty} dv D_{\mu,\nu}^{\text{Gamma}}(v) e^{-\nu p^2/2}, \quad \nu = 1/\delta, \quad \mu = \nu/\beta = 1/\beta\delta. \quad (20.100)$$

The average of the Gamma distribution is $\bar{v} = \nu/\mu = \beta$ [recall (20.71)], so that the left-hand side can also be written as $e_{\delta}^{-\bar{\nu} p^2/2}$.

The lowest cumulants in the Hamiltonian $H_{\delta,\beta}(p) = \frac{1}{2!}c_2 p^2 - \frac{1}{4!}c_4 p^4 + \dots$ are

$$c_2 = \frac{\nu}{\mu}, \quad c_4 = 3 \frac{\nu}{\mu^2}, \quad c_6 = \frac{5!!}{\mu^3} (2 + 3\nu - 2\nu^2 - \nu^3), \quad c_8 = \frac{7!!}{\mu^3} (2 + \nu - 3\nu^2 + \nu^3 + \nu^4). \quad (20.101)$$

For $\mu = 1/2T^2$ and $\nu = 1$, these reduce to those of the Boltzmann distribution in Eq. (20.80).

The superposition (20.99) can immediately be Fourier transformed to

$$\tilde{D}_{\delta,\beta}(z) = \frac{\mu^{1/\delta}}{\Gamma(1/\delta)} \int_0^\infty \frac{dv}{v} v^{1/\delta} e^{-\mu v} \frac{1}{\sqrt{2\pi v}} e^{-z^2/2v}, \quad \mu = 1/\beta\delta. \quad (20.102)$$

which is a superposition of Gaussians whose variances $v = \sigma^2$ follow a Gamma distribution (20.69) centered around $\bar{v} = 1/\delta\mu$ of width $(v - \bar{v})^2 = 1/\delta\mu^2$. Hence δ is given by the ratio $\delta = (\overline{v - \bar{v}})^2/\bar{v}^2$. Recalling Eq. (20.71) we see that δ determines the kurtosis of the distribution to be $\kappa = 6\delta$.

The integral over v in (20.102) can be done using Formula (2.559), yielding

$$\tilde{D}_{\delta,\beta}(z) = \frac{\sqrt{\mu}}{\Gamma(1/\delta)} \frac{1}{\sqrt{2\pi}} \left(\frac{\mu z^2}{2}\right)^{1/2\delta - 1/4} 2K_{1/\delta - 1/2}(\sqrt{2\mu}z), \quad \mu = 1/\beta\delta. \quad (20.103)$$

For $\delta = 1$ and $\mu = 1/2T^2$, we use (1.349) and recover the Boltzmann distribution (20.83)

The small- z behavior of $K_\nu(z)$ is $(1/2)\Gamma(\nu)(z/2)^{-\nu}$ for $\text{Re } \nu > 0$ [recall Eq. (1.351)]. If we assume $\delta < 2$, we obtain from (20.103) the value of the distribution function at the origin:

$$\tilde{D}_{\delta,\beta}(0) = \frac{\sqrt{\mu}\Gamma(1/\delta - 1/2)}{\Gamma(1/\delta)}. \quad (20.104)$$

The same result can, of course, be found directly from Eq. (20.102). This value diverges at $\delta = 2/(1 - 2n)$ ($n = 0, 1, 2, \dots$).

20.1.9 Relativistic Particle Boltzmann Distribution

A physically important distribution in momentum space is the Boltzmann distribution $e^{-\beta E(p)}$ of relativistic particle energies $E(p) = \sqrt{p^2 + M^2}$, where β is the inverse temperature $1/k_B T$. The exponential can be expressed as a superposition of Gaussian distributions

$$e^{-\beta\sqrt{p^2+M^2}} = \int_0^\infty dv \omega_\beta(v) e^{-\beta v(p^2+M^2)/2} \quad (20.105)$$

with a weight function

$$\omega_\beta(v) \equiv \sqrt{\frac{\beta}{2\pi v^3}} e^{-\beta/2v}. \quad (20.106)$$

This is a special case of a *Weibull distribution*

$$\tilde{D}_W(x) = \frac{b}{\Gamma(a/b)} x^{a-1} e^{-x^b}, \quad (20.107)$$

which has the simple moments

$$\langle x^n \rangle = \Gamma((a+n)/b)/\Gamma(a/b). \quad (20.108)$$

20.1.10 Meixner Distributions

Quite reasonable fits to financial data are provided by the *Meixner distributions* [34, 35] which read in configuration and momentum space:

$$\tilde{M}(z) = \frac{[2 \cos(b/2)]^{2d}}{2a\pi\Gamma(2d)} |\Gamma(d + iz/a)|^2 \exp[bz/a], \tag{20.109}$$

$$M(p) = \left\{ \frac{\cos(b/2)}{\cosh[(ap - ib)/2]} \right\}^{2d}. \tag{20.110}$$

They have the same semi-heavy tail behavior as the truncated Lévy distributions

$$\tilde{M}(z) \rightarrow C_{\pm} |z|^{\rho} e^{-\sigma_{\pm}|z|} \quad \text{for } z \rightarrow \pm\infty, \tag{20.111}$$

with

$$C_{\pm} = \frac{[2 \cos(b/2)]^{2d}}{2a\pi\Gamma(2d)} \frac{2\pi}{a^{2d-1}} e^{\pm 2\pi d \tan(b/2)}, \quad \rho = 2d - 1, \quad \sigma_{\pm} \equiv (\pi \pm b)/a. \tag{20.112}$$

The moments are

$$\mu = ad \tan(b/2), \quad \sigma^2 = a^2 d/2 \cos^2(b/2), \quad s = \sqrt{2} \sin(b/2)/\sqrt{d}, \quad \kappa = [2 - \cos b]/d, \tag{20.113}$$

such that we can calculate the parameters from the moments as follows:

$$a^2 = \sigma^2 (2\kappa - 3s^2), \quad d = \frac{1}{\kappa - s^2}, \quad b = 2 \arcsin \left(s\sqrt{d/2} \right). \tag{20.114}$$

As an example for the parameters of the distribution, a good fit of the daily Nikkei-225 index is possible with

$$a = 0.029828, \quad b = 0.12716, \quad d = 0.57295, \quad \langle z \rangle = -0.0011243. \tag{20.115}$$

The curve has to be shifted in z by Δz to make $\Delta z + \mu$ equal to $\langle z \rangle$. Such a Meixner distribution has been used for option pricing in Ref. [35].

The Meixner distributions can be fitted quite well to the truncated Lévy distribution in the regime of large probability. In doing so we observe that the variance σ^2 and the kurtosis κ are not the best parameters to match the two distributions. The large-probability regime of the distributions can be matched perfectly by choosing, in the symmetric case, the value and the curvature at the origin to be the same in both curves. This is seen in Fig. 20.14.

In the asymmetric case we have to match also the first and third derivatives. The derivatives of the Meixner distribution are:

$$\begin{aligned} \tilde{M}(0) &= \frac{2^{2d-1}\Gamma^2(d)}{\pi a\Gamma(2d)}, \\ \tilde{M}'(0) &= b \frac{2^{2d-1}\Gamma^2(d) [1 - d\psi(d)]}{\pi a^2\Gamma(2d)}, \\ \tilde{M}''(0) &= -\frac{2^{2d}\Gamma^2(d)\psi(d)}{\pi a^3\Gamma(2d)}, \\ \tilde{M}^{(3)}(0) &= -\frac{b}{2} \frac{2^{2d}\Gamma^2(d) [6\psi(d) - 6d\psi^2(d) - d\psi^{(3)}(d)]}{\pi a^4\Gamma(2d)}, \\ \tilde{M}^{(4)}(0) &= \frac{2^{2d}\Gamma^2(d) [6\psi^2(d) + \psi^{(3)}(d)]}{\pi a^5\Gamma(2d)}, \end{aligned} \tag{20.116}$$

where $\psi^{(n)}(z) \equiv d^{n+1} \log \Gamma(z)/dz^{n+1}$ are the Polygamma functions.

Figure 20.14 Comparison of best fit of Meixner distribution to truncated Lévy distributions. One of them (short dashed) has the same volatility σ and kurtosis κ . The other (long-dashed) has the same size and curvature at the origin. The parameters are $\sigma^2 = 0.280$ and $\kappa = 12.7$ as in the left-hand cumulative distribution in Fig. 20.7. The Meixner distribution with the same σ^2 and κ has parameters $a = 2.666$, $d = 0.079$, $b = 0$, the distribution with the same value and curvature at the origin has $a = 0.6145$, $d = 1.059$, $b = 0$. The very large σ -regime, however, is not fitted well as can be seen in the cumulative distributions which reach out to z of the order of 10σ in Fig. 20.7.

20.1.11 Generalized Hyperbolic Distributions

Another non-Gaussian distributions proposed in the literature is the so-called *generalized hyperbolic distributions*.⁶ As the truncated Lévy and Meixner distributions, these have simple analytic forms both in z - and p -space:

$$\tilde{H}_G(z) = \frac{(\gamma^2 - \beta^2)^{\lambda/2} e^{\beta z}}{\gamma^{\lambda-1/2} \delta^\lambda \sqrt{2\pi}} [\delta^2 + z^2]^{\lambda/2-1/4} \frac{K_{\lambda-1/2}(\gamma \sqrt{\delta^2 + z^2})}{K_\lambda(\delta \sqrt{\gamma^2 - \beta^2})} \tag{20.117}$$

and

$$G(p) = \frac{(\delta \sqrt{\gamma^2 - \beta^2})^\lambda}{K_\lambda(\delta \sqrt{\gamma^2 - \beta^2})} \frac{K_\lambda(\delta \sqrt{\gamma^2 - (\beta + ip)^2})}{[\delta \sqrt{\gamma^2 - (\beta + ip)^2}]^\lambda}, \tag{20.118}$$

the latter defining another Hamiltonian

$$H_G(p) \equiv -\log G(p). \tag{20.119}$$

But in contrast to the former, this set of functions is not closed under time evolution. The distributions at a later time t are obtained from the Fourier transforms $e^{-H(p)t}$. For truncated Lévy distributions and the Meixner distributions the factor t can simply be absorbed in the parameters of the functions ($\sigma^2 \rightarrow t\sigma^2$ in the first and $d \rightarrow td$ in the second case). For the generalized

⁶See the publications [36]–[74].

hyperbolic distributions, this is no longer true since $e^{-H_G(p)t} = [G(p)]^t$ involves higher powers of Bessel functions whose analytic Fourier transform cannot be found. In order to describe a complete temporal evolution we must therefore close the set of functions by adding all Fourier transforms of $e^{-H_G(p)t}$. In praxis, this is not a serious problem — it merely leads to a slowdown of numeric calculations which always involve a numeric Fourier transformation.

The asymptotic behavior of the generalized hyperbolic distributions has semi-heavy tails. From the large- z behavior of the Bessel function $K_\nu(z) \rightarrow \sqrt{\pi/2z}e^{-z}$ we find

$$\tilde{H}_G(z) \rightarrow \sqrt{\frac{\pi}{2\gamma}} \frac{(\gamma^2 - \beta^2)^{\lambda/2} e^{\beta z}}{\gamma^{\lambda-1/2} \delta^\lambda \sqrt{2\pi}} \frac{1}{K_\lambda(\delta\sqrt{\gamma^2 - \beta^2})} z^{\lambda-1} e^{-\gamma z}. \tag{20.120}$$

Introducing the variable $\zeta \equiv \delta\sqrt{\gamma^2 - \beta^2}$, this can again be expanded in powers of p as in Eq. (20.54), yielding the first two cumulants:

$$c_1 = \beta \frac{\delta^2}{\zeta} \frac{K_{1+\lambda}(\zeta)}{K_\lambda(\zeta)}; \tag{20.121}$$

$$c_2 = \frac{\delta^2}{\zeta} \frac{K_{1+\lambda}(\zeta)}{K_\lambda(\zeta)} + \frac{\beta^2 \delta^4}{\zeta^2} \left\{ \frac{K_{2+\lambda}(\zeta)}{K_\lambda(\zeta)} - \left[\frac{K_{1+\lambda}(\zeta)}{K_\lambda(\zeta)} \right]^2 \right\}. \tag{20.122}$$

Using the identity [50]

$$K_{\nu+1}(z) - K_{\nu-1}(z) = \frac{2\nu}{z} K_\nu(z), \tag{20.123}$$

the latter equation can be expressed entirely in terms of

$$\rho = \rho(\zeta) = \frac{K_{1+\lambda}(\zeta)}{K_\lambda(\zeta)} \tag{20.124}$$

as

$$c_2 = \frac{\delta^2}{\zeta} \rho + \frac{\beta^2 \delta^4}{\zeta^3} [\zeta + 2(1 + \lambda)\rho - \zeta\rho^2]. \tag{20.125}$$

Usually, the asymmetry of the distribution is small implying that c_1 is small, implying a small β . It is then useful to introduce the symmetric variance

$$\sigma_s^2 \equiv \delta^2 \rho / \zeta, \tag{20.126}$$

and write

$$c_1 = \beta \sigma_s, \quad c_2 = \sigma^2 = \sigma_s^2 + \beta^2 \left[\frac{\delta^4}{\zeta^2} + 2(1 + \lambda) \frac{\delta^2}{\zeta^2} \sigma_s - \sigma_s^2 \right]. \tag{20.127}$$

The cumulants c_3 and c_4 are most compactly written as

$$c_3 = \beta \left[\frac{3\delta^4}{\zeta^2} + 6(1 + \lambda) \frac{\delta^2}{\zeta^2} \sigma_s^2 - 3\sigma_s^4 \right] + \beta^3 \left\{ 2(2 + \lambda) \frac{\delta^6}{\zeta^4} + [4(1 + \lambda)(2 + \lambda) - 2\zeta^2] \frac{\delta^4}{\zeta^4} \sigma_s^2 - 6(1 + \lambda) \frac{\delta^2}{\zeta^2} \sigma_s^4 + 2\sigma_s^6 \right\} \tag{20.128}$$

and

$$c_4 = \kappa \sigma^4 = \frac{3\delta^4}{\zeta^2} + \frac{6\delta^2}{\zeta^2} (1 + \lambda) \sigma_s^2 - 3\sigma_s^4 + 6\beta^2 \left\{ 2(2 + \lambda) \frac{\delta^6}{\zeta^4} + [4(1 + \lambda)(2 + \lambda) - 2\zeta^2] \frac{\delta^4}{\zeta^4} \sigma_s^2 - 6(1 + \lambda) \frac{\delta^2}{\zeta^2} \sigma_s^4 + 2\sigma_s^6 \right\} + \beta^4 \left\{ [4(2 + \lambda)(3 + \lambda) - \zeta^2] \frac{\delta^8}{\zeta^6} + [4(1 + \lambda)(2 + \lambda)(3 + \lambda) - 2(5 + 4\lambda)\zeta^2] \frac{\delta^6}{\zeta^6} \sigma_s^2 - 2[(1 + \lambda)(11 + 7\lambda) - 2\zeta^2] \frac{\delta^4}{\zeta^4} \sigma_s^4 + 12(1 + \lambda) \frac{\delta^2}{\zeta^2} \sigma_s^6 - 3\sigma_s^8 \right\}. \tag{20.129}$$

The first term in c_4 is equal to σ_s^4 times the kurtosis of the symmetric distribution

$$\kappa_s \equiv \frac{3\delta^4}{\zeta^2\sigma_s^4} + \frac{6\delta^2}{\zeta^2\sigma_s^2}(1 + \lambda) - 3. \tag{20.130}$$

Inserting here σ_s^2 from (20.126), we find

$$\kappa_s \equiv \frac{3}{r^2(\zeta)} + (1 + \lambda)\frac{6}{\zeta r(\zeta)} - 3. \tag{20.131}$$

Since all Bessel functions $K_\nu(z)$ have the same large- z behavior $K_\nu(z) \rightarrow \sqrt{\pi/2z}e^{-z}$ and the small- z behavior $K_\nu(z) \rightarrow \Gamma(\nu)/2(z/2)^\nu$, the kurtosis starts out at $3/\lambda$ for $\zeta = 0$ and decreases monotonously to 0 for $\zeta \rightarrow \infty$. Thus a high kurtosis can be reached only with a small parameter λ .

The first term in c_3 is $\beta\kappa_s\sigma_s^4$, and the first two terms in c_4 are $\kappa_s\sigma_s^4 + 6(c_3/\beta - \kappa_s\sigma_s^4)$. For a symmetric distribution with certain variance σ_s^2 and kurtosis κ_s we select some parameter $\lambda < 3/\kappa_s$, and solve the Eq. (20.131) to find ζ . This is inserted into Eq. (20.126) to determine

$$\delta^2 = \frac{\sigma_s^2\zeta}{\rho(\zeta)}. \tag{20.132}$$

If the kurtosis is larger, it is not an optimal parameter to determine generalized hyperbolic distributions. A better fit to the data is reached by reproducing correctly the size and shape of the distribution near the peak and allow for some deviations in the tails of the distribution, on which the kurtosis depends quite sensitively.

For distributions which are only slightly asymmetric, which is usually the case, it is sufficient to solve the above symmetric equations and determine the small parameter β approximately by the skew $s = c_3/\sigma^3$ from the first line in (20.128) as

$$\beta \approx \frac{s}{\kappa_s\sigma_s}. \tag{20.133}$$

This approximation can be improved iteratively by reinserting β into the second equation in (20.127) to determine, from the variance σ^2 of the data, an improved value of σ_s^2 . Then Eq. (20.129) is used to determine from the kurtosis κ of the data an improved value of κ_s , and so on.

For the best fit near the origin where probabilities are large we use the derivatives

$$G(0) = \left(\frac{\delta}{\gamma}\right)^{\lambda-1/2} \zeta^{-\lambda} k_-, \tag{20.134}$$

$$G'(0) = \beta G(0), \tag{20.135}$$

$$G''(0) = -\left(\frac{\delta}{\gamma}\right)^{\lambda-3/2} \zeta^{-\lambda} k_+ + \left(\frac{\delta}{\gamma}\right)^{\lambda-1/2} \delta^{-2} \zeta^{-\lambda} (1 - 2\lambda - \beta^2 \delta^2) k_-,$$

$$G^{(3)}(0) = -\frac{\beta}{2} \left[3 \left(\frac{\delta}{\gamma}\right)^{\lambda-3/2} \zeta^{-\lambda} k_+ + \left(\frac{\delta}{\gamma}\right)^{\lambda-1/2} \delta^{-2} \zeta^{-\lambda} (3 - 6\lambda - \beta^2 \delta^2) \right] k_-, \tag{20.136}$$

where we have abbreviated

$$k_\pm \equiv \frac{1}{\sqrt{2\pi}} \frac{K_{\lambda\pm 1/2}(\delta\gamma)}{K_\lambda(\delta\gamma)}. \tag{20.137}$$

The generalized hyperbolic distributions with $\lambda = 1$ are called *hyperbolic distributions*. The option prices following from these can be calculated by inserting the appropriate parameters into an interactive internet page (see Ref. [51]). Another special case used frequently in the literature is $\lambda = -1/2$ in which case one speaks of a *normal inverse Gaussian distributions* also abbreviated as NIGs.

20.1.12 Debye-Waller Factor for Non-Gaussian Fluctuations

At the end of Section 3.10 we calculated the expectation value of an exponential function $\langle e^{Pz} \rangle$ of a Gaussian variable which led to the Debye-Waller factor of Bragg scattering (3.311). This factor was introduced in solid state physics to describe the reduction of intensity of Bragg peaks due to the thermal fluctuations of the atomic positions. It is derivable from the Fourier representation

$$\langle e^{Pz} \rangle \equiv \int dz \frac{1}{\sqrt{2\pi\sigma^2}} e^{-z^2/2\sigma^2} e^{Pz} = \int dz \int \frac{dp}{2\pi} e^{-\sigma^2 p^2/2} e^{ipz+Pz} = e^{\sigma^2 P^2/2}. \quad (20.138)$$

There exists a simple generalization of this relation to non-Gaussian distributions, which is

$$\langle e^{Pz} \rangle \equiv \int dz \int \frac{dp}{2\pi} e^{-H(p)} e^{ipz+Pz} = e^{-H(iP)}. \quad (20.139)$$

20.1.13 Path Integral for Non-Gaussian Distribution

Let us calculate the properties of the simplest process whose fluctuations are distributed according to any of the general non-Gaussian distributions. We consider the stochastic differential equation for the logarithms of the asset prices

$$\dot{x}(t) = r_x + \eta(t), \quad (20.140)$$

where the noise variable $\eta(t)$ is distributed according to an arbitrary distribution. The constant drift r_x in (20.140) is uniquely defined only if the average of the noise variable vanishes: $\langle \eta(t) \rangle = 0$. The general distributions discussed above can have a nonzero average $\langle x \rangle = c_1$ which has to be subtracted from $\eta(t)$ to identify r_x . The subsequent discussion will be simplest if we imagine r_x to have replaced c_1 in the above distributions, i.e. if the power series expansion of the Hamiltonian (20.54) is replaced as follows:

$$\begin{aligned} H(p) \rightarrow H_{r_x}(p) &\equiv H(p) - H'(0)p + ir_x p \equiv \bar{H}(p) + ir_x p \\ &\equiv ir_x p + \frac{1}{2}c_2 p^2 - i\frac{1}{3!}c_3 p^3 - \frac{1}{4!}c_4 p^4 + i\frac{1}{5!}c_5 p^5 + \dots \end{aligned} \quad (20.141)$$

Thus we may simply work with the original expansion (20.54) and replace at the end

$$c_1 \rightarrow r_x. \quad (20.142)$$

The stochastic differential equation (20.140) can be assumed to read simply

$$\dot{x}(t) = \eta(t). \quad (20.143)$$

With the ultimate replacement (20.142) in mind, the probability distribution of the endpoints $x_b = x(t_b)$ for the paths starting at a certain initial point $x_a = x(t_a)$ is given by a path integral of the form (18.342):

$$P(x_b t_b | x_a t_a) = \int \mathcal{D}\eta \int_{x(t_a)=x_a}^{x(t_b)=x_b} \mathcal{D}x \exp \left[- \int_{t_a}^{t_b} dt \tilde{H}(\eta(t)) \right] \delta[x - \eta]. \quad (20.144)$$

The function $\tilde{H}(\eta)$ is the negative logarithm of the chosen distribution of log-returns [recall (20.13)]

$$\tilde{H}(\eta) = -\log \tilde{D}(\eta). \tag{20.145}$$

For example, $\tilde{H}(\eta)$ is given by $-\log \tilde{L}_{\sigma^2}^{(\lambda, \alpha)}(\eta)$ of Eq. (20.24) for the truncated Lévy distribution or by $-\log \tilde{B}(\eta)$ of Eq. (20.77) or the Boltzmann distributions.

In the mathematical literature, the measure in the path integral over the noise

$$\mathcal{D}\mu \equiv \mathcal{D}\eta P[\eta] = \mathcal{D}\eta e^{-\int_{t_a}^{t_b} dt \tilde{H}(\eta(t))} \tag{20.146}$$

of the probability distribution (20.144) is called the *measure of the process* $\dot{x}(t) = \eta(t)$. The path integral

$$\int_{x(t_a)=x_a}^{x(t_b)=x_b} \mathcal{D}x \delta[\dot{x} - \eta] \tag{20.147}$$

is called the *filter* which determines the distribution of x_b at time t_b for all paths $x(t)$ starting out at x_a at time t_a .

A measure differing from (20.146) only by the drift

$$\mathcal{D}\mu' = \mathcal{D}\eta P[\eta - r] = \mathcal{D}\eta e^{-\int_{t_a}^{t_b} dt \tilde{H}(\eta(t)-r)} \tag{20.148}$$

is called *equivalent measure*. The ratio

$$\mathcal{D}\mu' / \mathcal{D}\mu = e^{-\int_{t_a}^{t_b} [\tilde{H}(\eta-r) - \tilde{H}(\eta)]} \tag{20.149}$$

is called the *Radon-Nikodym derivative*. For a Gaussian noise, this is simply

$$\mathcal{D}\mu' / \mathcal{D}\mu = e^{\int_{t_a}^{t_b} [r\eta(t) - r^2 t/2]}. \tag{20.150}$$

If one wants to calculate the expectation value of any function $f(x(t))$, one has to split the filter into a product

$$\left[\int_{x(t)=x}^{x(t_b)=x_b} \mathcal{D}x \delta[\dot{x} - \eta] \right] \times \left[\int_{x(t_a)=x_a}^{x(t)=x} \mathcal{D}x \delta[\dot{x} - \eta] \right], \tag{20.151}$$

and perform an integral over $f(x)$ with this filter in the path integral (20.146). Going over to the probabilities $P(x_b t_b | x_a t_a)$, we obtain the integral

$$\langle f(x(t)) \rangle = \int dx P(x_b t_b | x t) f(x) P(x t | x_a t_a). \tag{20.152}$$

The correlation functions of the noise variable $\eta(t)$ in the path integral (20.144) are given by a straightforward functional generalization of formulas (20.56). For this purpose, we express the noise distribution $P[\eta] \equiv \exp \left[-\int_{t_a}^{t_b} dt \tilde{H}(\eta(t)) \right]$ in (20.144) as a Fourier path integral

$$P[\eta] = \int \frac{\mathcal{D}p}{2\pi} \exp \left\{ \int_{t_a}^{t_b} dt [ip(t)\eta(t) - H(p(t))] \right\}, \tag{20.153}$$

and note that the correlation functions can be obtained from the functional derivatives

$$\langle \eta(t_1) \cdots \eta(t_n) \rangle = (-i)^n \int \mathcal{D}\eta \int \frac{\mathcal{D}p}{2\pi} \left[\frac{\delta}{\delta p(t_1)} \cdots \frac{\delta}{\delta p(t_n)} e^{i \int_{t_a}^{t_b} dt p(t) \eta(t)} \right] e^{-\int_{t_a}^{t_b} dt H(p(t))}.$$

After n partial integrations, this becomes

$$\begin{aligned} \langle \eta(t_1) \cdots \eta(t_n) \rangle &= i^n \int \mathcal{D}\eta \int \frac{\mathcal{D}p}{2\pi} e^{i \int_{t_a}^{t_b} dt p(t) \eta(t)} \frac{\delta}{\delta p(t_1)} \cdots \frac{\delta}{\delta p(t_n)} e^{-\int_{t_a}^{t_b} dt H(p(t))} \\ &= i^n \left[\frac{\delta}{\delta p(t_1)} \cdots \frac{\delta}{\delta p(t_n)} e^{-\int_{t_a}^{t_b} dt H(p(t))} \right]_{p(t) \equiv 0}. \end{aligned} \tag{20.154}$$

By expanding the exponential $e^{-\int_{t_a}^{t_b} dt H(p(t))}$ in a power series (20.54) we find immediately the lowest correlation functions

$$\langle \eta(t_1) \rangle \equiv Z^{-1} \int \mathcal{D}\eta \eta(t_1) \exp \left[-\int_{t_a}^{t_b} dt \tilde{H}(\eta(t)) \right] = 0, \tag{20.155}$$

$$\begin{aligned} \langle \eta(t_1) \eta(t_2) \rangle &\equiv Z^{-1} \int \mathcal{D}\eta \eta(t_1) \eta(t_2) \exp \left[-\int_{t_a}^{t_b} dt \tilde{H}(\eta(t)) \right] \\ &= c_2 \delta(t_1 - t_2) + c_1^2, \end{aligned} \tag{20.156}$$

$$\begin{aligned} \langle \eta(t_1) \eta(t_2) \eta(t_3) \rangle &\equiv Z^{-1} \int \mathcal{D}\eta \eta(t_1) \eta(t_2) \eta(t_3) \exp \left[-\int_{t_a}^{t_b} dt \tilde{H}(\eta(t)) \right] \\ &= c_3 \delta(t_1 - t_2) \delta(t_1 - t_3) \\ &\quad + c_2 c_1 [\delta(t_1 - t_2) + \delta(t_2 - t_3) + \delta(t_1 - t_3)] + c_1^3, \end{aligned} \tag{20.157}$$

$$\begin{aligned} \langle \eta(t_1) \eta(t_2) \eta(t_3) \eta(t_4) \rangle &\equiv Z^{-1} \int \mathcal{D}\eta \eta(t_1) \eta(t_2) \eta(t_3) \eta(t_4) \exp \left[-\int_{t_a}^{t_b} dt \tilde{H}(\eta(t)) \right] \\ &= c_4 \delta(t_1 - t_2) \delta(t_1 - t_3) \delta(t_1 - t_4) \\ &\quad + c_3 c_1 [\delta(t_1 - t_2) \delta(t_1 - t_3) + 3 \text{ cyclic perms}] \\ &\quad + c_2^2 [\delta(t_1 - t_2) \delta(t_3 - t_4) + \delta(t_1 - t_3) \delta(t_2 - t_4) + \delta(t_1 - t_4) \delta(t_2 - t_3)] \\ &\quad + c_2 c_1^2 [\delta(t_1 - t_2) + 5 \text{ pair terms}] + c_1^4, \end{aligned} \tag{20.158}$$

where

$$Z \equiv \int \mathcal{D}\eta \exp \left[-\int_{t_a}^{t_b} dt \tilde{H}(\eta(t)) \right]. \tag{20.159}$$

The higher correlation functions are obvious generalizations of (20.44). The different contributions on the right-hand side of (20.156)–(20.262) are distinguishable by their connectedness structure.

Note that the term proportional to c_3 in the three-point correlation function (20.158) and the terms proportional to c_3 and to c_4 in the four-point correlation function (20.262) do not obey Wick’s rule (3.305) since they contain contributions caused by the non-Gaussian terms $-ic_3 p^3/3!$ $-c_4 p^4/4!$ in the Hamiltonian (20.141).

20.1.14 Time Evolution of Distribution

The δ -functional in Eq. (20.144) may be represented by a Fourier integral leading to the path integral

$$P(x_b t_b | x_a t_a) = \int \mathcal{D}\eta \int \mathcal{D}x \int \frac{\mathcal{D}p}{2\pi} \exp \left\{ \int_{t_a}^{t_b} dt [ip(t)\dot{x}(t) - ip(t)\eta(t) - \tilde{H}(\eta(t))] \right\}. \quad (20.160)$$

Integrating out the noise variable $\eta(t)$ amounts to performing the inverse Fourier transform of the type (20.24) at each instant of time. Then we obtain

$$P(x_b t_b | x_a t_a) = \int \mathcal{D}x \int \frac{\mathcal{D}p}{2\pi} \exp \left\{ \int_{t_a}^{t_b} dt [ip(t)\dot{x}(t) - H(p(t))] \right\}. \quad (20.161)$$

Integrating over all $x(t)$ with fixed endpoints enforces a constant momentum along the path, and we remain with the single momentum integral

$$P(x_b t_b | x_a t_a) = \int_{-\infty}^{\infty} \frac{dp}{2\pi} \exp [ip(x_b - x_a) - (t_b - t_a)H(p)]. \quad (20.162)$$

Given an arbitrary noise distribution $\tilde{D}(z)$ extracted from the data of a given frequency $1/\Delta t$, we simply identify the Hamiltonian $H(p)$ from the Fourier representation

$$\tilde{D}(z) = \int_{-\infty}^{\infty} \frac{dp}{2\pi} e^{ikz - H(p)}, \quad (20.163)$$

and insert $H(p)$ into (20.170) to find the time dependence of the distribution. The time is then measured in units of the time interval Δt .

For a truncated Lévy distribution, the result is

$$P(x_b t_b | x_a t_a) = \tilde{L}_{\sigma^2(t_b - t_a)}^{(\lambda, \alpha)}(x_b - x_a). \quad (20.164)$$

This is a truncated Lévy distribution of increasing width. The result for other distributions is analogous.

Since the distribution (20.170) depends only on $t = t_b - t_a$ and $x = x_b - x_a$, we shall write it shorter as

$$P(x, t) = \int_{-\infty}^{\infty} \frac{dp}{2\pi} \exp [ipx - tH(p)]. \quad (20.165)$$

20.1.15 Central Limit Theorem

For large t , the distribution $P(x, t)$ becomes more and more Gaussian (see Fig. 20.18 for the Boltzmann distribution). This is a manifestation of the *central limit theorem* of statistical mechanics which states that the convolution of infinitely many arbitrary distribution functions of finite width always approaches a Gaussian distribution. This is easily proved. We simply note that after an integer number t of convolutions,

a probability distribution $\tilde{D}(z)$ with Hamiltonian $H(p)$ has the Fourier components $[D(p)]^t = e^{-tH(p)}$, so that it is given by the integral

$$\tilde{D}(z, t) = \int \frac{dp}{2\pi} e^{ipz} e^{-tH(p)}. \tag{20.166}$$

For large t , the integral can be evaluated in the saddle point approximation (4.51). Denoting the momentum at extremum of the exponent by p_z , which is determined implicitly by $tH'(p_z) = iz$, and setting $\sigma^2 = H''(p_z)$, we obtain the Gaussian distribution

$$\begin{aligned} \tilde{D}(z, t) &\xrightarrow{t \text{ large}} e^{ip_z z - tH(p_z)} \int \frac{dp}{2\pi} e^{i(p-p_z)z - t\sigma^2(p-p_z)^2/2} = \frac{e^{ip_z z - tH(p_z)}}{\sqrt{2\pi\sigma^2}} e^{-z^2/2t\sigma^2} \\ &= \frac{e^{\sigma^2 p_z^2/2 - tH(p_z)}}{\sqrt{2\pi\sigma^2}} e^{-(z - t\sigma^2 p_z)^2/2t\sigma^2}. \end{aligned} \tag{20.167}$$

The same procedure can be applied to the integral (20.165).

The transition from Boltzmann to Gaussian distributions is shown for the S&P 500 index in Fig. 20.15.

If a distribution has a heavy power tail $\propto |z|^{-\lambda-1}$ with $\lambda < 2$, so that the volatility σ is infinite, the Hamiltonian starts out for small p like $|p|^\lambda$, and the saddle point approximation is governed by this term rather than the quadratic term p^2 . For an asymmetric distribution, the leading terms in the Hamiltonian are those of the asymmetric Lévy distribution (20.21) plus a possible linear term irp accounting for a drift, and the asymptotic z -behavior will be given by Eq. (20.17) with an extra factor $(1 + \beta)$ [21].

Figure 20.15 Fits of Gaussian distribution to S&P 500 log-returns recorded in intervals of 60 min, 240 min, and 1 day.

If a distribution has no second moments, the central limit theorem does not apply. Such distributions tend to another limit, the so-called *Pareto-Lévy-stable distribution*. Their Hamiltonian has precisely the generic form (20.21), except for a possible additional linear drift term [21]:

$$H(p) = -irp + H_{\lambda,\sigma,\beta}(p). \tag{20.168}$$

In this context, the Lévy parameter λ is also called the *stability parameter*. The parameter α has to be in the interval $(0, 2]$. The parameter β is called *skewness parameter*. For plots of $\tilde{D}(z, 1)$ see Ref. [75].

The convergence of variable with heavy-tail distributions is the content of the *generalized central limit theorem*.

20.1.16 Additivity Property of Noises and Hamiltonians

At this point we make the useful observation that each term in the Hamiltonian (20.141) can be attributed to an independent noise term in the stochastic differential equation (20.140). Indeed, if this differential equation has two noise terms

$$\dot{x}(t) = r_x + \eta_1(t) + \eta_2(t) \tag{20.169}$$

whose fluctuations are governed by two different Hamiltonians, the probability distribution (20.144) is replaced by

$$P(x_b t_b | x_a t_a) = \int \mathcal{D}\eta_1 \int \mathcal{D}\eta_2 \int \mathcal{D}x \exp \left[- \int_{t_a}^{t_b} dt [\tilde{H}_1(\eta_1(t)) + \tilde{H}_2(\eta_2(t))] \right] \delta[\dot{x} - r_x - \eta_1 - \eta_2].$$

After a Fourier decomposition of the δ -functional, this becomes

$$P(x_b t_b | x_a t_a) = \int \mathcal{D}p_1 \int \mathcal{D}p_2 \int \mathcal{D}\eta_1 \int \mathcal{D}\eta_2 \int \mathcal{D}x \int \mathcal{D}p e^{- \int_{t_a}^{t_b} dt [ip(\dot{x} - r_x - \eta_1 - \eta_2)]} \\ \times \exp \left\{ - \int_{t_a}^{t_b} dt [H_1(p_1) - ip_1 \eta_1(t) + H_2(p_2) - ip_2 \eta_2(t)] \right\},$$

after which the path integrals over $\eta_1(t), \eta_2(t)$ lead to

$$P(x_b t_b | x_a t_a) = \int \mathcal{D}p \int \mathcal{D}x \exp \left\{ \int_{t_a}^{t_b} dt [ip\dot{x} - ir_x p - H_1(p) - H_2(p)] \right\}. \tag{20.170}$$

This is the integral representation Eq. (20.161) with the combined Hamiltonian $H(p) = ir_x p + H_1(p) + H_2(p)$, which can be rewritten as a pure integral (20.170). By rewriting this integral trivially as

$$P(x_b t_b | x_a t_a) = \int_{-\infty}^{\infty} \frac{dp_1}{2\pi} \frac{dp_2}{2\pi} e^{ip_1(x_b - x_c) - (t_b - t_a)[ir_x p + H_1(p_1)]} e^{ip_2(x_c - x_a) - (t_b - t_a)H_2(p_2)} \tag{20.171}$$

we see that the probability distribution associated with a sum of two Hamiltonians is the convolution of the individual probability distributions:

$$P(x_b t_b | x_a t_a) = \int_{-\infty}^{\infty} dx dx_c P_1(x_b t_b | x_c t_a) P_2(x_c t_b | x_a t_a). \tag{20.172}$$

Thus we may calculate the probability distributions associated with the noises $\eta_1(p)$ and $\eta_2(p)$ separately, and combine the results at the end by a convolution.

20.1.17 Lévy-Khintchine Formula

It is sometimes useful to represent the Hamiltonian in the form of a Fourier integral

$$H(p) = \int dz e^{ipz} F(z). \quad (20.173)$$

Due to the special significance of the linear term in $H(p)$ governing the drift, this is usually subtracted out of the integral by rewriting (20.173) as

$$H_r(p) = irp + \int dz (e^{ipz} - 1 - ipz) F(z). \quad (20.174)$$

The first subtraction ensures the property $H_r(0) = 0$ which guarantees the unit normalization of the distribution. This subtracted representation is known as the *Lévy-Khintchine formula*, and the function $F(z)$ is the so-called *Lévy weight* of the distribution. Some people also subtract out the quadratic term and write

$$H_r(p) = irp + \frac{\sigma^2}{2} p^2 + \int dz (e^{ipz} - 1) \bar{F}(z). \quad (20.175)$$

They employ a weight $\bar{F}(z)$ which has no first and second moment, i.e., $\int dz \bar{F}(z)z = 0$, $\int dz \bar{F}(z)z^2 = 0$, to avoid redundancy in the representation.

Note that according to the central limit theorem (20.167), the large-time probability distribution of x will become Gaussian for large t . Thus, in the Lévy-Khintchine decomposition (20.175) of the Hamiltonian $H(p)$, only the first two terms contribute for large t leading to the distribution:

$$P(x, t) \xrightarrow[t \text{ large}]{} \frac{e^{-(x-tr)^2/2t\sigma^2}}{\sqrt{2\pi\sigma^2}}. \quad (20.176)$$

The Lévy measure has been calculated explicitly for many non-Gaussian distributions. As an example, the generalized hyperbolic case has for $\lambda \geq 0$ a Lévy measure [76]

$$F(z) = \frac{e^{\beta z}}{|z|} \left\{ \frac{1}{\pi^2} \int_0^\infty \frac{dy}{y} \frac{e^{-\sqrt{y+\gamma^2}|z|}}{J_\lambda^2(\delta\sqrt{y}) + Y_\lambda^2(\delta\sqrt{y})} + \lambda e^{-\gamma|z|} \right\}, \quad (20.177)$$

where $J_\lambda(z)$ and $Y_\lambda(z)$ are standard Bessel functions.

The decomposition of the Hamiltonian according the Lévy-Khintchine formula and the additivity of the associated noises form the basis of the Lévy-Itô theorem which states that an arbitrary stochastic differential equation with Hamiltonian (20.175) can be decomposed in the form

$$\dot{x} = r_x t + \eta_G + \eta_{\leq 1} + \eta_{> 1}, \quad (20.178)$$

where η_G is a Gaussian noise

$$\eta_{\leq 1} = \int_{|x| \leq 1} dz (e^{ipz} - 1) \bar{F}(z) \quad (20.179)$$

a superposition of discrete noises called Poisson point process with jumps smaller than or equal to unity, and

$$\eta_{> 1} = \int_{|x| > 1} dz (e^{ipz} - 1) \bar{F}(z) \quad (20.180)$$

a noise with jumps larger than unity.

Consider the simplest noise of the type $\eta_{\leq 1}$ arising from a Lévy weight $\bar{F}_Z(z) = \tau_Z \delta(z + Z)$ with $0 < Z \leq 1$ in (20.179) so that the Hamiltonian is $H_Z(p) = \tau_Z (e^{-iZp} - 1)$. The associated distribution function $\tilde{D}_Z(z)$ is, according to (20.11),

$$\tilde{D}_Z(z) = \int \frac{dp}{2\pi} e^{ipz} e^{\tau_Z (e^{-ipZ} - 1)}. \quad (20.181)$$

Expanding the last exponential in powers of e^{ipZ} , we obtain

$$\tilde{D}_Z(z) = \int \frac{dp}{2\pi} e^{ipz} \sum_{n=0}^{\infty} e^{-\tau z} \frac{\tau_Z^n}{n!} \tau_Z^n e^{-ipnZ} = \sum_{n=0}^{\infty} e^{-\tau z} \frac{\tau_Z^n}{n!} \delta(z - nZ). \tag{20.182}$$

This function describes jumps by nZ ($n = 0, 1, 2, 3, \dots$) whose probability follows a *Poisson distribution*

$$P(n, \tau_Z) = e^{-\tau z} \frac{\tau_Z^n}{n!}, \tag{20.183}$$

which is properly normalized to unity: $\sum_{n=0}^{\infty} P(n, \tau_Z) = 1$. The expectation values of powers of the jump number are

$$\langle n^k \rangle = \sum_{n=0}^{\infty} n^k P(n, \tau_Z) = e^{-\tau z} (\tau_Z \partial_{\tau_z})^k e^{\tau z} \sum_{n=0}^{\infty} P(n, \tau_Z) = e^{-\tau z} (\tau_Z \partial_{\tau_z})^k e^{\tau z} = \frac{\Gamma(\lambda_Z + k)}{\Gamma(\lambda_Z)}. \tag{20.184}$$

Thus $\langle n \rangle = \lambda_Z$, $\langle n^2 \rangle = \lambda_Z(\lambda_Z + 1)$, $\langle n^3 \rangle = \lambda_Z(\lambda_Z + 1)(\lambda_Z + 2)$, $\langle n^4 \rangle = \lambda_Z(\lambda_Z + 1)(\lambda_Z + 2)(\lambda_Z + 3)$, so that $\sigma^2 = \lambda_Z$, $s = 2/\sqrt{\lambda_Z}$, and $\kappa = 6/\lambda_Z$.

As typical noise curve is displayed in Fig. 20.16. An arbitrary Lévy weight $\bar{F}(z)$ in $\eta_{\leq 1}$ may

Figure 20.16 Typical Noise of Poisson Process.

always be viewed as a superposition $\bar{F}(z) = \int_{-1}^1 dZ F(Z) \delta(z - Z)$ so that the distribution function becomes a superposition of Poisson noises:

$$\tilde{D}(z) = \int_{-1}^1 dZ F(Z) \sum_{n=0}^{\infty} e^{-\tau z} \frac{\tau_Z^n}{n!} \delta(z - nZ). \tag{20.185}$$

20.1.18 Semigroup Property of Asset Distributions

An important property of the probability (20.144) is that it satisfies the semigroup equation

$$P(x_c t_c | x_a t_a) = \int_{-\infty}^{\infty} dx_b P(x_c t_c | x_b t_b) P(x_b t_b | x_a t_a). \tag{20.186}$$

In the stochastic context this property is referred to as *Chapman-Kolmogorov equation* or *Smoluchowski equation*. It is a general property of processes which a without

memory. Such processes are referred to a *Markovian* [12]. Note that the semigroup property (20.186) implies the initial condition

$$P(x_c t_a | x_a t_a) = \delta(x_b - x_a). \tag{20.187}$$

In Fig. 20.17 we show that the property (20.186) is satisfied reasonably well by experimental asset distributions, except for small deviations in the low-probability tails.

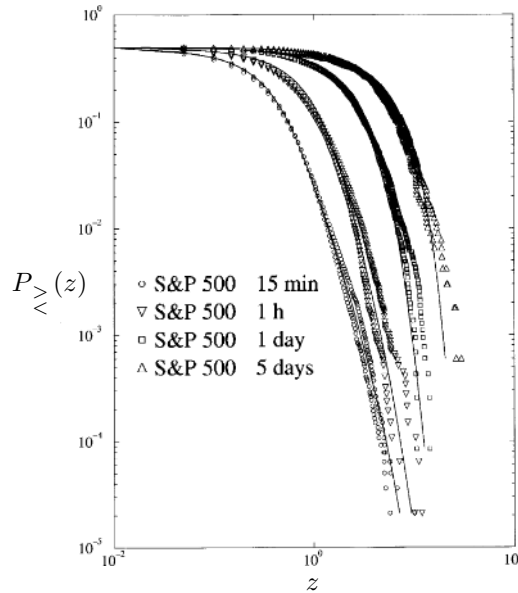

Figure 20.17 Cumulative distributions obtained from repeated convolution integrals of the 15-min distribution (from Ref. [13]). Apart from the far ends of the tails, the semigroup property (20.186) is reasonably well satisfied.

One may verify the semigroup property also using the high-frequency distributions of S&P 500 and NASDAQ 100 indices in Fig. 20.10 recorded by the minute, which display the Boltzmann distribution (20.77). If we convolute the minute distribution an integer number t times, the result agrees very well with the distribution of t -minute data. Only at the heavy tails of rare events do not follow this pattern

Note that due to the semigroup property (20.186) of the probabilities one has the trivial identity

$$\begin{aligned} \langle f(x(t_b), t_b) \rangle &= \int dx_b f(x_b, t_b) P(x_b t_b | x_a t_a) \\ &= \int dx \left[\int dx_b f(x_b, t_b) P(x_b t_b | x t) \right] P(x t | x_a t_a). \end{aligned} \tag{20.188}$$

In the mathematical literature, the expectation value on the left-hand side of Eq. (20.188) is written as

$$\mathbf{E}[f(x(t_b), t_b) | x_a t_a] \equiv \int dx_b f(x_b, t_b) P(x_b t_b | x_a t_a). \tag{20.189}$$

With this notation, the second line can be re-expressed in the form

$$\int dx \mathbf{E}[f(x_b, t_b)|x t]P(x t|x_a t_a) = \mathbf{E}[\mathbf{E}[f(x_b, t_b)|x t]|x_a t_a], \tag{20.190}$$

so that we obtain the property of expectation values

$$\mathbf{E}[f(x(t_b), t_b)|x_a t_a] = \mathbf{E}[\mathbf{E}[f(x_b, t_b)|x t]|x_a t_a]. \tag{20.191}$$

In mathematical finance, this complicated-looking but simple property is called the *towering property* of expectation values.

Note that since $P(x_b t_b|x_a t_a)$ is equal to $\delta(x_b - x_a)$ for $t_a = t_b$, the expectation value (20.189) has the obvious property

$$\mathbf{E}[f(x(t_a), t_a)|x_a t_a] = f(x_a, t_a) \tag{20.192}$$

20.1.19 Time Evolution of Moments of Distribution

From the time-dependent distribution (20.165) it is easy to calculate the time dependence of the moments:

$$\langle x^n \rangle(t) \equiv \int_{-\infty}^{\infty} dx x^n P(x, t) \tag{20.193}$$

Inserting (20.165), we obtain

$$\langle x^n \rangle(t) = \int_{-\infty}^{\infty} \frac{dp}{2\pi} e^{-tH(p)} \int_{-\infty}^{\infty} dx x^n e^{ipx} = \int_{-\infty}^{\infty} dp e^{-tH(p)} (-i\partial_p)^n \delta(p). \tag{20.194}$$

After n partial integrations, this becomes

$$\langle x^n \rangle(t) = (i\partial_p)^n e^{-tH(p)} \Big|_{p=0}. \tag{20.195}$$

All expansion coefficients c_n of $H(p)$ in Eq. (20.141) receive the same factor t , so that the cumulants of the moments all grow linearly in time:

$$\langle x^n \rangle_c(t) = -tH^{(n)}(0) = t\langle x^n \rangle_c(1) = tc_n. \tag{20.196}$$

Figure 20.18 Gaussian distributions of S&P 500 and NASDAQ 100 weekly log-returns.

20.1.20 Boltzmann Distribution

As an example, consider the Boltzmann distribution (20.77) of the minute data. The subsequent time-dependent variance and kurtosis are found by inserting the cumulants Eq. (20.80) into (20.196), yielding

$$\langle x^2 \rangle_c(t) = t 2T^2, \quad \kappa(t) = \frac{c_4}{tc_2^2} = \frac{3}{t}. \quad (20.197)$$

The first increases linearly in time, the second decreases like one over time, which makes the distribution more and more Gaussian, as required by the central limit theorem (20.167). The two quantities are plotted in Figs. 20.19 and 20.20. The agreement with the data is seen to be excellent.

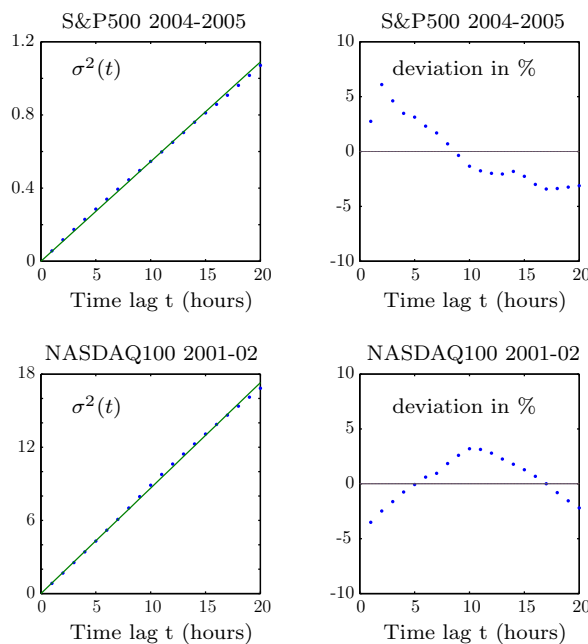

Figure 20.19 Variance of S&P 500 and NASDAQ 100 indices as a function of time. The slopes $\langle x^2 \rangle_c(t)/t$ are roughly $1.1/20 \times 1/60$ min and $18.1/20 \times 1/60$ min, respectively, so that Eq. (20.198) yields the temperatures $T_{\text{SP500}} \approx 0.075$ and $T_{\text{NASDAQ100}} \approx 0.15$. The right-hand side shows the relative deviation from the linear shape in percent.

Note that if the minute data are not available, but only data taken with a frequency $1/t_0$ (in units 1/min) and an expectation $\langle x^2 \rangle_c(t_0)$, then we can find the temperature of the minute distribution from the formula

$$T = \sqrt{\langle x^2 \rangle_c(t_0)/2t_0}. \quad (20.198)$$

Since κ goes to zero like $1/t$, the distribution becomes increasingly Gaussian as the time grows, this being a manifestation of the central limit theorem (20.167) of statistical mechanics according to which the convolution of infinitely many arbitrary distribution functions of finite width always approaches a Gaussian distribution.

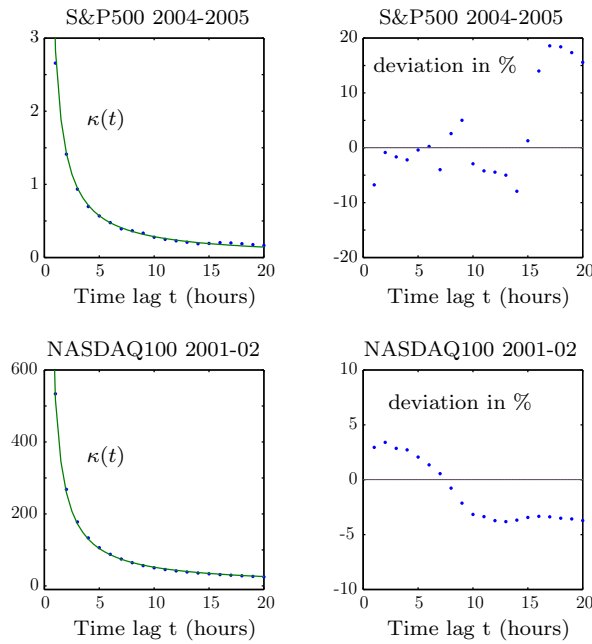

Figure 20.20 Kurtosis of S&P 500 and NASDAQ 100 indices as a function of time. The right-hand side shows the relative deviation from the $1/t$ behavior in percent.

This result is in contrast to the pure Lévy distribution in Subsection 20.1.2 with $\lambda < 2$, which has no finite width and therefore maintains its power falloff at large distances.

If we omit the time argument in the cumulants $\langle x^n \rangle_c(1)$, for brevity, and insert these into the decompositions (20.56) we obtain the time dependence of the moments:

$$\begin{aligned}
 \langle x \rangle(t) &= t \langle x \rangle_c, \\
 \langle x^2 \rangle(t) &= t \langle x^2 \rangle_c + t^2 \langle x \rangle_c^2, \\
 \langle x^3 \rangle(t) &= t \langle x^3 \rangle_c + 3t^2 \langle x \rangle_c \langle x^2 \rangle_c + t^3 \langle x \rangle_c^3, \\
 \langle x^4 \rangle(t) &= t \langle x^4 \rangle_c + 3t^2 \langle x^2 \rangle_c^2 - 4t^2 \langle x \rangle_c \langle x^3 \rangle_c + 6t^3 \langle x \rangle_c^2 \langle x^2 \rangle_c + t^4 \langle x \rangle_c^4, \\
 &\vdots
 \end{aligned}
 \tag{20.199}$$

Let us now calculate the time evolution of the Boltzmann distribution (20.77) of the minute data. The Hamiltonian $H(p)$ was identified in Eq. (20.79), so that

$$e^{-tH(p)} = \frac{1}{[1 + (Tp)^2]^t}.
 \tag{20.200}$$

The time-dependent distribution is therefore given by the Fourier integral

$$P(x, t) = \int_{-\infty}^{\infty} \frac{dp}{2\pi} e^{ipx - tH(p)} = \int_{-\infty}^{\infty} \frac{dp}{2\pi} \frac{1}{(1 + T^2p^2)^t} e^{ipx}.
 \tag{20.201}$$

The calculation proceeds most easily rewriting (20.200), by analogy with (20.81) and using again formula (2.499), as an integral

$$e^{-tH(p)} = \frac{1}{[1 + (Tp)^2]^t} = \frac{1}{\Gamma(t)} \int_0^\infty \frac{d\tau}{\tau} \tau^t e^{-\tau(1+T^2p^2)}. \tag{20.202}$$

The prefactor of p^2 is equal to $t\sigma^2 = tv$ a Gaussian distribution in x -space. We therefore change the variable of integration from τ to v , substituting $\tau = tv/2T^2$, and obtain [compare (20.82)]

$$e^{-tH(p)} = \left(\frac{t}{2T^2}\right)^t \frac{1}{\Gamma(t)} \int_0^\infty \frac{dv}{v} v^t e^{-tv/2T^2} e^{-tv p^2/2}. \tag{20.203}$$

The Fourier transform of this yields the time evolution of the Boltzmann distribution as a time-dependent superposition of Gaussian distributions of different widths [compare (20.83)]:

$$P(x, t) = \left(\frac{t}{2T^2}\right)^t \frac{1}{\Gamma(t)} \int_0^\infty \frac{dv}{v} v^t e^{-tv/2T^2} \frac{1}{\sqrt{2\pi tv}} e^{-x^2/2tv}. \tag{20.204}$$

The integral can be performed using the integral formula (2.559), and we find the time-dependent distribution

$$P(x, t) = \int_{-\infty}^\infty \frac{dp}{2\pi} e^{ipx - tH(p)} = \frac{1}{T\sqrt{\pi}\Gamma(t)} \left(\frac{|x|}{2T}\right)^{t-1/2} K_{t-1/2}(|x|/T), \tag{20.205}$$

where t is measured in minutes.

For $t = 1$, we reobtain the fundamental distribution (20.77), recalling the explicit form of $K_{1/2}(z)$ in Eq. (1.349).

In the limit of large t , the integral over v in (20.204) can be evaluated in the saddle-point approximation of Section 4.2. We expand the weight function in the integrand around the maximum at $v_m = 2T^2(1 - 1/t)$ as

$$v^{t-1} e^{-tv/2T^2} = [2T^2(1 - 1/t)]^{t-1} e^{-(t-1)} e^{-t\delta v^2/2[2T^2(1-1/t)]^2} [1 + \mathcal{O}(\delta v^3)], \tag{20.206}$$

where $\delta v = v - v_m$, and $\mathcal{O}(\delta v^3)$ is equal to $-t\delta v^3/3[2T^2(1 - 1/t)]^3$. Then we observe that for large t , the Gaussian can be expanded into derivatives of δ -functions as follows:

$$e^{-tz^2/2} \left[1 + \frac{a}{3} z^3 + \dots\right] = \sqrt{2\pi/t} \left[\delta(z) + \frac{1}{2t} \delta''(z) + \frac{a}{t^2} \delta'(z) \dots\right]. \tag{20.207}$$

This can easily be verified by multiplying both sides with $f(z) = f(0) + zf'(0) + z^2 f''(0)/2 + \dots$ and integrating over z . Thus we find to leading order

$$e^{-t\delta v^2/2[2T^2(1-1/t)]^2} \rightarrow \sqrt{\frac{2\pi}{t}} 2T^2(1 - 1/t) \delta(\delta v). \tag{20.208}$$

Using the large- t limit $(1 - 1/t)^t \rightarrow e^{-1}$, and including the first correction from (20.207), we obtain

$$v^{t-1} e^{-tv/2T^2} \rightarrow \sqrt{\frac{2\pi}{t}} (2T^2)^t e^{-t} \left\{ \delta(\delta v) + \frac{[2T^2(1 - 1/t)]^2}{2t} \delta''(\delta v) + \dots \right\}. \quad (20.209)$$

If we now employ Stirling's formula (17.286) to approximate $t^t/\Gamma(t) \rightarrow \sqrt{t/2\pi} e^t$, we see that the integral (20.204) converges for large t against the Gaussian distribution $e^{-x^2/2tv_m}/\sqrt{2\pi tv_m}$ with the saddle point variance $v_m \rightarrow 2T^2$.

The behavior near the peak of the distribution can be calculated from the small- z expansion⁷

$$\left(\frac{z}{2}\right)^\nu K_\nu(z) = \frac{\pi}{2 \sin \pi \nu \Gamma(1 - \nu)} \left[1 + \frac{\Gamma(1 - \nu)}{1! \Gamma(2 - \nu)} \frac{z^2}{4} + \mathcal{O}(z^4, z^{2\nu}) \right]. \quad (20.210)$$

For large ν and small z , this can be approximated by [recall (20.29)]

$$\left(\frac{z}{2}\right)^\nu K_\nu(z) \approx \frac{\Gamma(\nu)}{2} e^{-z^2/4(t-3/2)}. \quad (20.211)$$

We now use Stirling's formula (17.286) to find the large- t limit $\Gamma(t - 1/2)/\Gamma(t) \rightarrow 1$, leading to the Gaussian behavior near the peak:

$$P(x, t) \underset{\text{small } |x|}{\approx} \frac{1}{\sqrt{2\pi} 2T^2 t} e^{-x^2/2 2T^2(t-3/2)}. \quad (20.212)$$

This corresponds to the approximation of the Fourier transform (20.200) by $e^{-tT^2 p^2}$. The Gaussian shape reaches out to $x \approx T\sqrt{t}$. For very large t , it holds everywhere, as it should by virtue of the central limit theorem (20.167).

20.1.21 Fourier-Transformed Tsallis Distribution

For the Hamiltonian defined in Eq. (20.97), the time evolution is given by the Fourier transform

$$e^{-tH_{\delta,\beta}(p)} = [1 - \beta\delta p^2/2]^{-t/\delta} = \frac{1}{\Gamma(t/\delta)} \int_0^\infty \frac{ds}{s} s^{t/\delta} e^{-s} e^{-s\beta\delta p^2/2}, \quad \beta \equiv \frac{\nu}{\mu} = \frac{1}{\mu\delta}, \quad (20.213)$$

which can be rewritten, by analogy with (20.99), as

$$e^{-tH_{\delta,\beta}(p)} = \frac{\mu^{t/\delta}}{\Gamma(t/\delta)} \int_0^\infty \frac{dv}{v} v^{t/\delta} e^{-\mu v} e^{-v p^2/2}, \quad \mu = 1/\beta\delta. \quad (20.214)$$

Taking the Fourier transform of this yields the time-dependent distribution function

$$P_{\delta,\beta}(x, t) = \frac{\mu^{t/\delta}}{\Gamma(t/\delta)} \int_0^\infty \frac{dv}{v} v^{t/\delta} e^{-\mu v} \frac{1}{\sqrt{2\pi v}} e^{-x^2/2v}, \quad \mu = 1/\beta\delta, \quad (20.215)$$

⁷M. Abramowitz and I. Stegun, op. cit., Formulas 9.6.2 and 9.6.10.

which becomes with the help of Formula (2.499):

$$P_{\delta,\beta}(x,t) = \frac{\mu^{t/\delta}}{\Gamma(t/\delta)} \frac{1}{\sqrt{2\pi}} \left(\frac{x^2}{2\mu}\right)^{t/2\delta-1/4} 2K_{t/\delta-1/2}(\sqrt{2\mu}x), \quad \mu = \frac{1}{\beta\delta}. \quad (20.216)$$

For $\delta = 1$ and $\mu = 1/2T^2$, this reduces to the time-dependent Boltzmann distribution (20.205). At the origin, its value is [compare (20.104)]

$$P_{\delta,\beta}(0,t) = \sqrt{\mu} \Gamma(t/\delta - 1/2) / \Gamma(t/\delta). \quad (20.217)$$

20.1.22 Superposition of Gaussian Distributions

All time-dependent distributions whose Fourier transforms have the form $e^{-tH(p)}$ possess a path integral representation (20.161) and which obeys the semigroup equation (20.186). In several examples we have seen that the Fourier transforms $e^{-H(p)}$ can be obtained from a superposition of Gaussian distributions of different variances $e^{-vp^2/2}$ with some weight function $w(v)$:

$$e^{-H(p)} = \int_0^\infty dv w(v) e^{-vp^2/2}. \quad (20.218)$$

This was true for the Boltzmann distribution in Eq. (20.81), for the Fourier-transformed Tsallis distribution in Eq. (20.100), and for the Boltzmann Distribution of a relativistic particle in Eq. (20.105). In all these cases it was possible to write a similar superposition for the time-dependent distributions:

$$e^{-tH(p)} = \int_0^\infty dv' w_t(v') e^{-v'p^2/2} = \int_0^\infty dv \omega_t(v) e^{-vp^2/2}, \quad (20.219)$$

where we have introduced the time-dependent weight function

$$\omega_t(v) \equiv t w_t(vt). \quad (20.220)$$

See Eqs. (20.202), (20.214), and (20.105) for the above three cases.

The question arises as to general property of the time dependence of the weight function $w_t(v)$ which ensures that that the Fourier transform of the superposition (20.219) obtained as in Eq. (20.164) satisfies the semigroup condition (20.186) [52]. For this, the superposition has to depend on time as

$$e^{-(t_2+t_1)H(p)} = e^{-t_2H(p)} e^{-t_1H(p)},$$

or $e^{-tH(p)} = [e^{-H(p)}]^t$. This implies that the weight factor $w_t(v)$ has the property

$$\int dv_{12} w_{t_1+t_2}(v_{12}) e^{-v_{12}p^2/2} = \int dv_2 w_{t_2}(v_2) e^{-v_2p^2/2} \int dv_1 w_{t_1}(v_1) e^{-v_1p^2/2}. \quad (20.221)$$

For the Laplace transforms $\tilde{w}_t(p_v)$ of $w_t(v)$

$$\tilde{w}_t(p_v) \equiv \int dv e^{-p_v v} w_t(v) \quad (20.222)$$

this amounts to the factorization property

$$\tilde{w}_{t_1+t_2}(p_v) = \tilde{w}_{t_2}(p_v)\tilde{w}_{t_1}(p_v), \tag{20.223}$$

which is fulfilled by the exponential

$$\tilde{w}_t(p_v) = e^{-tH_v(p_v)}, \tag{20.224}$$

with some Hamiltonian $H_v(p_v)$. Since the integral over v in (20.222) runs only over the positive v -axis, the Hamiltonian $H_v(p_v)$ is analytic in the upper half-plane of p_v .

It is easy to relate $H_v(p_v)$ to $H(p)$. For this we form the inverse Laplace transformation, the so-called *Bromwich integral* [53]

$$w_t(v) = \int_{\gamma-i\infty}^{\gamma+i\infty} \frac{dp_v}{2\pi i} e^{p_v v - tH_v(p_v)}, \tag{20.225}$$

in which γ is some real number larger than the real parts of all singularities in $e^{-p_v v - tH_v(p_v)}$. Inserting this into (20.219) and performing the v -integral yields

$$e^{-tH(p)} = \int_{\gamma-i\infty}^{\gamma+i\infty} \frac{dp_v}{2\pi i} \frac{1}{p^2/2 - p_v} e^{-tH_v(p_v)}. \tag{20.226}$$

Closing the integral over p_v in the complex p_v -plane and deforming the contour to an anticlockwise circle around $p_v = p^2/2$ we find the desired relation:

$$H_v(p^2/2) = H(p). \tag{20.227}$$

The time-dependent distribution associated with any Hamiltonian $H(p)$ via the Fourier integral (20.170) can be represented as a superposition of Gaussian distributions with the help of Eq. (20.219) if we merely choose $H_v(p_v) = H(\sqrt{2p_v})$.

Recalling the derivation of the Fourier representation (20.165) from the path integral (20.153) and the descendance of that path integral from the stochastic differential equation (20.140) with the noise Hamiltonian $H(p)$ we conclude that the Hamiltonian $H_v(ip_v)$ governs the noise in a stochastic differential equation for the volatility fluctuations.

Take, for example, the superposition of Gaussians (20.105). The Laplace transform of the weight function $\omega_\beta(v)$ is

$$\tilde{\omega}_\beta(p_v) = \int dv e^{-vp_v} \omega_\beta(v) = \int dv e^{-vp_v} \sqrt{\frac{\beta}{2\pi v^3}} e^{-\beta/2v} = e^{-\sqrt{2\beta p_v}}. \tag{20.228}$$

The Laplace transform of $w_\beta(v)$ is related to this by

$$\int dv' e^{-v'p_v} w_\beta(v') = \int dv e^{-\beta vp_v} \omega_\beta(v) = \tilde{\omega}_\beta(\beta p_v). \tag{20.229}$$

Hence it is given by $\tilde{w}_\beta(p_v) = e^{-\beta\sqrt{2p_v}} = e^{-\beta H_v(p_v)}$, which satisfies the relation (20.223). Moreover, $H_v(p^2/2)$ is equal to $H(p) = \sqrt{p^2}$, as required by Eq. (20.227) and in accordance with Eq. (20.105) for $M = 0$.

Note that instead of the *Bromwich integral* (20.226) it is sometimes more convenient to use *Post's Laplace inversion formula* [54]

$$\omega_t(v) = \lim_{k \rightarrow \infty} \frac{(-1)^k}{k!} x^{k+1} \left. \frac{\partial^k \tilde{\omega}_t(x)}{\partial x^k} \right|_{x=k/v}. \tag{20.230}$$

20.1.23 Fokker-Planck-Type Equation

From the Fourier representation (20.170) it is easy to prove that the probability satisfies a Fokker-Planck-type equation

$$\partial_t P(x_b t_b | x_a t_a) = -H(-i\partial_x)P(x_b t_b | x_a t_a). \quad (20.231)$$

Indeed, the general solution $\psi(x, t)$ of this differential equation with the initial condition $\psi(x, 0)$ is given by the path integral generalizing (20.144)

$$\psi(x, t) = \int \mathcal{D}\eta \exp \left[- \int_{t_a}^{t_b} dt \tilde{H}(\eta(t)) \right] \psi \left(x - \int_{t_a}^t dt' \eta(t') \right). \quad (20.232)$$

This satisfies the Fokker-Planck-type equation (20.231). To show this, we take $\psi(x, t)$ at a slightly later time $t + \epsilon$ and expand

$$\begin{aligned} \psi(x, t + \epsilon) &= \int \mathcal{D}\eta \exp \left[- \int_{t_a}^{t_b} dt \tilde{H}(\eta(t)) \right] \psi \left(x - \int_{t_a}^t dt' \eta(t') - \int_t^{t+\epsilon} dt' \eta(t') \right). \\ &= \int \mathcal{D}\eta \exp \left[- \int_{t_a}^{t_b} dt \tilde{H}(\eta(t)) \right] \left\{ \psi \left(x - \int_{t_a}^t dt' \eta(t') \right) \right. \\ &\quad - \psi' \left(x - \int_{t_a}^t dt' \eta(t') \right) \int_t^{t+\epsilon} dt' \eta(t') \\ &\quad + \frac{1}{2} \psi'' \left(x - \int_{t_a}^t dt' \eta(t') \right) \int_t^{t+\epsilon} dt_1 dt_2 \eta(t_1) \eta(t_2) \\ &\quad - \frac{1}{3!} \psi''' \left(x - \int_{t_a}^t dt' \eta(t') \right) \int_t^{t+\epsilon} dt_1 dt_2 dt_3 \eta(t_1) \eta(t_2) \eta(t_3) \\ &\quad \left. + \frac{1}{4!} \psi^{(4)} \left(x - \int_{t_a}^t dt' \eta(t') \right) \int_t^{t+\epsilon} dt_1 dt_2 dt_3 dt_4 \eta(t_1) \eta(t_2) \eta(t_3) \eta(t_4) + \dots \right\}. \end{aligned} \quad (20.233)$$

Using the correlation functions (20.155)–(20.262) we obtain

$$\begin{aligned} \psi(x, t + \epsilon) &= \int \mathcal{D}\eta \exp \left[- \int_{t_a}^{t_b} dt \tilde{H}(\eta(t)) \right] \\ &\quad \times \left[-\epsilon c_1 \partial_x + \left(\epsilon c_2 + \epsilon^2 c_1 \right) \frac{1}{2} \partial_x^2 - \left(\epsilon c_3 + 3\epsilon^2 c_2 c_1 \right) \frac{1}{3!} \partial_x^3 \right. \\ &\quad \left. + \left(\epsilon c_4 + \epsilon^2 4c_3 c_1 + \epsilon^2 3c_2^2 + \epsilon^3 c_2 c_1^2 + \epsilon^4 c_1^2 \right) \frac{1}{4!} \partial_x^4 + \dots \right] \psi \left(x - \int_{t_a}^t dt' \eta(t') \right). \end{aligned} \quad (20.234)$$

In the limit $\epsilon \rightarrow 0$, only the linear terms in ϵ contribute, which are all due to the connected parts of the correlation functions of $\eta(t)$. The differential operators in the brackets can now be pulled out of the integral and we find the differential equation

$$\partial_t \psi(x, t) = \left[-c_1 \partial_x + \frac{c_2}{2!} \partial_x^2 - \frac{c_3}{3!} \partial_x^3 + \frac{c_4}{4!} \partial_x^4 + \dots \right] \psi(x, t). \quad (20.235)$$

We now replace $c_1 \rightarrow r_x$ and express using (20.141) the differential operators in brackets as Hamiltonian operator $-H_{r_x}(-i\partial_x)$. This leads to the Schrödinger-like equation [55]

$$\partial_t \psi(x, t) = -H_{r_x}(-i\partial_x) \psi(x, t). \quad (20.236)$$

Due to the many derivatives in $H(i\partial_x)$, this equation is in general non-local. This can be made explicit with the help of the Lévy-Khintchine weight function $F(x)$ in the Fourier representation (20.173). In this case, the right-hand side

$$-H(-i\partial_x)\psi(x, t) = \int dx' e^{-x'\partial_x} F(x')\psi(x, t) = \int dx' F(x')\psi(x - x', t), \quad (20.237)$$

and the Fokker-Planck-like equation (20.236) takes the form of an integro-differential equation. Some people like to use the subtracted form (20.175) of the Lévy-Khintchine formula and arrive at the integro-differential equation

$$\partial_t\psi(x, t) = \left[-c_1\partial_x - \frac{c_2}{2}\partial_x^2\right]\psi(x, t) + \int dx' \bar{F}(x')\psi(x - x', t). \quad (20.238)$$

The integral term can then be treated as a perturbation to an ordinary Fokker-Planck equation.

The initial condition of the probability is, of course, always given by (20.187), as a consequence of the semigroup property (20.186).

20.1.24 Kramers-Moyal Equation

The Fokker-Planck-type equation (20.231) is a special case of the most general time evolution equation satisfied by a probability distribution $P(x_b, t_b, |x_a t_a)$ which fulfills the Chapman-Kolmogorov or Smoluchowski equation (20.186). For a short time interval $t_c - t_b = \epsilon$, that equation can be written as

$$P(x_c t_b + \epsilon | x_a t_a) = \int_{-\infty}^{\infty} dx_b P(x_c t_b + \epsilon | x_b t_b) P(x_b t_b | x_a t_a). \quad (20.239)$$

We now re-express $P(x_c t_b + \epsilon | x_b t_b)$ as a trivial integral

$$P(x_c t_b + \epsilon | x_b t_b) = \int dx \delta(x - x_b + x_b - x_c) P(x t_b + \epsilon | x_b t_b), \quad (20.240)$$

and expand the δ -function in powers of $x - x_b$ to obtain

$$P(x_c t_b + \epsilon | x_b t_b) = \int dx \sum_{n=0}^{\infty} \frac{(x - x_b)^n}{n!} P(x t_b + \epsilon | x_b t_b) \partial_{x_b}^n \delta(x_b - x_c). \quad (20.241)$$

Introducing the moments

$$C_n(x_b t_b) \equiv \int dx (x - x_b)^n \partial_{x_b} P(x t_b | x_b t_b), \quad (20.242)$$

and inserting (20.241) into Eq. (20.239) the right-hand side reads

$$P(x_c t_b | x_b t_b) + \epsilon \sum_{n=1}^{\infty} \int dx_b \frac{C_n(x_b t_b)}{n!} [\partial_{x_b}^n \delta(x_b - x_c)] \partial_{t_b} P(x_b t_b | x_a t_a) + \mathcal{O}(\epsilon^2). \quad (20.243)$$

Taking the $n = 0$ -term to the left-hand side of (20.239) and going to the limit $\epsilon \rightarrow 0$, we obtain the *Kramers-Moyal equation*:

$$\partial_{t_b} P(x_b t_b | x_a t_a) = -H(-i\partial_{x_b}, x_b, t_b) P(x_b t_b | x_a t_a). \quad (20.244)$$

with the Hamiltonian operator

$$H(-i\partial_{x_b}, x_b, t_b) \equiv - \sum_{n=1}^{\infty} (-\partial_{x_b})^n \frac{C_n(x_b t_b)}{n!}, \quad (20.245)$$

which is the generalization of the Hamiltonian operator in Eqs. (20.235) and (20.231).

There is a simple formal solution of the time evolution equation (20.244) with the initial condition (20.187). It can immediately be written down by recalling the similar time evolution equation (1.233):

$$P(x_b t_b | x_a t_a) = \hat{T} e^{-\int_{t_a}^{t_b} dt H(-i\partial_{x_b}, x_b, t)} \delta(x_b - x_a), \quad (20.246)$$

where \hat{T} is the time-ordering operator (1.241). Using Dirac bra-ket states $\langle x_b |$ and $|x_a\rangle$ with the scalar product $\langle x_b | x_a \rangle = \delta(x_b - x_a)$ as in Eq. (18.462), and the rules (18.463), we can rewrite (20.246) as

$$P(x_b t_b | x_a t_a) = \langle x_b | \hat{T} e^{-\int_{t_a}^{t_b} dt H(-i\partial_{x_b}, x_b, t)} | x_a \rangle. \quad (20.247)$$

Due to the initial condition (20.187), the moments (20.242) can also be calculated from the short-time limit

$$C_n(x t) \stackrel{\epsilon \rightarrow 0}{=} \frac{1}{\epsilon} \int dx (x' - x)^n P(x' t + \epsilon | x t) \stackrel{\epsilon \rightarrow 0}{=} \frac{1}{\epsilon} \langle [x(t + \epsilon) - x(t)]^n \rangle, \quad n \geq 1. \quad (20.248)$$

Another way of writing the expectation value on the right-hand side is

$$C_n(x t) \stackrel{\epsilon \rightarrow 0}{=} \frac{1}{\epsilon} \int_t^{t+\epsilon} dt_1 \cdots \int_t^{t+\epsilon} dt_n \langle \dot{x}(t_1) \cdots \dot{x}(t_n) \rangle, \quad n \geq 1. \quad (20.249)$$

If $x(t)$ follows the Langevin equation (20.169) with the correlation functions (20.155)–(20.262), we obtain

$$C_n(x t) = c_n, \quad (20.250)$$

and the Kramers-Moyal equation (20.248) reduces to our previous Fokker-Planck-type equation (20.231).

For a Langevin equation

$$\dot{x}(t) = r(x, t) + \sigma(x, t)\eta(t), \quad (20.251)$$

with a white noise variable $\eta(t)$, we find instead

$$C_1(x t) = a(x, t) + b'(x, t)b(x, t) = a(x, t) + \frac{\partial_x C_2(x t)}{2}, \quad C_2(x t) = b^2(x, t). \quad (20.252)$$

According to a theorem due to Pawula [56], the positivity of the probability in the Kramers-Moyal equation (20.244) requires that the expansion (20.245) can only be truncated after the first or second terms, or must go on to infinity.

20.2 Itô-like Formula for Non-Gaussian Distributions

By a procedure similar to that in Subsection 18.13.3 it is possible to derive a generalization of the Itô-like expansions (18.412) and (18.432) for the fluctuations of functions containing non-Gaussian noise.

20.2.1 Continuous Time

As in (18.408) we expand $f(x(t + \epsilon))$:

$$f(x(t + \epsilon)) = f(x(t)) + f'(x(t))\Delta x(t) + \frac{1}{2}f''(x(t))[\Delta x(t)]^2 + \frac{1}{3!}f^{(3)}(x(t))[\Delta x(t)]^3 + \dots \quad (20.253)$$

where $\dot{x}(t) = \eta(t)$ is the stochastic differential equation with a nonzero expectation value $\langle \eta(t) \rangle = c_1$. In contrast to the expansion (18.426), which for $\epsilon \rightarrow 0$ had to be carried only up to the second order in $\Delta x(t) \equiv \int_t^{t+\epsilon} dt' \dot{x}(t')$, we must now keep *all* orders. Evaluating the noise averages of the multiple integrals on the right-hand side with the help of the correlation functions (20.155)–(20.262), we find the time dependence of the expectation value of an arbitrary function of the fluctuating variable $x(t)$

$$\begin{aligned} \langle f(x(t+\epsilon)) \rangle &= \langle f(x(t)) \rangle + \langle f'(x(t)) \rangle \epsilon c_1 + \frac{1}{2} \langle f''(x(t)) \rangle (\epsilon c_2 + \epsilon^2 c_1^2) \\ &\quad + \frac{1}{3!} \langle f^{(3)}(x(t)) \rangle (\epsilon c_3 + \epsilon^2 c_2 c_1 + \epsilon^3 c_1^3) + \dots \quad (20.254) \\ &= \langle f(x(t)) \rangle + \epsilon \left[c_1 \partial_x + c_2 \frac{1}{2} \partial_x^2 + c_3 \frac{1}{3!} \partial_x^3 + \dots \right] \langle f(x(t)) \rangle + \mathcal{O}(\epsilon^2). \end{aligned}$$

After the replacement $c_1 \rightarrow r_x$, the function $f(x(t))$ obeys therefore the following equation:

$$\dot{\langle f(x(t)) \rangle} = -H_{r_x}(i\partial_x) \langle f(x(t)) \rangle. \quad (20.255)$$

Separating the lowest-derivative term, this takes a form generalizing Eq. (18.412):

$$\dot{\langle f(x(t)) \rangle} = \langle f'(x(t)) \rangle \langle \dot{x}(t) \rangle - \bar{H}_{r_x}(i\partial_x) \langle f(x(t)) \rangle. \quad (20.256)$$

This might be viewed as the expectation value of the stochastic differential equation

$$\dot{f}(x(t)) = f'(x(t))\dot{x}(t) - \bar{H}_{r_x}(i\partial_x)f(x(t)), \quad (20.257)$$

which, if valid, would be a simple direct generalization of Itô's Lemma (18.413). However, this conclusion is not allowed. The reason lies in the increased size of the fluctuations of the higher expansion terms $[\Delta x(t)]^n$ for $n \geq 2$. In the harmonic case of Subsection 18.13.3, these were negligible in comparison with the leading term $z_1(t)$ in Eq. (18.413). Let us see what happens in the present case, where all higher

cumulants c_n in the Hamiltonian (20.141) may be nonzero. For the argument we proceed as in Eq. (18.405) by working with the stochastic differential equation

$$\dot{x}(t) = \langle \dot{x}(t) \rangle + \eta(t) = c_1 + \eta(t). \tag{20.258}$$

rather than (20.169). Then the correlation functions of $\eta(t)$ consist only of the connected parts of (20.155)–(20.262):

$$\langle \eta(t_1) \rangle = c_1, \tag{20.259}$$

$$\langle \eta(t_1)\eta(t_2) \rangle = c_2\delta(t_1 - t_2) \tag{20.260}$$

$$\langle \eta(t_1)\eta(t_2)\eta(t_3) \rangle = c_3\delta(t_1-t_2)\delta(t_1-t_3), \tag{20.261}$$

$$\langle \eta(t_1)\eta(t_2)\eta(t_3)\eta(t_4) \rangle = c_4\delta(t_1-t_2)\delta(t_1-t_3)\delta(t_1-t_4) \tag{20.262}$$

$$+ c_2^2[\delta(t_1-t_2)\delta(t_3-t_4) + \delta(t_1-t_3)\delta(t_2-t_4) + \delta(t_1-t_4)\delta(t_2-t_3)].$$

⋮

We now estimate the size of the fluctuations z_n of $[\Delta x(t)]^n$. The first contribution $z_{2,1}$ to z_2 defined in Eq. (18.415) is still negligible since it is smaller than the leading one $z_1(t) \equiv \int_t^{t+\epsilon} dt' \eta(t')$ by a factor ϵ . The second contribution $z_{2,3}$ to z_2 defined in Eq. (18.415), however, has now a larger variance, due to the c_4 -term in (20.262), which contains one more δ -function than the c_2^2 -term, so that

$$\langle [z_{2,2}(t)]^2 \rangle = \int_t^{t+\epsilon} dt_1 \int_t^{t+\epsilon} dt_2 \int_t^{t+\epsilon} dt_3 \int_t^{t+\epsilon} dt_4 \langle \eta(t_1)\eta(t_2)\eta(t_3)\eta(t_4) \rangle = \epsilon c_4 + \epsilon^2 c_2^2. \tag{20.263}$$

This is larger than the harmonic estimate (18.420) by a factor $1/\epsilon$, which makes $z_{2,2}(t)$, in general, as large as the leading fluctuation $z_1(t)$ of $x_1(t)$. It can therefore *not* be ignored. The subtraction of the second term $\langle z_{2,2}(t) \rangle^2 = \epsilon^2 c_2^2$ in the variance does not help since that is ignorable.

A similar estimate holds for the higher powers. Take for instance $[\Delta x(t)]^3$:

$$[\Delta x(t)]^3 = \epsilon^3 c_1^3 + 3\epsilon^2 c_1^2 z_1(t) + \epsilon c_1 [z_1(t)]^2 + [z_1(t)]^3, \tag{20.264}$$

and calculate the variance of the strongest fluctuating last term in this: $\langle \{[z_1(t)]^3\}^2 \rangle - \langle [z_1(t)]^3 \rangle^2$. The first contribution is equal to

$$\int_t^{t+\epsilon} dt_1 \int_t^{t+\epsilon} dt_2 \int_t^{t+\epsilon} dt_3 \int_t^{t+\epsilon} dt_4 \int_t^{t+\epsilon} dt_5 \int_t^{t+\epsilon} dt_6 \langle \eta(t_1)\eta(t_2)\eta(t_3)\eta(t_4)\eta(t_5)\eta(t_6) \rangle, \tag{20.265}$$

and becomes, after an obvious extension of the expectation values (20.155)–(20.262) to the six-point function:

$$\langle \{[z_1(t)]^3\}^2 \rangle = \epsilon c_6 + \mathcal{O}(\epsilon^2). \tag{20.266}$$

The second contribution $\langle [z_1(t)]^3 \rangle^2$ in (20.264) is equal to $\epsilon^2 c_3^2$ and can be ignored for $\epsilon \rightarrow 0$. Thus, due to (20.266), the size of the fluctuations $[z_1(t)]^3$ is of the same order as of the leading one $x_1(t)$ [compare again (18.421)].

This is an important result which is the reason why we cannot derive a direct generalization (20.257) of the Itô formula (18.413) to non-Gaussian fluctuations, but only the weaker formula (20.256) for the expectation value.

For an exponential function $f(x) = e^{Px}$ this implies the relation

$$\frac{d}{dt}\langle e^{Px(t)} \rangle = [P\langle \dot{x}(t) \rangle - \bar{H}_{r_x}(iP)] \langle e^{Px(t)} \rangle, \quad (20.267)$$

and it is not allowed to drop the expectation values.

A consequence of the weaker Eq. (20.267) for $P = 1$ is that the rate r_S with which the average of the stock price $S(t) = e^{x(t)}$ grows is given by formula (20.1), where the rate r_x is related to r_S by

$$r_S = r_x - \bar{H}(i) = r_x - [H(i) - iH'(0)] = -H_{r_x}(i), \quad (20.268)$$

which replaces the simple Itô relation $r_S = r_x + \sigma^2/2$ in Eq. (20.5). Recall the definition of $\bar{H}(p) \equiv H(p) - H'(0)p$ in Eq. (20.141). The corresponding version of the left-hand part of Eq. (20.4) reads

$$\left\langle \frac{\dot{S}}{S} \right\rangle = \langle \dot{x}(t) \rangle - \bar{H}(i) = \langle \dot{x}(t) \rangle - [H(i) - iH'(0)] = \langle \dot{x}(t) \rangle - r_x - H_{r_x}(i). \quad (20.269)$$

The forward price of a stock must therefore be calculated with the generalization of formula (20.8), in which we assume again $\eta(t)$ to fluctuate around zero rather than r_x :

$$\langle S(t) \rangle = S(0)e^{r_S t} = S(0)\langle e^{r_x t + \int_0^t dt' \eta(t')} \rangle = S(0)e^{-H_{r_x}(i)t} = S(0)e^{\{r_x t - [H(i) - iH'(0)]t\}}. \quad (20.270)$$

If $\eta(t)$ fluctuates around r_x this takes the simpler form

$$\langle S(t) \rangle = S(0)e^{r_S t} = S(0)\langle e^{\int_0^t dt' \eta(t')} \rangle = S(0)e^{-H_{r_x}(i)t}. \quad (20.271)$$

This result may be viewed as a consequence of the following generalization of the Gaussian Debye-Waller factor (18.425):

$$\left\langle e^{P \int_0^t dt' \eta(t')} \right\rangle = e^{-H_{r_x}(iP)t}. \quad (20.272)$$

Note that we may derive the differential equation (20.255) of an arbitrary function $f(x(t))$ from a simple mnemonic rule, expanding sloppily [similar to Eq. (18.426) but restricted to the expectation values]

$$\begin{aligned} \langle f(x(t+dt)) \rangle &= \langle f(x(t)) \rangle + \langle f'(x(t)) \rangle \langle \dot{x}(t) \rangle dt + \frac{1}{2} \langle f''(x(t)) \rangle \langle \dot{x}^2(t) \rangle dt^2 \\ &+ \frac{1}{3!} \langle f^{(3)}(x(t)) \rangle \langle \dot{x}^3(t) \rangle dt^3 + \dots, \end{aligned} \quad (20.273)$$

and replacing

$$\langle \dot{x}(t) \rangle dt \rightarrow c_1 dt, \quad \langle \dot{x}^2(t) \rangle dt^2 \rightarrow c_2 dt, \quad \langle \dot{x}^3(t) \rangle dt^3 \rightarrow c_3 dt, \dots \quad (20.274)$$

In contrast to Eq. (18.429), this replacement holds now only on the average.

For the same reason, portfolios containing assets with non-Gaussian fluctuations cannot be made risk-free in the continuum limit $\epsilon \rightarrow 0$, as will be seen in Section 20.7.

20.2.2 Discrete Times

The prices of financial assets are recorded in the form of a discrete time series $x(t_n)$ in intervals $\Delta t = t_{n+1} - t_n$, rather than the continuous function $x(t)$. For stocks with a large turnover, or for market indices, the smallest time interval is typically $\Delta t = 1$ minute. We have seen at the end of Section 18.13.3 that this makes Itô's Lemma (18.413) an approximate statement. Without the limit $\Delta t \rightarrow 0$, the fluctuations of the higher expansion terms in (20.253) no longer disappear but are merely suppressed by a factor $\sigma\sqrt{\Delta t_n}$. In quiet economic periods this is usually quite small for $\Delta t = 1$ minute, so that the higher-order fluctuations can usually be neglected after all.

While this approximate validity is a disadvantage of the discrete time series over the continuous one, it is an advantage with respect to processes with non-Gaussian noise, at least as long as the financial markets are not in turmoil. Then the non-Gaussian higher-order fluctuations of the expansion terms in (20.253) are suppressed by the same order $\sigma\sqrt{\Delta t}$ as the corrections to Itô's rule in the Gaussian case [recall (18.432)]. As a typical example, take the Boltzmann distribution (20.77). Its cumulants c_n carry a factor T^n [see Eq. (20.80)] where the market temperature T is a small number of the order of a few percent in the natural time units of one minute used in this context [see Fig. (20.11)]. The smallness of T is, of course, a consequence that the minute data do not usually possess large volatility, except near a crash. In the natural units of minutes, the time interval ϵ in the calculations after Eq. (20.257) is unity, so that powers of ϵ can no longer be used for size estimates. This role is now taken over by T . In fact, since c_n is of order T^n , the fluctuations of $z_n(t)$ are of the order T^n . Thus, in non-Gaussian fluctuations of a discrete time series, the smallness of T leads to a suppression of the higher fluctuations after all. Moreover, the suppression is just as good as for time series with Gaussian fluctuations, where the corrections are of the order $(\sigma\sqrt{\Delta t})^{n-1}$ for $z_n(t)$ with $n \geq 2$. These have the size of T^{n-1} for the Boltzmann distribution [recall (20.198)]. A similar estimate holds for all non-Gaussian noise distributions with semi-heavy tails as defined on at the end of Subsection 20.1.1.

For all semi-heavy tails for which the cumulants c_n decrease with power T^n of a small parameter such as the temperature T , we may drop the expectations values of the Itô-like expansion (20.256), and remain with an approximate Itô formula for the fluctuating difference $\Delta f(x(t_n)) \equiv f(x(t_{n+1}))$:

$$\Delta f(x(t_n)) = f'(x(t_n))\Delta x(t_n) - \bar{H}_{r_x}(i\partial_x)f(x(t_n)) + \mathcal{O}(\sigma\sqrt{\Delta t}), \quad (20.275)$$

which is a direct generalization of the discrete version (18.432) of Itô's Lemma (18.413).

A characteristic property of the Boltzmann distribution (20.77) and others with semi-heavy tails is that their Hamiltonian possesses a power series in p^2 of the type (20.141) with finite cumulants c_n of the order of σ^n , where σ is the volatility of the minute data. This property is violated only by power tails of price distributions which do exist in the data (see Fig. 20.10). These do not go away upon multiple

convolution which turns the Boltzmann distribution more and more into a Gaussian as required by the central limit theorem (20.167). These heavy tails are caused by drastic price changes in short times observed in nervous markets near a crash. If these are taken into account, the discrete version (18.432) of Itô's Lemma (18.413) is no longer valid. This will be an obstacle to setting up a risk-free portfolio in Section 20.7.

20.3 Martingales

In financial mathematics, an often-encountered concept is that of a *martingale*. The name stems from a casino strategy in which a gambler doubles his stake each time a bet is lost. A stochastic variable $m(t)$ is called a martingale, if its expectation value is time-independent.

A trivial martingale is provided by any noise variable $m(t) = \eta(t)$.

20.3.1 Gaussian Martingales

For a harmonic noise variable, the exponential $m(t) = e^{\int_0^t dt' \eta(t') - \sigma^2 t/2}$ is a nontrivial martingale, due to Eq. (20.8). For the same reason, a stock price $S(t) = e^{x(t)}$ with $x(t)$ obeying the stochastic differential equation (20.140) can be made a martingale by a time-dependent multiplicative factor associated with the average growth rate r_S , i.e.,

$$e^{-r_S t} S(t) = e^{-r_S t} e^{x(t)} = e^{-r_S t} e^{r_S t + \int^t dt' \eta(t')} \quad (20.276)$$

is a martingale. The prefactor $e^{-r_S t}$ is referred to as a *discount factor* with the rate r_S . If we calculate the probability distribution (20.170) associated with the stochastic differential equation (20.140), which for harmonic fluctuations of standard deviation σ corresponds to a Hamiltonian

$$H(p) = ir_x p + \frac{\sigma^2}{2} p^2, \quad (20.277)$$

The integral representation (20.170) for the probability distribution,

$$P^{r_x}(x_b t_b | x_a t_a) = \int_{-\infty}^{\infty} \frac{dp}{2\pi} \exp \left[ip(x_b - x_a) - \Delta t \left(ir_x p + \sigma^2 p^2 / 2 \right) \right] \quad (20.278)$$

with $\Delta t = t_b - t_a$ has obviously a time-independent expectation value of $e^{-r_S t} S(t) = e^{-r_S t} e^{x(t)}$. Indeed, the expectation value at the time t_b is given by the integral over x_b

$$e^{-r_S t_b} \int dx_b e^{x_b} P^{r_x}(x_b t_b | x_a t_a) = e^{-r_S t_b} \int dx_b e^{x_b} \int_{-\infty}^{\infty} \frac{dp}{2\pi} \exp \left[ip(x_b - x_a) - \Delta t \sigma^2 p^2 / 2 \right],$$

which yields

$$e^{-r_S t_b} \int_{-\infty}^{\infty} \frac{dp}{2\pi} \delta(p - i) e^{-ipx_a} e^{\Delta t \sigma^2 p^2 / 2} = e^{-r_S t} e^{x_a} e^{(r_x - \sigma^2 / 2) \Delta t} = e^{-r_S t_a} e^{x_a}, \quad (20.279)$$

where we have used the Itô relation $r_S = r_x + \sigma^2/2$ of Eq. (20.5). The result implies that

$$\langle e^{-rs t_b} S(t_b) \rangle^{r_x} = \langle e^{-rs t_b} e^{x(t_b)} \rangle^{r_x} = e^{-rs t_a} S(t_a). \tag{20.280}$$

Since this holds for all t_b we may drop the subscripts b , thus proving the time independence and thus the martingale nature of $e^{-rs t} S(t)$.

In mathematical finance, where the expectation value in Eq. (20.280) is written according to the definition (20.189) as $\mathbb{E}[e^{-rs(t_b-t_a)} e^{x_b} | x_a t_a]$, the martingale property of $e^{-rs(t_b-t_a)} S(t)$ is expressed as

$$\mathbb{E}[e^{-rs(t_b-t_a)} S(t_b) | x_a t_a] = S(t_a) \tag{20.281}$$

or as $\mathbb{E}[e^{-rs(t_b-t_a)} e^{x_b} | x_a t_a] = e^{x_a}$.

For the martingale $f(x_b, t_b) = e^{-rs(t_b-t_a)} e^{x_b}$, the expectation values on the right-hand side of the towering formula (20.191) reduces with the help of (20.281) and (20.192) to

$$\mathbb{E}[\mathbb{E}[f(x_b, t_b) | x t] | x_a t_a] = \mathbb{E}[\mathbb{E}[f(x, t) | x t] | x_a t_a] = \mathbb{E}[f(x, t) | x_a t_a]. \tag{20.282}$$

Using once more the relations (20.281) and (20.192) to leads to

$$\mathbb{E}[\mathbb{E}[f(x_b, t_b) | x t] | x_a t_a] = f(x_a, t_a). \tag{20.283}$$

Performing the momentum integral in (20.278) gives the explicit distribution

$$P^{r_x}(x_b t_b | x_a t_a) \equiv \frac{1}{\sqrt{2\pi\sigma^2(t_b - t_a)}} \exp \left\{ -\frac{[x_b - x_a - r_x(t_b - t_a)]^2}{2\sigma^2(t_b - t_a)} \right\}. \tag{20.284}$$

We may incorporate the discount factor $e^{-rs(t_b-t_a)}$ into the probability distribution (20.284) and define a martingale distribution for the stock price

$$P^{(M,r_x)}(x_b t_b | x_a t_a) = e^{-rs(t_b-t_a)} P^{r_x}(x_b t_b | x_a t_a), \tag{20.285}$$

whose normalization falls off like $e^{-rs(t_b-t_a)}$. If we define expectation values with respect to $P^{M,r_x}(x_b t_b | x_a t_a)$ by the integral (without normalization)

$$\langle f(x_b) \rangle^{(M,r_x)} \equiv \int dx_b f(x_b) P^{(M,r_x)}(x_b t_b | x_a t_a), \tag{20.286}$$

then the stock price itself is a martingale:

$$\langle e^{x_b} \rangle^{(M,r_x)} = e^{x_a}. \tag{20.287}$$

Note that there exists an entire family of equivalent martingale distributions

$$P^{(M,r)}(x_b t_b | x_a t_a) = e^{-r\Delta t} \int_{-\infty}^{\infty} \frac{dp}{2\pi} \exp [ip(x_b - x_a) - \Delta t H_r(p)], \tag{20.288}$$

with an *arbitrary* rate r and $r_x \equiv r + \bar{H}(i)$. Indeed, multiplying this with e^{x_b} and integrating over x_b gives rise to a δ -function $\delta(p - i)$ and produces the same result e^{x_a} for any time difference $\Delta t = t_b - t_a$. Performing the integral yields

$$P^{(M,r)}(x_b t_b | x_a t_a) \equiv \frac{e^{-r(t_b-t_a)}}{\sqrt{2\pi\sigma^2(t_b - t_a)}} \exp \left\{ -\frac{[x_b - x_a - r(t_b - t_a)]^2}{2\sigma^2(t_b - t_a)} \right\}. \tag{20.289}$$

These martingale distributions are called *risk-neutral*.

20.3.2 Non-Gaussian Martingale Distributions

For $S(t) = e^{x(t)}$ with an arbitrary non-Gaussian noise $\eta(t)$, there are many ways of constructing distributions which make the stock price a martingale.

Natural Martingale Distribution

The relation (20.268) allows us to write down immediately the simplest martingale distribution. It is given by an obvious generalization of the Gaussian expression (20.276):

$$e^{-r_S t} S(t) = e^{-r_S t} e^{r_x t + \int_0^t dt' \eta(t')} \quad (20.290)$$

where r_S and r_x are related by $r_S = r_x - \bar{H}(i) = -H_{r_x}(i)$. It is easy to prove this. The distribution function associated with the stochastic differential equation (20.140) with non-Gaussian fluctuations is given by

$$P^{r_x}(x_b t_b | x_a t_a) = \int \mathcal{D}\eta \int \mathcal{D}x \exp \left\{ - \int_{t_a}^{t_b} dt \tilde{H}_{r_x}(\eta(t)) \right\} \delta[\dot{x} - r_x(t_b - t_a)\eta], \quad (20.291)$$

where $\Delta t \equiv (t_b - t_a)$ and $r_x = r_S + \bar{H}(i)$. As explained in Subsection 20.1.23, the path integral is solved by the Fourier integral [compare (20.170)]

$$P^{r_x}(x_b t_b | x_a t_a) = \int_{-\infty}^{\infty} \frac{dp}{2\pi} \exp [ip(x_b - x_a) - \Delta t H_{r_x}(p)]. \quad (20.292)$$

Using this distribution we can again calculate the time independence of the expectation value (20.280), so that $P^{M, r_x}(x_b t_b | x_a t_a) = e^{-r_S(t_b - t_a)} P^{r_x}(x_b t_b | x_a t_a)$ is a martingale distribution which makes the stock price time-independent, as in Eq. (20.287).

Note that there exists an entire family of equivalent martingale distributions

$$P^{(M, r)}(x_b t_b | x_a t_a) = e^{-r \Delta t} \int_{-\infty}^{\infty} \frac{dp}{2\pi} \exp [ip(x_b - x_a) - \Delta t H_{r_x}(p)], \quad (20.293)$$

with an *arbitrary* rate r and $r_x \equiv r + \bar{H}(i)$. Indeed, multiplying this with e^{x_b} and integrating over x_b gives rise to a δ -function $\delta(p - i)$ and produces the same result e^{x_a} for any time difference $\Delta t = t_b - t_a$.

For non-Gaussian fluctuations there exists an infinite set martingale distributions for the stock price of which we are now going to discuss the one proposed by Esscher.

Esscher Martingales

In the literature on mathematical finance, much attention is paid to another family of equivalent martingale distributions. It has been used a long time ago to estimate risks of actuaries [67] and introduced more recently into the theory of option prices [68, 69] where it is now of wide use [70]–[76]. This family is constructed as follows. Let $\tilde{D}(z)$ be an arbitrary distribution function with a Fourier transform

$$\tilde{D}(z) = \int_{-\infty}^{\infty} \frac{dp}{2\pi} e^{-H(p)} e^{ipz}, \quad (20.294)$$

and $H(0) = 0$, to guarantee a unit normalization $\int dz \tilde{D}(z) = 1$. We now introduce an *Esscher-transformed* distribution function. It is obtained by slightly tilting the initial distribution $\tilde{D}(z)$, multiplying it with an asymmetric exponential factor $e^{\theta z}$:

$$D^\theta(z) \equiv e^{H(i\theta)} e^{\theta z} \tilde{D}(z). \quad (20.295)$$

The constant prefactor $e^{H(i\theta)}$ is necessary to conserve the total probability. This distribution can be written as a Fourier transform

$$D^\theta(z) = \int_{-\infty}^{\infty} \frac{dp}{2\pi} e^{-H^\theta(p)} e^{ipz}, \quad (20.296)$$

with the Esscher-transformed Hamiltonian

$$H^\theta(p) \equiv H(p + i\theta) - H(i\theta). \quad (20.297)$$

Since $H^\theta(0) = 0$, the transformed distribution is properly normalized: $\int dz D^\theta(z) = 1$. We now define the Esscher-transformed expectation value

$$\langle F(z) \rangle^\theta \equiv \int dz D^\theta(z) F(z). \quad (20.298)$$

It is related to the original expectation value by

$$\langle F(z) \rangle^\theta \equiv e^{H(i\theta)} \langle e^{\theta z} F(z) \rangle. \quad (20.299)$$

For the specific function $F(z) = e^z$, Eq. (20.299) becomes

$$\langle e^z \rangle^\theta = e^{-H^\theta(i)} \equiv e^{H^\theta(i\theta)} \langle e^{(\theta+1)z} \rangle = e^{H^\theta(i\theta) - H^\theta(i\theta+i)}. \quad (20.300)$$

Applying the transformation (20.296) to each time slice in the general path integral (20.144), we obtain the *Esscher-transformed* path integral

$$P^\theta(x_b t_b | x_a t_a) = e^{-r_S \Delta t} e^{H_{r_x}(i\theta) \Delta t} \int \mathcal{D}\eta \int \mathcal{D}x \exp \left\{ \int_{t_a}^{t_b} dt [\theta \eta(t) - \tilde{H}_{r_x}(\eta(t))] \right\} \delta[x - \eta], \quad (20.301)$$

where $\Delta t \equiv t_b - t_a$ is the time interval. This leads to the Fourier integral [compare (20.293)]

$$P^\theta(x_b t_b | x_a t_a) = e^{-r_S \Delta t} e^{H_{r_x}(i\theta) \Delta t} \int_{-\infty}^{\infty} \frac{dp}{2\pi} \exp [ip(x_b - x_a) - \Delta t H_{r_x}(p + i\theta)]. \quad (20.302)$$

Let us denote the expectation values calculated with this probability by $\langle \dots \rangle^\theta$. Then we find for $S(t) = e^{x(t)}$ the time dependence

$$\langle S(t) \rangle^\theta = e^{-H_{r_x}^\theta(i)t}. \quad (20.303)$$

This equation shows that the exponential of a stochastic variable $x(t)$ can be made a martingale with respect to any Esscher-transformed distribution if we remove the exponential growth factor $\exp(r^\theta \Delta t)$ with

$$r^\theta \equiv -H_{r_x}^\theta(i) = -H_{r_x}(i + i\theta) + H_{r_x}(i\theta). \quad (20.304)$$

Thus, a family of equivalent martingale distributions for the stock price $S(t) = e^{x(t)}$ is

$$P^{M\theta}(x_b t_b | x_a t_a) \equiv e^{-r^\theta t} P^\theta(x_b t_b | x_a t_a), \quad (20.305)$$

for any choice of the parameter θ .

For a harmonic distribution function (20.284), the Esscher martingales and the previous ones are equivalent. Indeed, starting from (20.284) in which $r_S = r_x + \sigma^2/2$, the Esscher transform leads, after a quadratic completion, to the family of natural martingales (20.284) with the rate parameter $r = r_x + \theta\sigma^2$.

Other Non-Gaussian Martingales

Many other non-Gaussian martingales have been discussed in the literature. Mathematicians have invented various sophisticated criteria under which one would be preferable over the others for calculating financial risks. Davis, for instance, has introduced a so-called *utility function* [77] which is supposed to select optimal martingales for different purposes. There exists also a so-called minimal martingale [83], but the mathematical setup in these discussions is hard to understand.

For the upcoming development of a theory of option pricing, only the initial *natural martingale* will be relevant.

20.4 Origin of Semi-Heavy Tails

We have indicated at the end of Subsection 20.1.1 that semi-heavy tails of the type used in the previous discussions may be viewed as a phenomenological description of a nontrivial Gaussian process with fluctuating volatility. This has been confirmed in Subsection 20.1.22 where we have expressed a number of non-Gaussian distributions as a superposition of Gaussian distributions. We have further seen that the weight functions $w_t(v)$ for the superpositions can be Laplace-transformed to find a Hamiltonian $H_v(p_v)$ from which we can derive which governs the noise distribution a stochastic differential equation for the volatility whose noise distribution is which governed by $H_v(ip_v)$.

There exist a simple solvable model due to Heston [78] which shows this explicitly.⁸

⁸The discussion in this section follows a paper by Drăgulescu and Yakovenko [79].

20.4.1 Pair of Stochastic Differential Equations

Starting point is a coupled pair of ordinary stochastic differential equations with Gaussian noise, one for the fluctuating logarithm $x(t)$ of the stock price, and one for the fluctuating time-dependent variance $\sigma^2(t)$. Since this will appear frequently in the upcoming discussion, we shall name it $v(t)$. For simplicity, we remove the growth rate of the share price. Replacing σ^2 in the stochastic differential equation (20.4) by the time-dependent variance $v(t)$ we obtain

$$\dot{x}(t) = -\frac{v(t)}{2} + \sqrt{v(t)}\eta(t), \quad (20.306)$$

where the noise variable $\eta(t)$ has zero average and *unit* volatility

$$\langle \eta(t) \rangle = 0, \quad \langle \eta(t)\eta(t') \rangle = \delta(t - t'). \quad (20.307)$$

The variance is assumed to satisfy an equation with another noise variable $\eta_v(t)$ [7]

$$\dot{v}(t) = -\gamma[v(t) - \bar{v}] + \varepsilon\sqrt{v(t)}\eta_v(t). \quad (20.308)$$

The time in $\sqrt{v(t)}$ is supposed to lie slightly *before* the time in the noise $\eta_v(t)$. The parameter ε determines the volatility of the variance. The parameter \bar{v} will become the average of the variance at large times. It is proportional to the variance σ^2 of the Gaussian distribution to which the distribution converges in the long-time limit by the central limit theorem. The precise relation will be given in Eq. (20.363).

In general, the noise variables $\eta(t)$ and $\eta_v(t)$ are expected to exhibit correlations which are accounted for by introducing an independent noise variable $\eta'(t)$ and setting

$$\eta_v(t) \equiv \rho\eta(t) + \sqrt{1 - \rho^2}\eta'(t). \quad (20.309)$$

The pair correlation functions are then

$$\langle \eta(t)\eta(t') \rangle = \delta(t - t'), \quad \langle \eta(t)\eta_v(t') \rangle = \rho\delta(t - t'), \quad \langle \eta_v(t)\eta_v(t') \rangle = \delta(t - t'). \quad (20.310)$$

20.4.2 Fokker-Planck Equation

If $\boldsymbol{\eta}(t)$ denotes the pair of noise variables $(\eta(t), \eta_v(t))$, the probability distribution analogous to (18.324) for paths $x(t), v(t)$ starting out at x_a, v_a and arriving at x, v is

$$P_{\boldsymbol{\eta}}(x v t | x_a v_a t_a) = \delta(x_{\boldsymbol{\eta}}(t) - x)\delta(v_{\boldsymbol{\eta}_v}(t) - v). \quad (20.311)$$

The time evolution of this is calculated using the differentiation rule (18.381) as

$$\partial_t P_{\boldsymbol{\eta}}(x v t | x_a v_a t_a) = -[\partial_x \dot{x}_{\boldsymbol{\eta}}(t) + \partial_v \dot{v}_{\boldsymbol{\eta}_v}(t)] P_{\boldsymbol{\eta}}(x v t | x_a v_a t_a), \quad (20.312)$$

or more explicitly

$$\begin{aligned} \partial_t P_{\mathbf{\eta}}(x v t | x_a v_a t_a) = & \left\{ \partial_x \left[\frac{v(t)}{2} - \sqrt{v(t)} \eta(t) \right] \right. \\ & \left. + \partial_v \left[\gamma(v(t) - \bar{v}) - \varepsilon \sqrt{v(t)} \eta_v(t) \right] \right\} P_{\mathbf{\eta}}(x v t | x_a v_a t_a). \end{aligned} \quad (20.313)$$

We now take the noise average (18.325) with the distribution

$$P[\mathbf{\eta}] = \exp \left\{ -\frac{1}{2} \int dt \left[\eta^2(t) + \eta_v^2(t) \right] \right\} = \exp \left\{ -\frac{1}{1-\rho^2} \int dt \left[\eta^2(t) + \eta_v^2(t) - 2\rho \eta \eta_v \right] \right\}. \quad (20.314)$$

Applying the rules (18.385) and (18.386), we may replace $\eta(t)$ and $\eta_v(t)$ on the right-hand side of (20.313):

$$\eta(t) \rightarrow -\delta/\delta\eta(t) - \rho \delta/\delta\eta_v(t) \quad (20.315)$$

$$\eta_v(t) \rightarrow -\rho \delta/\delta\eta(t) - \delta/\delta\eta_v(t). \quad (20.316)$$

The functional derivatives are evaluated by analogy with (18.388) as

$$\frac{\delta}{\delta\eta(t')} \delta(x_{\eta}(t) - x) \delta(v_{\eta_v}(t) - v) = - \left[\frac{\delta x_{\eta}(t)}{\delta\eta(t')} \partial_x + \frac{\delta v_{\eta_v}(t)}{\delta\eta(t')} \partial_v \right] \delta(x_{\eta}(t) - x) \delta(v_{\eta_v}(t) - v), \quad (20.317)$$

with a similar equation for $\delta/\delta\eta_v(t)$. Under the above-made assumption that $\sqrt{v(t)}$ lies before $\eta_v(t)$, we find the evolution equation

$$\partial_t P(x v t | x_a v_a t_a) = -\hat{H} P(x v t | x_a v_a t_a), \quad (20.318)$$

where \hat{H} is the Hamiltonian operator

$$\hat{H} = -\frac{1}{2} \partial_x^2 v - \frac{1}{2} \partial_x v - \frac{\varepsilon^2}{2} \partial_v^2 v - \gamma \partial_v (v - \bar{v}) - \rho \varepsilon \partial_x \partial_v v. \quad (20.319)$$

The probability distribution can thus be written as a path integral

$$\begin{aligned} P(x_b v_b t_b | x_a v_a t_a) = & \int \mathcal{D}x \int \frac{\mathcal{D}p}{2\pi} \int \mathcal{D}v \int \frac{\mathcal{D}p_v}{2\pi} \\ & \times \exp \left\{ \int_{t_a}^{t_b} dt \left[i(p\dot{x} + p_v \dot{v}) - H(p, p_v, v) \right] \right\}, \end{aligned} \quad (20.320)$$

with the Hamiltonian

$$H(p, p_v, v) = \frac{p^2}{2} v - i \frac{1}{2} p v + \varepsilon^2 \frac{p_v^2}{2} v - i \gamma p_v (v - \bar{v}) + \rho \varepsilon p p_v v - \frac{3\varepsilon^2}{4} i p_v - \frac{\gamma}{2} - \frac{i}{2} \rho \varepsilon p. \quad (20.321)$$

The last two terms arise from the fact that the order of the operators in \hat{H} obtained from the path integral is always symmetric in v and p_v , such that the order in Eq. (20.319) is reached only after the replacement of $p_v v \rightarrow (1/2) \{ \hat{p}_v, v \} = \hat{p}_v v + i/2$

in the fourth and fifth terms of (20.321). Recall the discussions in Sections 10.5, 11.3, and Subsection 18.9.2.

The third-last term in (20.321) is present to ensure the appearance of the operator $\partial_v^2 v$ in (20.319) with no extra ∂_v due to operator ordering. The term $p_v^2 v$ in (20.321) can be understood as a kinetic term $g_{\mu\nu} p^\mu p^\nu$ in a one-dimensional Riemannian space with a metric $g^{\mu\nu} = \delta^{\mu\nu}/v$. According to Subsection 11.1.1, this turns into the Laplace-Beltrami operator $\Delta = \sqrt{v}\partial_v^2 \sqrt{v}\partial_v = v\partial_v^2 + \frac{1}{2}\partial_v = \partial_v^2 v - \frac{3}{2}\partial_v$. The extra ∂_v is canceled by the third-last term in (20.319).

The stochastic differential equation (20.308) can, in principle, lead to negative variances. Since this would be unphysical, we must guarantee that this does not happen. The condition for this is that the fluctuation width of the variance is sufficiently small, satisfying

$$\frac{\varepsilon^2}{2\gamma\bar{v}} \leq 1. \quad (20.322)$$

Then an initially positive $v(t)$ will always stay positive. Indeed, consider the partial differential equation (20.318) for $v = 0$:

$$(\partial_t + \alpha\partial_v)P(xvt|x_av_at_a) = (\gamma + \rho\varepsilon\partial_x)P(xvt|x_av_at_a), \quad (20.323)$$

where $\alpha \equiv \gamma\bar{v} - \varepsilon^2/2$. It is solved by some function

$$P(xvt|x_av_at_a) = f(v - \alpha t, x), \quad (20.324)$$

which shows that a nonvanishing f for positive v can never propagate to negative- v .⁹

The time dependence of the variance is given by the integral

$$P(vt|v_at_a) \equiv \int dx P(xvt|x_av_at_a). \quad (20.325)$$

It satisfies the equation

$$\frac{\partial}{\partial t}P(vt|v_at_a) = \left[\frac{\varepsilon^2}{2}\partial_v^2 v + \gamma\partial_v(v - \bar{v}) \right] P(vt|v_at_a), \quad (20.326)$$

which follows from (20.318) by integration over x . After a long time, the solution becomes stationary and reads

$$P^*(v) = \frac{\mu^\nu}{\Gamma(\nu)} v^{\nu-1} e^{-\mu v}, \quad \text{where } \mu \equiv \frac{2\gamma}{\varepsilon^2}, \quad \nu \equiv \mu\bar{v}. \quad (20.327)$$

This is the Gamma distribution found in Fig. 20.3. Hence the pair of stochastic differential equations (20.306) and (20.308) produces precisely the type of volatility fluctuations observed in the previous financial data.

The maximum of $P^*(v)$ lies slightly below \bar{v} at $v_{\max} = (\nu - 1)/\mu = \bar{v} - \varepsilon^2/2\gamma$ [recall (20.72)]. If we define the w of $P^*(v)$ by the curvature at the maximum, we

⁹See also p. 67 in the textbook [8].

find $w = \sqrt{v_{\max}\varepsilon^2/2\gamma}$. The shape of $P^*(v)$ is characterized by the dimensionless ratio

$$\frac{v_{\max}}{w} = \sqrt{\frac{2\gamma\bar{v}}{\varepsilon^2}} - 1. \tag{20.328}$$

The size of the fluctuations of the variance are restricted by the condition (20.322) which guarantees positive $v(t)$ for all times. The distribution (20.327) is plotted in Fig. 20.21. As a cross check, we go to the limit $\varepsilon^2/2\gamma\bar{v} \rightarrow 0$ where the fluctuations of the variance are frozen out. The ratio v_{\max}/w diverges and the distribution $P^*(v)$ tends to $\delta(v - \bar{v})$, as expected.

Figure 20.21 Stationary distribution (20.327) of variances for parameters of fits to the Dow-Jones data in Fig. 20.22 listed in Table 20.1. Compare with Fig. 20.3.

20.4.3 Solution of Fokker-Planck Equation

Since the Hamiltonian operator (20.319) does not depend explicitly on x , we can take advantage of translational invariance and write $P(x v t | x_a v_a t_a)$ as a Fourier integral

$$P(x v t | x_a v_a t_a) = \int \frac{dp}{2\pi} e^{ip(x-x_a)} \bar{P}_p(v t | v_a t_a). \tag{20.329}$$

The fixed-momentum probability satisfies the Fokker-Planck equation

$$\partial_t \bar{P}_p(v t | v_a t_a) = \left[\gamma \frac{\partial}{\partial v} (v - \bar{v}) - \frac{p^2 - ip}{2} v - i\rho\varepsilon p \frac{\partial}{\partial v} v - \frac{\varepsilon^2}{2} \frac{\partial^2}{\partial v^2} v \right] \bar{P}_p(v t | v_a t_a). \tag{20.330}$$

This partial differential equation is of second-order. The variable v occurs only linearly. It is therefore convenient to go to Fourier space also in v and write

$$\tilde{\bar{P}}_p(v t | v_a t_a) = \int \frac{dp_v}{2\pi} e^{ip_v v} \tilde{\bar{P}}_p(p_v t | v_a t_a), \tag{20.331}$$

which solves the first-order partial differential equation

$$\left[\frac{\partial}{\partial t} + \left(\Gamma p_v + \frac{i\varepsilon^2}{2} p_v^2 + \frac{ip^2 + p}{2} \right) \frac{\partial}{\partial p_v} \right] \tilde{P}_p(p_v t | v_a t_a) = -i\gamma\bar{v} p_v \tilde{P}_p(p_v t | v_a t_a), \tag{20.332}$$

where we have used the abbreviation

$$\Gamma(p) \equiv \gamma + i\rho\varepsilon p. \tag{20.333}$$

Since the initial condition for $\tilde{P}_p(v t | v_a t_a)$ is $\delta(v - v_a)$, the Fourier transform has the initial condition

$$\tilde{P}_p(p_v t_a | v_a t_a) = e^{-ip_v v_a}. \tag{20.334}$$

The solution of the first-order partial differential equation (20.332) is found by the method of characteristics [9]:

$$\tilde{P}_p(p_v t | v_a t_a) = \exp \left[-i\tilde{p}_v(t_a)v_a - i\gamma\bar{v} \int_{t_a}^t dt' \tilde{p}_v(t') \right], \tag{20.335}$$

where the function $\tilde{p}_v(t)$ is the solution of the characteristic differential equation

$$\frac{d\tilde{p}_v(t)}{dt} = \Gamma(p)\tilde{p}_v(t) + \frac{i\varepsilon^2}{2}\tilde{p}_v^2(t) + \frac{i}{2}(p^2 - ip), \tag{20.336}$$

with the boundary condition $\tilde{p}_v(t_b) = p_v$. The differential equation is of the Riccati type with constant coefficients [10], and its solution is

$$\tilde{p}_v(t) = -i \frac{2\Omega(p)}{\varepsilon^2} \frac{1}{\zeta(p, p_v) e^{\Omega(p)(t_b-t)} - 1} + i \frac{\Gamma(p) - \Omega(p)}{\varepsilon^2}, \tag{20.337}$$

where we introduced the complex frequency

$$\Omega(p) = \sqrt{\Gamma^2(p) + \varepsilon^2(p^2 - ip)}, \tag{20.338}$$

and the coefficient are

$$\zeta(p, p_v) = 1 - i \frac{2\Omega(p)}{\varepsilon^2 p_v - i[\Gamma(p) - \Omega(p)]}. \tag{20.339}$$

Taking the Fourier transform we obtain the solution of the original Fokker-Planck equation (20.318):

$$P(x v t | x_a v_a t_a) = \int \int_{-\infty}^{+\infty} \frac{dp}{2\pi} \frac{dp_v}{2\pi} e^{ipx + ip_v v} \times \exp \left\{ -i\tilde{p}_v(t_a)v_a + \frac{\gamma\bar{v}[\Gamma(p) - \Omega(p)]}{\varepsilon^2} \Delta t - \frac{2\gamma\bar{v}}{\varepsilon^2} \ln \frac{\zeta(p, p_v) - e^{-\Omega(p)\Delta t}}{\zeta(p, p_v) - 1} \right\}, \tag{20.340}$$

where $\Delta t \equiv t - t_a$ is the time interval.

20.4.4 Pure α -Distribution

We now show that upon averaging over the variance we obtain a non-Gaussian distribution of x with semi-heavy tails of the type observed in actual financial data. Thus we go over to the probability distribution

$$P(x t | x_a v_a t_a) \equiv \int_{-\infty}^{+\infty} dv P(x v t | x_a v_a t_a), \tag{20.341}$$

where the final variable v is integrated out. The integration of (20.340) over v generates the delta-function $\delta(p_v)$ which enforces $p_v = 0$. Thus we obtain

$$P(x t | x_a v_a t_a) = \int_{-\infty}^{+\infty} \frac{dp}{2\pi} e^{ipx - \frac{p^2 - ip}{\Gamma + \Omega \coth(\Omega \Delta t / 2)} v_a + \frac{\gamma \Gamma \bar{v}}{\varepsilon^2} \Delta t - \frac{2\gamma \bar{v}}{\varepsilon^2} \ln(\cosh \frac{\Omega \Delta t}{2} + \frac{\Gamma}{\Omega} \sinh \frac{\Omega \Delta t}{2})}, \tag{20.342}$$

where we have omitted the arguments of $\Gamma(p)$ and $\Omega(p)$, for brevity. As a cross check of this result we consider the special case $\varepsilon = 0$ where the time evolution of the variance is deterministic:

$$v(t) = \bar{v} + (v_a - \bar{v})e^{-\gamma \Delta t}. \tag{20.343}$$

Performing the integral over p in Eq. (20.342) we obtain

$$P(x t | x_a t_a v_a) = \frac{1}{\sqrt{2\pi(t - t_a)\bar{v}(t)}} \exp \left\{ -\frac{[x + \bar{v}(t)(t - t_a)/2]^2}{2\bar{v}(t)} \right\}, \tag{20.344}$$

where $\bar{v}(t)$ denotes the time-averaged variance

$$\bar{v}(t) \equiv \frac{1}{\Delta t} \int_{t_a}^t dt' v(t'). \tag{20.345}$$

The distribution becomes Gaussian in this limit. The same result could, of course, have been obtained directly from the stochastic differential equation (20.306).

The result (20.342) cannot be compared directly with financial time series data, because it depends on the unknown initial variance v_a . Let us assume that v_a has initially a stationary probability distribution $P^*(v_a)$ of Eq. (20.327).¹⁰ Then we evaluate the probability distribution $P(x t | x_a t_a)$ by averaging (20.342) over v_a with the weight $P^*(v_a)$:

$$P(x t | x_a t_a) = \int_0^\infty dv_a P^*(v_a) P(x t | x_a t_a v_a). \tag{20.346}$$

The final result has the Fourier representation

$$P(x t | x_a t_a) = \int_{-\infty}^{+\infty} \frac{dp}{2\pi} e^{ip\Delta x - \Delta t H(p, \Delta t)}, \tag{20.347}$$

¹⁰For a determination of the empirical probability distribution of volatilities for the S&P 500 index see Ref. [2].

where $\Delta x \equiv x - x_a$ and $H(p, \Delta t)$ is the Hamiltonian

$$H(p, \Delta t) = -\frac{\gamma\Gamma(p)\bar{v}}{\varepsilon^2} + \frac{2\gamma\bar{v}}{\varepsilon^2\Delta t} \ln \left[\cosh \frac{\Omega(p)\Delta t}{2} + \frac{\Omega^2(p) - \Gamma^2(p) + 2\gamma\Gamma(p)}{2\gamma\Omega(p)} \sinh \frac{\Omega(p)\Delta t}{2} \right]. \quad (20.348)$$

In the absence of correlations between the fluctuations of stock price and variance, i.e. for $\rho = 0$, the second term in the right-hand side of Eq. (20.348) vanishes. The simplified result is discussed in Appendix 20B.

The general Hamiltonian (20.348) vanishes for $p = 0$. This guarantees the unit normalization of the distribution (20.347) at all times: $\int dx P(xt|x_at_a) = 1$. The first expansion coefficient of $H(p, \Delta t)$ in powers of p is [recall the definition in Eq. (20.54)]

$$c_1(\Delta t) = -\frac{\bar{v}}{2} - \frac{\rho}{\varepsilon\Delta t} (1 - e^{-\gamma\Delta t}). \quad (20.349)$$

We have added the argument Δt to emphasize the time dependence. By adding $ic_1(\Delta t)p$ to $H(p, \Delta t)$, we obtain the Hamiltonian $\bar{H}(p, \Delta t)$ which starts out quadratically in p in accordance with our general definition in Eq. (20.65):

$$\bar{H}(p, \Delta t) \equiv H(p, \Delta t) - ic_1(\Delta t)p = H(p, \Delta t) + i \left[\frac{\bar{v}}{2} + \frac{\rho}{\varepsilon\Delta t} (1 - e^{-\gamma\Delta t}) \right] p. \quad (20.350)$$

The distribution $P(xt|x_at_a)$ is real since $\text{Re } H$ is an even function and $\text{Im } H$ is an odd function of p .

In general, the integral in (20.347) must be calculated numerically. The interesting limit regimes $\Delta t \gg 1$ and $x \gg 1$, however, can be understood analytically. These will be treated in Subsections 20.4.5 and 20.4.6. In Fig. 20.22, the calculated distributions $P(xt|x_at_a)$ with increasing time intervals are displayed as solid curves and compared with the corresponding Dow-Jones data indicated by dots. The technical details of the data analysis are explained in Appendix 20C. The figure demonstrates that with a fixed set of the five parameters γ , \bar{v} , ε , μ , and ρ , the distribution (20.347) with (20.348) reproduce extremely well the data for *all* time scales Δt . In the logarithmic plot the far tails of the distributions fall off linearly.

20.4.5 Long-Time Behavior

According to Eq. (20.308), the variance approaches the equilibrium value \bar{v} within the characteristic relaxation time $1/\gamma$. Let us study the limit in which the time interval Δt is much longer than the relaxation time: $\gamma\Delta t \gg 1$. According to Eqs. (20.333) and (20.338), this condition also implies that $\Omega(p)\Delta t \gg 1$. Then Eq. (20.348) reduces to

$$H(p, \Delta t) \approx \frac{\gamma\bar{v}}{\varepsilon^2} [\Omega(p) - \Gamma(p)]. \quad (20.351)$$

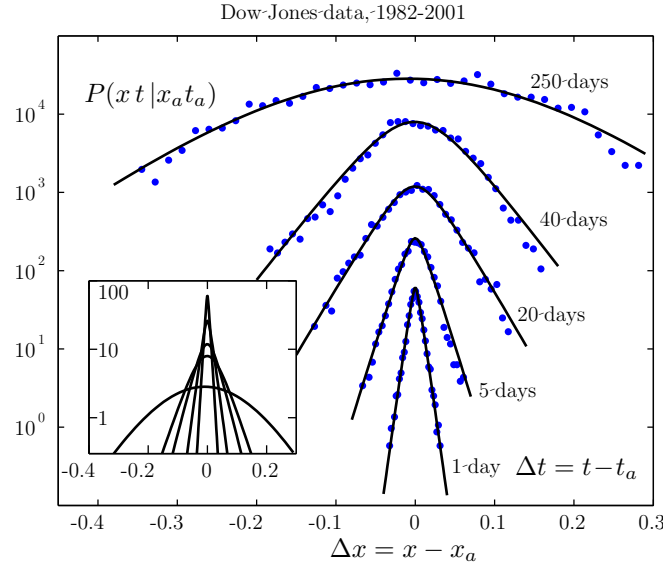

Figure 20.22 Probability distribution of logarithm of stock price for different time scales (from Ref. [79]). For a better comparison of the shapes, the data points for increasing Δt are shifted upwards by a factor 10 each. The unshifted positions are shown in the insert.

The Fourier integral (20.347) can easily be performed after changing the variable of integration to

$$p = C \tilde{p} + ip_0, \quad (20.352)$$

where

$$C \equiv \frac{\omega_0}{\varepsilon \sqrt{1 - \rho^2}}, \quad \omega_0 \equiv \sqrt{\gamma^2 + \varepsilon^2(1 - \rho^2)p_0^2}, \quad p_0 \equiv \frac{\varepsilon - 2\rho\gamma}{2\varepsilon(1 - \rho^2)}. \quad (20.353)$$

Then the integral (20.347) takes the form

$$P(x, t | x_a, t_a) = \frac{C}{\pi} e^{-p_0 \Delta x + \Lambda \Delta t} \int_0^\infty d\tilde{p} \cos(A\tilde{p}) e^{-B\sqrt{1 + \tilde{p}^2}}, \quad (20.354)$$

where

$$A = C \left(\Delta x + \rho \frac{\gamma \bar{v}}{\varepsilon} \Delta t \right), \quad B = \frac{\gamma \bar{v} \omega_0}{\varepsilon^2} \Delta t, \quad (20.355)$$

and

$$\Lambda = \frac{\gamma \bar{v}}{2\varepsilon^2} \frac{2\gamma - \rho\varepsilon}{1 - \rho^2}. \quad (20.356)$$

The integral in (20.354) is equal to¹¹ $BK_1(\sqrt{A^2 + B^2})/\sqrt{A^2 + B^2}$, where $K_1(y)$ is a modified Bessel function, such that the probability distribution (20.347) for $\gamma\Delta t \gg 1$ can be represented in the scaling form

$$P(x, t | x_a, t_a) = N(\Delta t) e^{-p_0 \Delta x} F^*(y), \quad F^*(y) = K_1(y)/y, \quad (20.357)$$

¹¹See I.S. Gradshteyn and I.M. Ryzhik, *op. cit.*, Formula 3.914.

with the argument

$$y \equiv \sqrt{A^2 + B^2} = \frac{\omega_0}{\varepsilon} \sqrt{\frac{(\Delta x + \rho\gamma\bar{v}\Delta t/\varepsilon)^2}{1 - \rho^2} + \left(\frac{\gamma\bar{v}\Delta t}{\varepsilon}\right)^2}, \quad (20.358)$$

and the time-dependent normalization factor

$$N(\Delta t) = \frac{\omega_0^2 \gamma \bar{v}}{\pi \varepsilon^3 \sqrt{1 - \rho^2}} \Delta t e^{\Lambda \Delta t}. \quad (20.359)$$

Thus, up to the factors $N(\Delta t)$ and $e^{-p_0 \Delta x}$, the dependence of $P(xt|x_a t_a)$ on the arguments Δx and Δt is given by the function $F^*(y)$ of the single scaling argument y . When plotted as a function of y , the data for different Δx and Δt should collapse on the single universal curve $F^*(y)$. This does indeed happen as illustrated in Fig. 20.23, where the Dow-Jones data for different time differences Δt follows the curve $F^*(y)$ for seven decades.

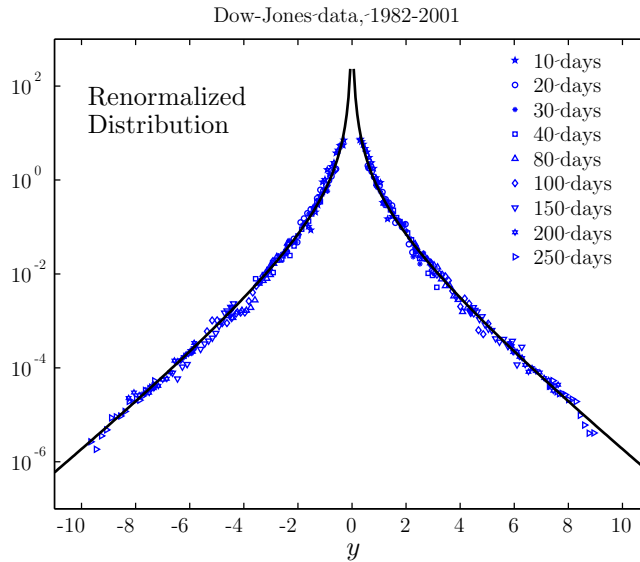

Figure 20.23 Renormalized distribution function $P(xt|x_a t_a)e^{p_0 \Delta x}/N(\Delta t)$ plotted as a function of the scaling argument y defined in Eq. (20.358). The solid curve shows the universal function $F^*(y) = K_1(y)/y$ (from Ref. [79]).

In the limit $y \gg 1$, we can use the asymptotic expression $K_1(y) \approx e^{-y} \sqrt{\pi/2y}$ and find the asymptotic behavior

$$\ln \frac{P(xt|x_a t_a)}{N(\Delta t)} \approx -p_0 \Delta x - y. \quad (20.360)$$

Let us examine this expression for large and small $|\Delta x|$. In the first case $|\Delta x| \gg \gamma\bar{v}\Delta t/\varepsilon$, and Eq. (20.358) shows that $y \approx \omega_0 |\Delta x|/\varepsilon \sqrt{1 - \rho^2}$, so that (20.360) becomes

$$\ln \frac{P(xt|x_a t_a)}{N(\Delta t)} \approx -p_0 \Delta x - c |\Delta x|. \quad (20.361)$$

Figure 20.24 Solid curve showing slope $-d \log P(xt | x_a t_a) / dx$ of exponential tail of distribution as a function of time. The dots indicate the analytic short-time approximation (20.369) to the curve (from [79]).

This shows that the probability distribution $P(xt | x_a t_a)$ has exponential tails (20.361) for large $|\Delta x|$. Note that in the present limit $\gamma \Delta t \gg 1$ the slopes of the exponential tails are independent of Δt . The presence of p_0 causes the slopes for positive and negative Δx to be different, so that the distribution $P(xt | x_a t_a)$ is not up-down symmetric with respect to price changes. From the definition of p_0 in Eq. (20.353) we see that this asymmetry increases for a negative correlation $\rho < 0$ between stock price and variance.

In the second case $|\Delta x| \ll \gamma \bar{v} \Delta t / \varepsilon$, by Taylor-expanding y in (20.358) near its minimum and substituting the result into (20.360), we obtain

$$\ln \frac{P(xt | x_a t_a)}{N'(\Delta t)} \approx -p_0 \Delta x - \frac{\omega_0 (\Delta x + \rho \gamma \bar{v} \Delta t / \varepsilon)^2}{2(1 - \rho^2) \gamma \bar{v} \Delta t}, \quad (20.362)$$

where $N'(\Delta t) = N(\Delta t) \exp(-\omega_0 \gamma \bar{v} \Delta t / \varepsilon^2)$. Thus, for small $|\Delta x|$, the probability distribution $P(xt | x_a t_a)$ is a Gaussian, whose width

$$\sigma^2 = \frac{(1 - \rho^2) \gamma \bar{v}}{\omega_0} \Delta t \quad (20.363)$$

grows linearly with Δt . The maximum of $P(xt | x_a t_a)$ lies at

$$\Delta x_m(t) = \Delta r_S \Delta t, \quad \text{with} \quad \Delta r_S \equiv -\frac{\gamma \bar{v}}{2\omega_0} \left[1 + 2 \frac{\rho(\omega_0 - \gamma)}{\varepsilon} \right]. \quad (20.364)$$

The position moves with a constant rate Δr_S which adds to the average growth rate r_S of $S(t)$ removed at the beginning of the discussion. The true final growth rate of $S(t)$ is $\bar{r}_S = r_S + \Delta r_S$.

The above discussion explains the property of the data in Fig. 20.22 that the logarithmic plots of $P(xt|x_at_a)$ are linear in the tails and quadratic near the peaks with the parameters specified in Eqs. (20.361) and (20.362).

As time progresses, the distribution broadens in accordance with the scaling form (20.357) and (20.358). In the limit $\Delta t \rightarrow \infty$, the asymptotic expression (20.362) is valid for all Δx and the distribution becomes a pure Gaussian, as required by the central limit theorem [22].

It is interesting to quantify the fraction $f(\Delta t)$ of the total probability contained in the Gaussian portion of the curve. This fraction is plotted in Fig. 20.25. The precise way of defining and calculating the fraction $f(\Delta t)$ is explained in Appendix 20B. The inset in Fig. 20.25 illustrates that the time dependence of the probability density at the maximum x_m approaches $\Delta t^{-1/2}$ for large time, a characteristic property of evolution of Gaussian distributions.

Figure 20.25 Fraction $f(\Delta t)$ of total probability contained in Gaussian part of $P(xt|x_at_a)$ as function of time interval Δt . The inset shows the time dependence of the probability density at maximum $P(x_mt|x_at_a)$ (points), compared with the falloff $\propto \Delta t^{-1/2}$ of a Gaussian distribution (solid curve).

20.4.6 Tail Behavior for all Times

For large $|\Delta x|$, the integrand in (20.347) oscillates rapidly as a function of p , so that the integral can be evaluated in the saddle point approximation of Section 4.2. As in the evaluation of the integral (17.9) we shift the contour of integration in the complex p -plane until it passes through the leading saddle point of the exponent $ip\Delta x - \Delta tH(p, \Delta t)$. To determine its position we note that the function $H(p, \Delta t)$ in Eq. (20.348) has singularities in the complex p -plane, where the argument of the

Figure 20.26 Singularities of $H(p, \Delta t)$ in complex p -plane (dots). Circled crosses indicate the limiting positions $\pm iq_*^\pm$ of the singularities for $\gamma\Delta t \gg 1$. The cross shows the saddle point p_s located in the upper half-plane for $\Delta x > 0$. The dashed line is the shifted contour of integration to pass through the saddle point p_s .

logarithm vanish. These points are located on the imaginary p -axis and are shown by dots in Fig. 20.26. The relevant singularities are those lying closest to the real axis. They are located at the points p_1^+ and p_1^- , where the argument of the second logarithm in (20.348) vanishes. Near these zeros, we can approximate $H(p, \Delta t)$ by the singular term:

$$\bar{H}(p, \Delta t) \approx \frac{2\gamma\bar{v}}{\varepsilon^2\Delta t} \log(p - p_1^\pm). \quad (20.365)$$

With this approximation, the position of the saddle point $p_s = p_s(\Delta x)$ is determined by the equation

$$i\Delta x = \Delta t \left. \frac{dH(p, \Delta t)}{dp} \right|_{p=p_s} \approx \frac{2\gamma\bar{v}}{\varepsilon^2} \times \begin{cases} \frac{1}{p_s - p_1^+}, & \Delta x > 0, \\ \frac{1}{p_s - p_1^-}, & \Delta x < 0. \end{cases} \quad (20.366)$$

The solutions are indicated in Fig. 20.26 by the cross. The approximation (20.366) is obviously applicable since for a large $|\Delta x|$ satisfying the condition $|\Delta x p_1^\pm| \gg \gamma\bar{v}/\varepsilon^2$, the saddle point p_s is very close to one of the singularities. Inserting the approximation (20.366) into the Fourier integral (20.347), we obtain the asymptotic expression for the probability distribution

$$P(x t | x_a t_a) \sim \begin{cases} e^{-\Delta x q_t^+}, & \Delta x > 0, \\ e^{-|\Delta x| q_t^-}, & \Delta x < 0, \end{cases} \quad (20.367)$$

where $q_t^\pm \equiv \mp ip_1^\pm(t)$ are real and positive. Thus the tails of the probability distribution $P(xt|x_at_a)$ for large $|\Delta x|$ are exponential for all times t . The slopes of the logarithmic plots in the tails $q^\pm \equiv \mp d \log(xt|x_at_a)/dx$ are determined by the positions p_1^\pm of the singularities closest to the real axis.

These positions p_1^\pm depend on the time interval Δt . For times much shorter than the relaxation time ($\gamma t \ll 1$), the singularities lie far away from the real axis. As time increases, the singularities approach the real axis. For times much longer than the relaxation time ($\gamma \Delta t \gg 1$), the singularities approach the limiting points $p_1^\pm \rightarrow \pm iq_*^\pm$, marked in Fig. 20.26 by circled crosses. The limiting values are

$$q_*^\pm = \pm p_0 + \frac{\omega_0}{\varepsilon \sqrt{1 - \rho^2}} \quad \text{for } \gamma \Delta t \gg 1. \quad (20.368)$$

The slopes $q^\pm(\Delta t)$ approach these limiting slopes monotonously from above. The behavior is shown in Fig. 20.24. The slopes (20.368) are of course in agreement with Eq. (20.361) in the limit $\gamma \Delta t \gg 1$. In the opposite limit of short time ($\gamma \Delta t \ll 1$), we find the analytic time behavior

$$q^\pm(\Delta t) \approx \pm p_0 + \sqrt{p_0^2 + \frac{4\gamma}{\varepsilon^2(1 - \rho^2)\Delta t}} \quad \text{for } \gamma \Delta t \ll 1. \quad (20.369)$$

This approximation is shown in Fig. 20.24 as dots.

20.4.7 Path Integral Calculation

Instead of solving the Fokker-Planck equation (20.330) we may also study directly the path integral for the probability distribution using the Hamiltonian (20.321). Note the extra two terms at the end in comparison with the operator expression (20.319). They account for the symmetric operator order implied by the path integral. The distribution $\bar{P}_p(v_b, t_b|v_at_a)$ at fixed momentum introduced in Eq. (20.329) has the path integral representation

$$\bar{P}_p(v_b, t_b|v_at_a) = \int \mathcal{D}v \frac{\mathcal{D}p_v}{2\pi} e^{\mathcal{A}_p[p_v, v]}, \quad (20.370)$$

with the action

$$\mathcal{A}_p[p_v, v] = \int_{t_a}^{t_b} dt [ip_v \dot{v} - H(p, p_v, v)]. \quad (20.371)$$

The path integral (20.370) sums over all paths $p_v(t)$ and $v(t)$ with the boundary conditions $v(t_a) = v_a$ and $v(t_b) = v_b$.

It is convenient to integrate the first term in the (20.371) by parts, and to separate $H(p, p_v, v)$ into a v -independent part $i\gamma \bar{v} p_v - i\gamma/2 - i\rho \varepsilon p/2$ and a linear term $[\partial H(p, p_v, v)/\partial v]v$. Thus we write

$$\begin{aligned} \mathcal{A}_p[p_v, v] &= i[p_v(t_b)v_b - p_v(t_a)v_a] - i\gamma \bar{v} \int_{t_a}^{t_b} dt p_v(t)(t_b - t_a) \\ &\quad - \int_{t_a}^{t_b} dt \left[i\dot{p}_v(t) + \frac{\partial H}{\partial v(t)} \right] v(t). \end{aligned} \quad (20.372)$$

Since the path $v(t)$ appears linearly in this expression, we can integrate it out to obtain a delta-functional $\delta[p_v(t) - \tilde{p}_v(t)]$, where $\tilde{p}_v(t)$ is the solution of the Hamilton equation $\dot{p}_v(t) = i\partial H/\partial v(t)$. This, however, coincides exactly with the characteristic differential equation (20.336) which was solved by Eq. (20.337) with a boundary condition $\tilde{p}_v(t_b) = p_v$. Taking the path integral over $\mathcal{D}p_v$ removes the delta-functional, and we find

$$\bar{P}_p(v_b, t_b | v_a t_a) = \int_{-\infty}^{+\infty} \frac{dp_v}{2\pi} J e^{i[p_v v - \tilde{p}_v(t_a)v_a] - i\gamma\theta \int_0^t dt \tilde{p}_v(t) + (\gamma - i\rho\epsilon p)(t_b - t_a)/2}, \quad (20.373)$$

where J denotes the Jacobian

$$J = \text{Det}^{-1} \left(i\partial_t + \frac{\partial^2 H(p, p_v, v)}{\partial p_v \partial v} \right). \quad (20.374)$$

From (20.321) we see that

$$\frac{\partial^2 H(p, p_v, v)}{\partial p_v \partial v} = -i\gamma + \rho\epsilon p. \quad (20.375)$$

According to Formula (18.254), this is equal to

$$J = e^{-(\gamma - i\rho\epsilon p)(t_b - t_a)/2}, \quad (20.376)$$

thus canceling the last term in the exponent of the integrand in (20.373). The result for $\bar{P}_p(v_b, t_b | v_a t_a)$ is therefore the same as the one obtained from the Fokker-Planck equation in Eq. (20.331) with the Fourier transform (20.335).

20.4.8 Natural Martingale Distribution

Let us calculate the natural martingales associated with the Hamiltonian (20.348). Reinserting the initially removed drift r_S , the total Hamiltonian reads

$$H^{\text{tot}}(p, \Delta t) = H(p, \Delta t) + ir_S p. \quad (20.377)$$

To construct the martingale according to the rule of Subsection 20.1.11, we need to know the value of $\bar{H}(p, \Delta t)$ at the momentum $p = i$. The expression is somewhat complicated, but the analysis of the Dow-Jones data in Appendix 20C shows that the parameter ρ determining the strength of correlations between the noise functions $\eta(t)$ and $\eta_v(t)$ [see (20.310)] is small. It is therefore sufficient to find only the first two terms of the Taylor series of $H(i, \Delta t)$ in powers of ρ :

$$H(i, \Delta t) \approx \frac{\bar{v}}{\epsilon\Delta t} (1 - e^{-\gamma\Delta t}) \rho + \frac{\bar{v}}{4\gamma\Delta t} [3 - 2e^{-\gamma\Delta t} (1 + 2\gamma\Delta t) - e^{-2\gamma\Delta t}] \rho^2. \quad (20.378)$$

From this we obtain

$$\bar{H}(i, \Delta t) = H(i, \Delta t) + c_1(\Delta t). \quad (20.379)$$

The analog of the martingale (20.291) is given by a Fourier integral (20.292) with $H_{r_x}(p)$ replaced by $H_{r_x(\Delta t)}^{\text{tot}}(p, \Delta t)$ of Eq. (20.350):

$$P^{(M, r_S)}(x_b t_b | x_a t_a) = e^{-r(\Delta t)\Delta t} \int_{-\infty}^{\infty} \frac{dp}{2\pi} \exp \left[ip(x_b - x_a) - \Delta t H_{r_x(\Delta t)}^{\text{tot}}(p, \Delta t) \right]. \quad (20.380)$$

The linear term $ir_x(\Delta t)p$ in $H_{r_x(\Delta t)}^{\text{tot}}(p, \Delta t)$ is now time-dependent:

$$r_x(\Delta t) = r_S + c_1(\Delta t) + \bar{H}(i, \Delta t). \quad (20.381)$$

This makes the rate in the exponential prefactor, by which the distribution becomes a martingale distribution, a time-dependent quantity:

$$r(\Delta t) = r_S + c_1(\Delta t). \quad (20.382)$$

By analogy with (20.293), there exists again an entire family of natural martingales, which is obtained by replacing r_S by an *arbitrary* growth rate r in which case $r(\Delta t)$ becomes equal to $r + c_1(\Delta t)$.

20.5 Time Series

True market prices are not continuous functions of time but recorded in discrete time intervals. For stocks which have a low turnover, only the daily prices are recorded. For others which are traded in large amounts, the prices change by the minute. They are listed as time series $S(t_n)$. In the year 2003, Robert Engle received the Nobel prize for his description of time series with the help of the so called *ARCH models* (autoregressive conditional heteroskedasticity model) and its generalization proposed by Tim Bollerslev [85], the *GARCH models*. The first contains an integer parameter q and is defined by a discrete modification of the pair of stochastic differential equations (20.306) and (20.308) for log-return and variance

$$x(t_n) = \sqrt{v(t_{n-1})} \eta(t_n), \quad v(t_n) = v_0 + \sum_{k=1}^q \alpha_k(t_{n-k}) x^2(t_{n-k}), \quad (20.383)$$

with a white noise variable $\eta(t_n)$. The drift is omitted so that $\langle x(t_n) \rangle = 0$. This is called the ARCH(q) model. The second is a generalization of this in which the equation for the variance contains extra terms involving the past p values of σ^2 :

$$v(t_n) = v_0 + \sum_{k=1}^q \alpha_k(t_{n-k}) x^2(t_{n-k}) + \sum_{k=1}^p \beta_k(t_{n-k}) v(t_{n-k}). \quad (20.384)$$

The ARCH(1) process has the time-independent expectations of variance and kurtosis

$$\sigma^2 = \langle v(t_n) \rangle = \frac{v_0}{1 - \alpha_1}, \quad \kappa = \frac{\langle x^4(t_n) \rangle_c}{\langle x^2(t_n) \rangle_c^2} = \frac{6\alpha_1^2}{1 - 3\alpha_1^2}. \quad (20.385)$$

For the GARCH(1,1) process, these quantities are

$$\sigma^2 = \langle v(t_n) \rangle = \frac{v_0}{1 - \alpha_1 - \beta_1}, \quad \kappa = \frac{\langle x^4(t_n) \rangle_c}{\langle x^2(t_n) \rangle_c^2} = \frac{6\alpha_1^2}{1 - 3\alpha_1^2 - 2\alpha_1\beta_1 - \beta_1^2}. \quad (20.386)$$

Figure 20.27 Left: Comparison of GARCH(1,1) process with $v_0 = 2.3 \times 10^{-5}$, $\alpha_1 = 0.091$, $\beta = 0.9$ with S&P 500 index (minute data). Right: Comparison of GARCH(1,1), Heston model, and Gaussian of the same σ with daily market data. Parameters of GARCH process are $v_0 = 7.7 \times 10^{-6}$, $\alpha_1 = 0.07906$, $\beta_1 = 0.90501$ and of Heston model $\gamma = 4.5 \times 10^{-2}$, $\bar{v} = 8.62 \times 10^{-8}$, $r_S = 5.67 \times 10^{-4}$, $\varepsilon = 10.3 \times 10^{-3}$ [79, 81, 82].

20.6 Spectral Decomposition of Power Behaviors

Plots of the log return curves taken over short time intervals reveal a richer structure than the simple model functions discussed so far. In fact, it seems reasonable to distinguish different types of stocks according to the characters of the investors. For instance, the bubble of the computer stocks was partly caused by quite inexperienced people who were not investing mainly to develop an industry but who wanted to earn fast money. There was, on the other hand also a substantial portion of institutional investors who poured in money more steadily. It appears that one should distinguish the sources of noise coming from the different groups of investors.

We therefore improve the stochastic differential equation (20.4) by extending it to

$$\dot{x}(t) = r_x + \sum_{\lambda} \eta_{\lambda}(t), \quad (20.387)$$

where the sum runs over different groups of investors, each producing a different a noise $\eta_{\lambda}(t)$ with Lévy distributions falling off with different powers $|x|^{-1-\lambda_i}$. Their probability distributions are

$$P_{\lambda}[\eta_{\lambda}] = \exp \left[- \int_{t_a}^{t_b} dt \tilde{H}_{\lambda}(\eta_{\lambda}(t)) \right] = \int \frac{\mathcal{D}p}{2\pi} \exp \left\{ \int_{t_a}^{t_b} dt [ip(t)\eta_{\lambda}(t) - H_{\lambda}(p(t))] \right\}, \quad (20.388)$$

with a Hamiltonian [compare (20.10)]

$$H_{\lambda}(p) \equiv \frac{\sigma_{\lambda}^2 |p|^{\lambda}}{2}. \quad (20.389)$$

The probability (20.144) of returns becomes now

$$P(x_b t_b | x_a t_a) = \prod_{\lambda} \left\{ \int \mathcal{D}\eta_{\lambda} \int \mathcal{D}x \exp \left[- \int_{t_a}^{t_b} dt \tilde{H}_{\lambda}(\eta_{\lambda}(t)) \right] \right\} \delta[\dot{x} - \sum_{\lambda} \eta_{\lambda}]. \quad (20.390)$$

If we insert here a Fourier representation of the δ -functional, we obtain

$$P(x_b t_b | x_a t_a) = \int_{-\infty}^{\infty} \frac{\mathcal{D}p}{2\pi} \prod_{\lambda} \left[\int \mathcal{D}\eta_{\lambda} \right] \int \mathcal{D}x e^{\int_{t_a}^{t_b} dt [ip(t)\dot{x}(t) - \tilde{H}_{\lambda}(\eta_{\lambda}(t))]} e^{-i \sum_{\lambda} \int_{-\infty}^{\infty} dt p(t)\eta_{\lambda}(t)}. \quad (20.391)$$

Performing the path integrals over $\eta_{\lambda}(t)$, this becomes

$$P(x_b t_b | x_a t_a) = \int_{-\infty}^{\infty} \frac{\mathcal{D}p}{2\pi} \int \mathcal{D}x e^{\int_{t_a}^{t_b} dt [ip(t)\dot{x}(t) - H_{\lambda}(p)]}, \quad (20.392)$$

where the Hamiltonian is the sum of the group Hamiltonians

$$H(p) \equiv \sum_{\lambda} H_{\lambda}(p). \quad (20.393)$$

The continuous generalization of this is

$$H(p) = H(|p|) \equiv \int_0^{\infty} d\lambda \sigma_{\lambda}^2 |p|^{\lambda}. \quad (20.394)$$

The spectral function σ_{λ}^2 must be extracted from the data by forming the integral

$$\sigma_{\lambda}^2 = \int_{-\infty}^{i\infty} \frac{d \log |p|}{2\pi i} p^{-\lambda} H(p). \quad (20.395)$$

20.7 Option Pricing

Historically, the most important use of path integrals in financial markets was made in the context of determining a fair price of financial derivatives, in particular options.¹² Options are an ancient financial tool. They are used for speculative purposes or for hedging major market transactions against unexpected changes in the market environment. These can sometimes produce dramatic price explosions or erosions, and options are supposed to prevent the destruction of large amounts of capital. Ancient Romans, Grecians, and Phoenicians traded options against outgoing cargos from their local seaports. In financial markets, options are contracted between two parties in which one party has the right but not the obligation to do something, usually to buy or sell some underlying asset. Having rights without obligations has a value, so option holders must pay a price for acquiring them. The price depends on the value of the associated asset, which is why they are also called *derivative assets* or briefly *derivatives*. *Call options* are contracts giving the option holder the right to buy something, while *put options* entitle the holder to sell something. The price of an option is called *premium*. Usually, options are associated with stock, bonds, or commodities like oil, metals or other raw materials. In the sequel we shall consider call options on stocks, to be specific.

Modern option pricing techniques have their roots in early work by Charles Castelli who published in 1877 a book entitled *The Theory of Options in Stocks*

¹²An introduction is found on the site <http://bradley.bradley.edu/~arr/bsm/model.html>.

and Shares. This book presented an introduction to the hedging and speculation aspects of options. Twenty three years later, Louis Bachelier offered the earliest known analytical valuation for options in his dissertation at the Sorbonne [86]. Remarkably, Bachelier discovered the treatment of stochastic phenomena five years before Einstein's related but much more famous work on Brownian motion [87], and twenty-three years before Wiener's mathematical development [88]. The stochastic differential equations considered by him still had an important defect of allowing for negative security prices, and for option prices exceeding the price of the underlying asset. Bachelier's work was continued by Paul Samuelson, who wrote in 1955 an unpublished paper entitled *Brownian Motion in the Stock Market*. During that same year, Richard Krueger, one of Samuelson's students, cited Bachelier's work in his dissertation *Put and Call Options: A Theoretical and Market Analysis*. In 1962, a dissertation by A. James Boness entitled *A Theory and Measurement of Stock Option Value* developed a more satisfactory pricing model which was further improved by Fischer Black and Myron Scholes. In 1973 they published their famous *Black and Scholes Model* [89] which, together with the improvements introduced by Robert Merton, earned them the Nobel prize in 1997.¹³

As discussed before, the Gaussian distribution severely underestimates the probability of large jumps in asset prices and this was the main reason for the catastrophic failure in the early fall of 1998 of the hedge fund *Long Term Capital Management*, which had Scholes and Merton on the advisory board (and as shareholders). The fund contained derivatives with a notional value of 1,250 Billion US\$. The fund collected 2% for administrative expenses and 25% of the profits, and was initially extremely profitable. It offered its shareholders returns of 42.8% in 1995, 40.8% in 1996, and 17.1% even in the disastrous year of the Asian crisis 1997. But in September 1998, after mistakenly gambling on a convergence in interest rates, it almost went bankrupt. A number of renowned international banks and Wall Street institutions had to bail it out with 3.5 Billion US\$ to avoid a chain reaction of credit failures.

In spite of this failure, the simple model is still being used today for a rough but fast orientation on the fairness of an option price.

20.7.1 Black-Scholes Option Pricing Model

In the early seventies, Fischer Black was working on a valuation model for stock warrants and observed that his formulas resembled very much the well-known equations for heat transfer. Soon after this, Myron Scholes joined Black and together they discovered an approximate option pricing model which is still of wide use.

The Black and Scholes Model is based on the following assumptions:

1. The returns are normally distributed.

The shortcomings of this assumption have been discussed above in Section 20.1. The appropriate improvement of the model will be developed below.

¹³For F. Black the prize came too late — he had died two years earlier.

2. Markets are efficient.

This assumption implies that the market operates continuously with share prices following a continuous stochastic process without memory. It also implies that different markets have the same asset prices.

This is not quite true. Different markets do in general have slightly different prices. Their differences are kept small by the existence of arbitrage dealers. There also exist correlations over a short time scale which make it possible, in principle, to profit without risk from the so-called *statistical arbitrage*. This possibility is, however, strongly limited by transaction fees.

3. No commissions are charged.

This assumption is not satisfied. Usually, market participants have to pay a commission to buy or sell assets. Even floor traders pay some kind of fee, although this is usually very small. The fees paid by individual investors is more substantial and can distort the output of the model.

4. Interest rates remain constant and known.

The Black and Scholes model assumes the existence of a *riskfree interest rate* to represent this constant and known rate. In reality there is no such thing as the riskfree rate. As an approximation, one uses the discount rate on U.S. Government Treasury Bills with 30 days left until maturity. During periods of rapidly changing interest rates, these 30 day rates are often subject to change, thereby violating one of the assumptions of the model.

5. The stock pays no dividends during the option's life.

Most companies pay dividends to their share holders, so this is a limitation to the model since higher dividends lead to lower call premiums. There is, however, a simple possibility of adjusting the model to the real situation by subtracting the discounted value of a future dividend from the stock price.

6. European exercise terms are used.

European exercise terms imply the exercise of an option only on the expiration date. This is in contrast to the American exercise terms which allow for this at any time during the life of the option. This greater flexibility makes an American option more valuable than the European one.

The difference is, however, not dramatic in praxis because very few calls are ever exercised before the last few days of their life, since an early exercise means giving away the remaining time value on the call. Different exercise times towards the end of the life of a call are irrelevant since the remaining time value is very small and the intrinsic value has a small time dependence, barring a dramatic event right before expiration date.

Since 1973, the original Black and Scholes Option Pricing Model has been improved and extended considerably. In the same year, Robert Merton [90] included the effect of dividends. Three years later, Jonathan Ingersoll relaxed the assumption of no taxes or transaction costs, and Merton removed the restriction of constant interest rates. In recent years, the model has been generalized to determine the prices of options with many different properties.

The relevance of path integrals to this field was recognized in 1988 by the theoretical physicist J.W. Dash, who wrote two unpublished papers on the subject entitled *Path Integrals and Options I* and *II* [91]. Since then many theoretical physicists have entered the field, and papers on this subject have begun appearing on the Los Alamos server [13, 92, 93].

20.7.2 Evolution Equations of Portfolios with Options

The option price $O(t)$ has larger fluctuations than the associated stock price. It usually varies with a slope $\partial O(S(t), t)/\partial S(t)$ which is commonly denoted by $\Delta(S(t), t)$ and called the *Delta* of the option. If $\Delta(S(t), t)$ depends only weakly on $S(t)$ and t it is possible, in the ideal case of Gaussian price fluctuations, to guarantee a steady growth of a portfolio. One merely has to mix a suitable number $N_S(t)$ stocks with $N_O(t)$ options and short-term bonds whose number is denoted by $N_B(t)$. As mentioned before, these are typically U.S. Government Treasury Bills with 30 days left to maturity which have only small price fluctuations. The composition $[N_S(t), N_O(t), N_B(t)]$ is referred to as the *strategy* of the portfolio manager. The total wealth has the value

$$W(t) = N_S(t)S(t) + N_O(t)O(S, t) + N_B(t)B(t). \quad (20.396)$$

The goal is to make $W(t)$ grow with a smooth exponential curve *without fluctuations*

$$\dot{W}(t) \approx r_W W(t). \quad (20.397)$$

As an idealization, the short-term bonds are assumed to grow deterministically without any fluctuations:

$$\dot{B}(t) \approx r_B B(t). \quad (20.398)$$

The rate r_B is the earlier-introduced riskfree interest rate encountered in true markets only if there are no events changing excessively the value of short-term bonds.

The existence of arbitrage dealers will ensure that the growth rate r_W is equal to that of the short-term bonds

$$r_W \approx r_B. \quad (20.399)$$

Otherwise the dealers would change from one investment to the other.

In the decomposition (20.396), the desired growth (20.397) reads

$$\begin{aligned} N_S(t)\dot{S}(t) + N_O(t)\dot{O}(S, t) + N_B(t)\dot{B}(t) + \dot{N}_S(t)S(t) + \dot{N}_O(t)O(S, t) + \dot{N}_B(t)B(t) \\ = r_W [N_S(t)S(t) + N_O(t)O(S, t) + N_B(t)B(t)]. \end{aligned} \quad (20.400)$$

Due to (20.398) and (20.399), the terms containing $N_B(t)$ without a dot drop out. Moreover, if no extra money is inserted into or taken from the system, i.e., if stocks, options, and bonds are only traded against each other, this does not change the total wealth, assuming the absence of commissions. This so-called *self-financing strategy* is expressed in the equation

$$\dot{N}_S(t)S(t) + \dot{N}_O(t)O(S, t) + \dot{N}_B(t)B(t) = 0. \quad (20.401)$$

Thus the growth equation (20.397) translates into

$$\dot{W}(t) = N_S\dot{S} + N_O\dot{O} + N_B\dot{B} = r_W(N_S S + N_O O + N_B B). \quad (20.402)$$

Due to the equality of the rates $r_W = r_B$ and Eq. (20.398), the entire contribution of $B(t)$ cancels, and we obtain

$$N_S\dot{S} + N_O\dot{O} = r_W(N_S S + N_O O). \quad (20.403)$$

The important observation is now that there exists an optimal ratio between the number of stocks N_S and the number of options N_O , which is equal to the negative slope $\Delta(S(t), t)$:

$$\frac{N_S(t)}{N_O(t)} = -\Delta(S(t), t) = -\frac{\partial O(S(t), t)}{\partial S(t)}. \quad (20.404)$$

Then Eq. (20.403) becomes

$$N_S\dot{S} + N_O\dot{O} = N_O r_W \left(-\frac{\partial O}{\partial x} + O \right). \quad (20.405)$$

The two terms on the left-hand side are treated as follows: First we use the relation (20.404) to rewrite

$$N_S\dot{S} = -N_O \frac{\partial O(S, t)}{\partial S} \dot{S} = -N_O \frac{\partial O(S, t)}{\partial x} \frac{\dot{S}}{S}. \quad (20.406)$$

In the second term on the left-hand side of (20.405), we expand the total time dependence of the option price in a Taylor series

$$\begin{aligned} \frac{dO}{dt} &= \frac{1}{dt} [O(x(t) + \dot{x}(t) dt, t + dt) - O(x(t), t)] \\ &= \frac{\partial O}{\partial t} + \frac{\partial O}{\partial x} \dot{x} + \frac{1}{2} \frac{\partial^2 O}{\partial x^2} \dot{x}^2 dt + \frac{1}{3!} \frac{\partial^3 O}{\partial x^3} \dot{x}^3 dt^2 + \dots \end{aligned} \quad (20.407)$$

We have gone over to the logarithmic stock price variable $x(t)$ rather than $S(t)$ itself. In financial mathematics, the lowest derivatives on the right-hand side are all denoted by special Greek symbols. We have already introduced the name Delta for the slope $\partial O/\partial S$. The curvature $\Gamma \equiv \partial^2 O/\partial S^2 = (\partial^2 O/\partial x^2 - \partial O/\partial x)/S^2$ is called the *Gamma* of an option. Another derivative with a standard name is the

Vega $V \equiv \partial O / \partial \sigma$. The partial time derivative $\partial O / \partial t$ is denoted by Θ . The set of these quantities is collectively called the *Greeks* [94].

In general, the expansion (20.407) is carried to arbitrary powers of \dot{x} as in (20.273). It is, of course, only an abbreviated notation for the proper expansion in powers of a stochastic variable to be performed as in Eq. (20.273). After inserting (20.407) and (20.406) on the left-hand side of Eq. (20.405), this becomes

$$\begin{aligned} N_S \dot{S} + N_O \dot{O} &= -N_O \frac{\partial O}{\partial x} \frac{\dot{S}}{S} \\ &+ N_O \left(\frac{\partial O}{\partial t} + \frac{\partial O}{\partial x} \dot{x} + \frac{1}{2} \frac{\partial^2 O}{\partial x^2} \dot{x}^2 dt + \frac{1}{3!} \frac{\partial^3 O}{\partial x^3} \dot{x}^3 dt + \dots \right) \quad (20.408) \\ &= N_O \left[\frac{\partial O}{\partial t} + \left(\dot{x} - \frac{\dot{S}}{S} \right) \frac{\partial O}{\partial x} + \frac{1}{2} \frac{\partial^2 O}{\partial x^2} \dot{x}^2 dt + \frac{1}{3!} \frac{\partial^3 O}{\partial x^3} \dot{x}^3 dt + \dots \right]. \end{aligned}$$

Replacing further the left-hand side by the right-hand side of (20.405) we obtain

$$\frac{\partial O}{\partial t} = -r_W O - \left(\dot{x} - \frac{\dot{S}}{S} + r_W \right) \frac{\partial O}{\partial x} - \frac{1}{2} \frac{\partial^2 O}{\partial x^2} \dot{x}^2 dt - \frac{1}{3!} \frac{\partial^3 O}{\partial x^3} \dot{x}^3 dt + \dots = 0. \quad (20.409)$$

The crucial observation which earned Black and Scholes the Nobel prize is that for Gaussian fluctuations with a Hamiltonian $H(p) = \sigma^2 p^2 / 2$, the equation (20.409) becomes very simple. First, due to the Itô relation (20.4), the prefactor of $-\partial O / \partial x$ becomes a constant

$$r_W - \frac{\sigma^2}{2} \equiv r_{x_W}, \quad (20.410)$$

where the notation r_{x_W} is chosen by analogy with r_x in the Itô relation (20.5). Thus there are no more fluctuations in the prefactor of $\partial O / \partial x$.

Moreover, also the fluctuations of all remaining terms

$$-\frac{1}{2} \frac{\partial^2 O}{\partial x^2} \dot{x}^2 dt - \frac{1}{6} \frac{\partial^3 O}{\partial x^3} \dot{x}^3 dt^2 + \dots \quad (20.411)$$

can be neglected due to the result (18.429) and the estimates (18.431), which make truncate the expansion (20.411) and make it equal to $-(\sigma^2/2) \partial^2 O / \partial x^2$. Thus Eq. (20.409) loses its stochastic character, and the fair option price $O(x, t)$ is found to obey the Fokker-Planck-like differential equation

$$\frac{\partial O}{\partial t} = r_W O - r_{x_W} \frac{\partial O}{\partial x} - \frac{\sigma^2}{2} \frac{\partial^2 O}{\partial x^2}, \quad (20.412)$$

At the same time, the total wealth (20.402) loses its stochastic character and grows with the riskfree rate r_W following the deterministic Eq. (20.398). The cancellation of the fluctuations is a consequence of choosing the ratio between options and stocks according to Eq. (20.404). The portfolio is now hedged against fluctuation.

The Fokker-Planck equation (20.412) can be expressed completely in terms of the Greeks of the option, using the relation (20.410):

$$\Theta = r_W O - r_{x_W} S \Delta - \frac{\sigma^2}{2} \left(S \frac{\partial O}{\partial S} + S^2 \frac{\partial^2 O}{\partial S^2} \right) = r_W O - r_W S \Delta - \frac{\sigma^2}{2} S^2 \Gamma. \quad (20.413)$$

The strategy to make a portfolio riskfree by balancing the fluctuations of N_S stocks by N_O options to satisfy Eq. (20.404) is called Delta-hedging. Hedging is of course imperfect. Since $\Delta(S(t), t)$ depends on the stock price, a Delta hedge requires frequent re-balancing of the portfolio, even several times per day. After a time span δt , the Delta has changed by

$$\delta \Delta = \frac{d}{dt} \frac{\partial^2 O(S(t), t)}{\partial S(t)} \delta t = \left[\frac{\partial}{\partial t} \frac{\partial O(S(t), t)}{\partial S(t)} + \frac{\partial^2 O(S(t), t)}{\partial S(t)^2} \right] \delta t = \left[\frac{\partial \Theta}{\partial S} + \Gamma \right] \delta t. \quad (20.414)$$

So one has to readjust the ratio of stocks and options in Eq. (20.404) by

$$\delta \frac{N_S}{N_O} = -\delta \Delta = - \left(\frac{\partial \Theta}{\partial S} + \Gamma \right) \delta t. \quad (20.415)$$

This procedure is called *dynamical Δ -hedging*. Since buying and selling costs money, δt cannot be made too small, otherwise dynamical hedging becomes too expensive.

In principle it is possible to buy a third asset to hedge also the curvature Gamma. This procedure is not so popular, again because of the transaction costs.

For non-Gaussian noise, the differential equation (20.409) is still stochastic due to remaining fluctuations in the expansion terms (20.411). This is an obstacle to building a riskfree portfolio with deterministically growing total wealth $W(t)$. As in Eq. (20.255) we can only derive the equation of motion for the average value

$$\left\langle \frac{1}{2} \frac{\partial^2 O}{\partial x^2} \dot{x}^2 dt + \frac{1}{6} \frac{\partial^3 O}{\partial x^3} \dot{x}^3 dt^2 + \dots \right\rangle = -\bar{H}(i\partial_x) O. \quad (20.416)$$

Hence a fair option price can only be calculated on the average from the Fokker-Planck-like differential equation

$$\frac{\partial}{\partial t} \langle O \rangle = \left[r_W - r_{x_W} \frac{\partial}{\partial x} + \bar{H}(i\partial_x) \right] \langle O \rangle, \quad (20.417)$$

where we have defined, by analogy with (20.268) and (20.410), an auxiliary rate parameter

$$r_{x_W} \equiv r_W + \bar{H}(i). \quad (20.418)$$

However, as pointed out in Subsection 20.2.2, this limitation is not really stringent for discrete short-time data if the tails of the noise distribution are non-Gaussian

with semi-heavy tails. Then the higher expansion terms in Eq. (20.411) are suppressed by a small factor $\sigma\sqrt{\Delta t}$, and the expectation values in Eqs. (20.416) and (20.417) can again be dropped approximately.

For Gaussian fluctuations, the Fokker-Planck equation (20.412) can easily be solved. If we rename $t \rightarrow t_a$, and $x \rightarrow x_a$, for symmetry reasons, the solution which starts out, at some time t_b , like $\delta(x_a - x_b)$, has the Fourier representation

$$P^{(M,r_x)}(x_b t_b | x_a t_a) = e^{-r_W(t_b-t_a)} \int_{-\infty}^{\infty} \frac{dp}{2\pi} e^{ip(x_b-x_a)} e^{-(\sigma^2 p^2/2 + ir_{x_W} p)(t_b-t_a)}. \quad (20.419)$$

A convergent integral exists for $t_b > t_a$.

For non-Gaussian fluctuations with semi-heavy tails, there exists an approximate solution whose Fourier representation is

$$P^{(M,r_x)}(x_b t_b | x_a t_a) = e^{-r_W(t_b-t_a)} \int_{-\infty}^{\infty} \frac{dp}{2\pi} e^{ip(x_b-x_a)} e^{-[\bar{H}(p) + ir_{x_W} p](t_b-t_a)}, \quad (20.420)$$

with $\bar{H}(p)$ of Eq. (20.141).

Recalling the discussion in Section 20.3, this distribution function is recognized as a member of the equivalent family of martingale distributions (20.293) for the stock price $S(t) = e^{x(t)}$. It is the particular distribution in which the discount factor r coincides with the riskfree interest rate r_W .

20.7.3 Option Pricing for Gaussian Fluctuations

For Gaussian fluctuations where $H(p) = \sigma^2 p^2/2$, the integral in (20.419) can easily be performed and yields for $t_b > t_a$ the martingale distribution

$$P^{(M,r_x)}(x_b t_b | x_a t_a) = \frac{e^{-r_W(t_b-t_a)}}{\sqrt{2\pi\sigma^2(t_b-t_a)}} \exp\left\{-\frac{[x_b - x_a - r_{x_W}(t_b-t_a)]^2}{2\sigma^2(t_b-t_a)}\right\}. \quad (20.421)$$

This is the risk-neutral martingale distribution of Eq. (20.289) for $r = r_x$.

This distribution is obviously the solution of the path integral

$$P^{(M,r_x)}(x_b t_b | x_a t_a) = e^{-r_W(t_b-t_a)} \int \mathcal{D}x \exp\left\{-\frac{1}{2\sigma^2} \int_{t_a}^{t_b} [\dot{x} - r_{x_W}]^2\right\}. \quad (20.422)$$

An option is written for a certain *strike price* E of the stock. The value of the option at its expiration date t_b is given by the difference between the stock price on expiration date and the strike price:

$$O(x_b, t_b) = \Theta(x_b - x_E)(e^{x_b} - e^{x_E}), \quad (20.423)$$

where

$$x_E \equiv \log E. \quad (20.424)$$

The Heaviside function in (20.423) accounts for the fact that only for $S_b > E$ it is worthwhile to execute the option.

From (20.423) we calculate the option price at an arbitrary earlier time using the time evolution probability (20.421)

$$O(x_a, t_a) = \int_{-\infty}^{\infty} dx_b O(x_b, t_b) P^{(M, r_W)}(x_b t_b | x_a t_a). \quad (20.425)$$

Inserting (20.423) we obtain the sum of two terms

$$O(x_a, t_a) = O_S(x_a, t_a) - O_E(x_a, t_a), \quad (20.426)$$

where

$$O_S(x_a, t_a) = \frac{e^{-r_W(t_b-t_a)}}{\sqrt{2\pi\sigma^2(t_b-t_a)}} \int_{x_E}^{\infty} dx_b e^{x_b} \exp\left\{-\frac{[x_b - x_a - r_{x_W}(t_b-t_a)]^2}{2\sigma^2(t_b-t_a)}\right\}, \quad (20.427)$$

and

$$O_E(x_a, t_a) = E e^{-r_W(t_b-t_a)} \frac{1}{\sqrt{2\pi\sigma^2(t_b-t_a)}} \int_{x_E}^{\infty} dx_b \exp\left\{-\frac{[x_b - x_a - r_{x_W}(t_b-t_a)]^2}{2\sigma^2(t_b-t_a)}\right\}. \quad (20.428)$$

In the second integral we set

$$x_- \equiv x_a + r_{x_W}(t_b-t_a) = x_a + \left(r_W - \frac{1}{2}\sigma^2\right)(t_b-t_a), \quad (20.429)$$

and obtain

$$O_E(x_a, t_a) = E \frac{e^{-r_W(t_b-t_a)}}{\sqrt{2\pi\sigma^2(t_b-t_a)}} \int_{x_E-x_-}^{\infty} dx_b \exp\left\{-\frac{x_b^2}{2\sigma^2(t_b-t_a)}\right\}. \quad (20.430)$$

After rescaling the integration variable $x_b \rightarrow -\xi\sigma\sqrt{t_b-t_a}$, this can be rewritten as

$$O_E(x_a, t_a) = e^{-r_W(t_b-t_a)} E N(y_-), \quad (20.431)$$

where $N(y)$ is the cumulative Gaussian distribution function

$$N(y) \equiv \int_{-\infty}^y \frac{d\xi}{\sqrt{2\pi}} e^{-\xi^2/2} = \frac{1}{2} \left[1 + \operatorname{erf}\left(\frac{y}{\sqrt{2}}\right) \right], \quad (20.432)$$

evaluated at

$$\begin{aligned} y_- &\equiv \frac{x_- - x_E}{\sqrt{\sigma^2(t_b-t_a)}} = \frac{\log[S(t_a)/E] + r_{x_W}(t_b-t_a)}{\sqrt{\sigma^2(t_b-t_a)}} \\ &= \frac{\log[S(t_a)/E] + \left(r_W - \frac{1}{2}\sigma^2\right)(t_b-t_a)}{\sqrt{\sigma^2(t_a-t_b)}}. \end{aligned} \quad (20.433)$$

The integral in the first contribution (20.427) to the option price is found after completing the exponent in the integrand quadratically as follows:

$$\begin{aligned} x_b - \frac{[x_b - x_a - r_{x_W}(t_b - t_a)]^2}{2\sigma^2(t_b - t_a)} \\ = -\frac{[x_b - x_a - (r_{x_W} + \sigma^2)(t_b - t_a)]^2 - 2r_W\sigma^2(t_b - t_a) - 2x_a\sigma^2(t_b - t_a)}{2\sigma^2(t_b - t_a)}. \end{aligned} \quad (20.434)$$

Introducing now

$$x_+ \equiv x_a + (r_{x_W} + \sigma^2)(t_b - t_a) = x_a + \left(r_W + \frac{1}{2}\sigma^2\right)(t_b - t_a), \quad (20.435)$$

and rescaling x_b as before, we obtain

$$O_S(x_a, t_a) = S(t_a)N(y_+), \quad (20.436)$$

with

$$\begin{aligned} y_+ &\equiv \frac{x_+ - x_E}{\sqrt{\sigma^2(t_a - t_b)}} = \frac{\log[S(t_a)/E] + (r_{x_W} + \sigma^2)(t_b - t_a)}{\sqrt{\sigma^2(t_a - t_b)}} \\ &= \frac{\log[S(t_a)/E] + \left(r_W + \frac{1}{2}\sigma^2\right)(t_b - t_a)}{\sqrt{\sigma^2(t_a - t_b)}}. \end{aligned} \quad (20.437)$$

The combined result

$$O(x_a, t_a) = S(t_a)N(y_+) - e^{-r_W(t_b - t_a)}E N(y_-) \quad (20.438)$$

is the celebrated *Black-Scholes formula* of option pricing.

In Fig. 20.28 we illustrate how the dependence of the call price on the stock price varies with different times to expiration $t_b - t_a$ and with different volatilities σ .

Floor dealers of stock markets use the Black-Scholes formula to judge how expensive options are, so they can decide whether to buy or to sell them. For a given riskfree interest rate r_W and time to expiration $t_b - t_a$, and a set of option, stock, and strike prices O , S , E , they calculate the volatility from (20.438). The result is called the *implied volatility*, and denoted by $\Sigma(x - x_E)$. As typical plot as a function of $x - x_E$ is shown in Fig. 20.29.

If the Black-Scholes formula were exactly valid, the data should lie on a horizontal line $\Sigma(x - x_E) = \sigma$. Instead, they scatter around a parabola which is called the *smile* of the option. The smile indicates the presence of a nonzero kurtosis in the distribution of the returns, as we shall see in Subsection 20.7.8.

It goes without saying that if the integral (20.427) is carried out over the entire x_b axis, it becomes independent of time, due to the martingale character of the risk-neutral distribution $P^{(M, r_W)}(x_b t_b | x_a t_a)$.

Figure 20.28 Left: Dependence of call price O on stock price S for different times before expiration date (increasing dash length: 1, 2, 3, 4, 5 months). The parameters are $E = 50$ US\$, $\sigma = 40\%$, $r_W = 6\%$ per month. Right: Dependence on the strike price E for fixed stock price 35 US\$ and the same times to expiration (increasing with dash length). Bottom: Dependence on the volatilities (from left to right: 80%, 60%, 20%, 10%, 1%) at a fixed time $t_b - t_a = 3$ months before expiration.

Figure 20.29 Smile deduced from options (see [13]).

20.7.4 Option Pricing for Asian Option

In an Asian option one does not bet on an option price at the expiration date but on an average option price over the option life. The calculation is very simple if we recall the time amplitude amplitude (3.200) of a particle at a fixed average x_0 . The stochastic version of the quantum-mechanical expression (3.200) is

$$P(x_b t_b | x_a t_a)^{x_0} = \frac{\sqrt{3}}{\pi \sigma^2 (t_b - t_a)} \exp \left\{ -\frac{1}{2\sigma^2 (t_b - t_a)} \left[(x_b - x_a)^2 + 12 \left(x_0 - \frac{x_b + x_a}{2} \right)^2 \right] \right\}. \tag{20.439}$$

For the growth rate r_W , the associated martingale becomes

$$P^{(M,r_x)}(x_b t_b | x_a t_a)^{x_0} = e^{-r_W(t_b-t_a)} \frac{\sqrt{3}}{\pi \sigma^2(t_b-t_a)} \times \exp \left\{ -\frac{1}{2\sigma^2(t_b-t_a)} \left[(x_b - x_a - r_{x_W}(t_b - t_a))^2 + 12 \left(x_0 - \frac{x_b + x_a}{2} \right)^2 \right] \right\}, \quad (20.440)$$

whose integral over x_0 yields back the previous martingale distribution (20.421)

$$\int_{-\infty}^{\infty} dx_0 P^{(M,r_x)}(x_b t_b | x_a t_a)^{x_0} = P^{(M,r_x)}(x_b t_b | x_a t_a). \quad (20.441)$$

Instead of (20.423), the option price at expiration is now

$$O(x_b, t_b) = \Theta(x_b - x_0)(e^{x_b} - e^{x_0}), \quad (20.442)$$

so that instead of (20.426) is replaced by the difference between

$$O_S(x_a, t_a) = \int_{-\infty}^{\infty} dx_0 \int_{x_0}^{\infty} dx_b e^{x_b} P^{(M,r_x)}(x_b t_b | x_a t_a)^{x_0}, \quad (20.443)$$

which is the same as (20.427), due to (20.441), and

$$O_{\bar{x}}(x_a, t_a) = \int_{-\infty}^{\infty} dx_0 e^{x_0} \int_{x_0}^{\infty} dx_b P^{(M,r_x)}(x_b t_b | x_a t_a)^{x_0}, \quad (20.444)$$

which replaces (20.430). Since both expressions involve integrals over errorfunctions it is useful to represent the δ -function in (20.442) as a Fourier integral and rewrite the option price at t_a as

$$O(x_a, t_a) = \int_{-\infty}^{\infty} \frac{dt}{2\pi i} \frac{e^{i(x_b-x_0)t}}{t - i\eta} \times \int_{-\infty}^{\infty} dx_0 \int_{-\infty}^{\infty} dx_b (e^{x_b} - e^{x_0}) P^{(M,r_x)}(x_b t_b | x_a t_a)^{x_0}, \quad (20.445)$$

The result of the double integral in the second line is simply

$$e^{-A(t)} - e^{-A_0(t)}, \quad (20.446)$$

with

$$A(t) = -r_W(t_b - t_a) - \frac{i}{2} \left(r_W + \frac{\sigma^2}{2} \right) t(t_b - t_a) + \frac{\sigma^2 t^2 (t_b - t_a)}{6},$$

$$A_0(t) = \left(-r_W + \frac{\sigma^2}{6} \right) \frac{t_b - t_a}{2} - \frac{i}{2} \left(r_W - \frac{\sigma^2}{6} \right) t(t_b - t_a) + \frac{\sigma^2 t^2 (t_b - t_a)}{6}. \quad (20.447)$$

Now we use the integral formula

$$\int_{-\infty}^{\infty} \frac{dt}{2\pi i} \frac{e^{-a^2 t^2 / 2 + i b t}}{t - i\eta} = N[b/a]. \quad (20.448)$$

and find [95]

$$O(x_a, t_a) = S(t_a)[N(z_+) - e^{-(r_W + \sigma^2/6)(t_b - t_a)/2} N(z_-)], \tag{20.449}$$

where

$$z_+ = \sqrt{\frac{3(t_b - t_a)}{4\sigma^2}} \left(r_W + \frac{\sigma^2}{2} \right), \quad z_- = \sqrt{\frac{3(t_b - t_a)}{4\sigma^2}} \left(r_W - \frac{\sigma^2}{6} \right). \tag{20.450}$$

20.7.5 Option Pricing for Boltzmann Distribution

The above result can easily be extended to price the options for assets whose returns obey the Boltzmann distribution (20.204). Since this is a superposition of Gaussian distributions, we merely have to perform the same superposition over the Black-Scholes formula (20.438). Thus we insert (20.438) into the integral (20.204) and obtain the option price for the Boltzmann-distributed assets of variance σ^2 :

$$O^B(x_a, t_a) = \left(\frac{t}{\sigma^2} \right)^t \frac{1}{\Gamma(t)} \int_0^\infty \frac{dv}{v} v^t e^{-tv/\sigma^2} O^v(x_a, t_a), \tag{20.451}$$

where $O^v(x_a, t_a)$ is the Black-Scholes option price (20.438) of variance v . The superscript indicates that the variance σ^2 in the variables of y_+ and y_- in (20.433) and (20.437) is now exchanged by the integration variable v .

Since the Boltzmann distribution for the minute data turns rapidly into a Gaussian (recall Fig. 20.15), the price changes with respect to the Black-Scholes formula are relevant only for short-term options running less than a week. The changes can most easily be estimated by using the expansion (20.209) to write

$$O^B(x_a, t_a) = O^v(x_a, t_a) + \frac{[2T^2(1 - 1/t)]^2}{2t} \partial_v^2 O^v(x_a, t_a) + \dots \tag{20.452}$$

20.7.6 Option Pricing for General Non-Gaussian Fluctuations

For general non-Gaussian fluctuations with semi-heavy tails, the option price must be calculated numerically from Eqs. (20.425) and (20.423). Inserting the Fourier representation (20.419) and using the Hamiltonian

$$H_{r_{x_W}}(p) \equiv \bar{H}(p) + ir_{x_W} p \tag{20.453}$$

defined as in (20.141), this becomes

$$\begin{aligned} O(x_a, t_a) &= \int_{x_E}^\infty dx_b (e^{x_b} - e^{x_E}) P(x_b t_b | x_a t_a) \\ &= e^{-r_W(t_b - t_a)} \int_{x_E}^\infty dx_b (e^{x_b} - e^{x_E}) \int_{-\infty}^\infty \frac{dp}{2\pi} e^{ip(x_b - x_a) - H_{r_{x_W}}(p)(t_b - t_a)}. \end{aligned} \tag{20.454}$$

The integrand can be rearranged as follows:

$$O(x_a, t_a) = e^{-r_W(t_b-t_a)} \int_{x_E}^{\infty} dx_b \int_{-\infty}^{\infty} \frac{dp}{2\pi} \left[e^{x_a} e^{i(p-i)(x_b-x_a)} - e^{x_E} e^{ip(x_b-x_a)} \right] e^{-H_{r_{x_W}}(p)(t_b-t_a)}. \quad (20.455)$$

Two integrations are required. This would make a numerical calculation quite time consuming. Fortunately, one integration can be done analytically. For this purpose we change the momentum variable in the first part of the integral from p to $p+i$ and rewrite the integral in the form

$$O(x_a, t_a) = e^{-r_W(t_b-t_a)} \int_{x_E}^{\infty} dx_b \int_{-\infty}^{\infty} \frac{dp}{2\pi} e^{ip(x_b-x_a)} f(p), \quad (20.456)$$

with

$$f(p) \equiv e^{x_a} e^{-H_{r_{x_W}}(p+i)(t_b-t_a)} - e^{x_E} e^{-H_{r_{x_W}}(p)(t_b-t_a)}. \quad (20.457)$$

We have suppressed the arguments $x_a, x_E, t_b - t_a$ in $f(p)$, for brevity. The integral over x_b in (20.456) runs over the Fourier transform

$$\tilde{f}(x_b - x_a) = \int_{-\infty}^{\infty} \frac{dp}{2\pi} e^{ip(x_b-x_a)} f(p) \quad (20.458)$$

of the function $f(p)$. It is then convenient to express the integral $\int_{x_E}^{\infty} dx_b$ in terms of the Heaviside function $\Theta(x_b - x_E)$ as $\int_{-\infty}^{\infty} dx_b \Theta(x_b - x_E)$ and use the Fourier representation (1.312) of the Heaviside function to write

$$\int_{x_E}^{\infty} dx_b \tilde{f}(x_b - x_a) = \int_{-\infty}^{\infty} dx_b \int_{-\infty}^{\infty} \frac{dq}{2\pi} \frac{i}{q+i\eta} e^{-iq(x_b-x_E)} \tilde{f}(x_b - x_a). \quad (20.459)$$

Inserting here the Fourier representation (20.458), we can perform the integral over x_b and obtain the momentum space representation of the option price

$$O(x_a, t_a) = e^{-r_W(t_b-t_a)} \int_{-\infty}^{\infty} \frac{dp}{2\pi} e^{ip(x_E-x_a)} \frac{i}{p+i\eta} f(p). \quad (20.460)$$

For numerical integrations, the singularity at $p=0$ is inconvenient. We therefore employ the decomposition (18.54)

$$\frac{1}{p+i\eta} = \frac{\mathcal{P}}{p} - i\pi\delta(p), \quad (20.461)$$

to write

$$O(x_a, t_a) = e^{-r_W(t_b-t_a)} \left[\frac{1}{2} f(0) + i \int_{-\infty}^{\infty} \frac{dp}{2\pi} \frac{e^{ip(x_E-x_a)} f(p) - f(0)}{p} \right]. \quad (20.462)$$

We have used the fact that the principal value of the integral over $1/p$ vanishes to subtract the constant $f(0)$ from $e^{ip(x_E-x_a)} f(p)$. After this, the integrand is regular and does not need any more the principal-value specification, and allows for a numerical integration.

Figure 20.30 Difference between call price $O(S, t)$ obtained from truncated Lévy distribution with kurtosis $\kappa = 4$ and Black-Scholes price $O_{BS}(S, t)$ with $\sigma^2 = \bar{v}$ as function of stock price S for different times before expiration date (increasing dash length: 1, 2, 3, 4, 5 months). The parameters are $E = 50$ US\$, $\sigma = 40\%$, $r_W = 6\%$ per month.

For x_a very much different from x_E , we may approximate

$$\int_{-\infty}^{\infty} \frac{dp}{2\pi} \frac{e^{ip(x_E - x_a)} f(p) - f(0)}{p} \approx \frac{1}{2} \epsilon(x_a - x_E) f(0), \tag{20.463}$$

where $\epsilon(x) \equiv 2\Theta(x) - 1$ is the step function (1.315), and obtain

$$O(x_a, t_a) \approx \frac{e^{-r_W(t_b - t_a)}}{2} [1 + \Theta(x_a - x_E)] f(0). \tag{20.464}$$

Using (20.418) we have $e^{-H_{r_{x_W}}(i)} = e^{r_W}$, and since $e^{-H_{r_{x_W}}(0)} = 1$ we see that $O(x_a, t_a)$ goes to zero for $x_a \rightarrow -\infty$ and has the large- x_a behavior

$$O(x_a, t_a) \approx e^{x_a} - e^{x_E} e^{-r_W(t_b - t_a)} = S(t_a) - e^{-r_W(t_b - t_a)} E. \tag{20.465}$$

This is the same behavior as in the Black-Scholes formula (20.438).

In Fig. 20.30 we display the difference between the option prices emerging from our formula (20.462) with a truncated Lévy distribution of kurtosis $\kappa = 4$, and the Black-Scholes formula (20.438) for the same data as in the upper left of Fig. 20.28.

For truncated Lévy distributions, the Fourier integral in Eq. (20.454) can be expressed directly in terms of the original distribution function which is the Fourier transform of (20.52):

$$\tilde{L}_{\sigma^2}^{(\lambda, \alpha, \beta)}(x) = \int_{-\infty}^{\infty} \frac{dp}{2\pi} e^{ipx - H(p)}. \tag{20.466}$$

By inspecting Eq. (20.53) we see that the factor $t_b - t_a$ multiplying $H_{r_{x_W}}(p)$ in (20.454) can be absorbed into the parameters $\sigma, \lambda, \alpha, \beta$ of the truncated Lévy distributions by replacing

$$\sigma^2 \rightarrow \sigma^2(t_b - t_a), \quad r_{x_W} \rightarrow r_{x_W}(t_b - t_a). \tag{20.467}$$

Let us denote the truncated Lévy distribution with zero average by $\bar{L}_{\sigma^2}^{(\lambda, \alpha, \beta)}(x)$. It is the Fourier transform of $e^{-\bar{H}(p)}$:

$$\bar{L}_{\sigma^2}^{(\lambda, \alpha, \beta)}(x) = \int_{-\infty}^{\infty} \frac{dp}{2\pi} e^{ipx - \bar{H}(p)}. \tag{20.468}$$

The Fourier transform of $e^{-\bar{H}(p)(t_b-t_a)}$ is then simply given by $\bar{L}_{\sigma^2(t_b-t_a)}^{(\lambda,\alpha,\beta)}(x)$. The additional term r_{xW} in the exponent of the integral (20.454) via (20.453) leads to a drift r_{xW} in the distribution, and we obtain

$$\int_{-\infty}^{\infty} \frac{dp}{2\pi} e^{ipx - [\bar{H}(p) + ir_{xW}p](t_b-t_a)} = \tilde{L}_{\sigma^2(t_b-t_a)}^{(\lambda,\alpha,\beta)}(x - r_{xW}(t_b - t_a)). \tag{20.469}$$

Inserting this into (20.419), we find the riskfree martingale distribution to be inserted into (20.454):

$$P(x_b t_b | x_a t_a) = e^{-r_W(t_b-t_a)} \bar{L}_{\sigma^2(t_b-t_a)}^{(\lambda,\alpha,\beta)}(x_b - x_a - r_{xW}(t_b - t_a)). \tag{20.470}$$

The result is therefore a truncated Lévy distribution of increasing width and uniformly moving average position. Since all expansion coefficients c_n of $H(p)$ in Eq. (20.40) receive the same factor $t_b - t_a$, the kurtosis $\kappa = c_4/c_2^2$ decreases inversely proportional to $t_b - t_a$. As time proceeds, the distribution becomes increasingly Gaussian, this being a manifestation of the central limit theorem of statistical mechanics. This is in contrast to the pure Lévy distribution which has no finite width and therefore maintains its power falloff at large distances.

Explicitly, the formula (20.454) for the option price becomes

$$O(x_a, t_a) = e^{-r_W(t_b-t_a)} \int_{x_E}^{\infty} dx_b (e^{x_b} - e^{x_E}) \bar{L}_{\sigma^2(t_b-t_a)}^{(\lambda,\alpha,\beta)}(x_b - x_a - r_{xW}(t_b - t_a)). \tag{20.471}$$

This and similar equations derived from any of the other non-Gaussian models lead to fairer formulas for option prices.

20.7.7 Option Pricing for Fluctuating Variance

If the fluctuations of the variance are taken into account, the dependence of the price of an option on $v(t)$ needs to be considered in the derivation of a time evolution equation for the option price. Instead of Eq. (20.407) we write the time evolution as

$$\begin{aligned} \frac{dO}{dt} &= \frac{1}{dt} [O(x(t) + \dot{x}(t) dt, v(t) + \dot{v}(t) dt, t + dt) - O(x(t), v(t), t)] \\ &= \frac{\partial O}{\partial t} + \frac{\partial O}{\partial x} \dot{x} + \frac{\partial O}{\partial v} \dot{v} + \frac{1}{2} \frac{\partial^2 O}{\partial x^2} \dot{x}^2 dt + \frac{\partial^2 O}{\partial x \partial v} \dot{x} \dot{v} dt + \frac{1}{2} \frac{\partial^2 O}{\partial v^2} \dot{v}^2 dt + \dots \end{aligned} \tag{20.472}$$

The expansion can be truncated after the second derivative due to the Gaussian nature of the fluctuations. We use Itô's rule to replace

$$\dot{x}^2 \longrightarrow v(t), \quad \dot{v}^2 \longrightarrow \epsilon^2 v(t), \quad \dot{x} \dot{v} \longrightarrow \rho \epsilon v(t). \tag{20.473}$$

These replacements follow directly from Eqs. (20.306) and (20.308) and the correlation functions (20.310). Thus we obtain

$$\begin{aligned} \frac{dO}{dt} &= \frac{1}{dt} [O(x(t) + \dot{x}(t) dt, v(t) + \dot{v}(t) dt, t + dt) - O(x(t), v(t), t)] \\ &= \frac{\partial O}{\partial t} + \frac{\partial O}{\partial x} \dot{x} + \frac{\partial O}{\partial v} \dot{v} + \frac{1}{2} \frac{\partial^2 O}{\partial x^2} v + \frac{\partial^2 O}{\partial x \partial v} \rho \epsilon v + \frac{1}{2} \frac{\partial^2 O}{\partial v^2} \epsilon^2 v. \end{aligned} \tag{20.474}$$

This is inserted into Eq. (20.403). If we adjust the portfolio according to the rule (20.404), and use the Itô relation $\dot{S}/S = \dot{x} + v/2$, we obtain the equation [compare (20.409)]

$$\begin{aligned} N_O r_W \left(-\frac{\partial O}{\partial x} + O \right) &= -N_O \frac{\partial O}{\partial x} \left(\dot{x} + \frac{v^2}{2} \right) + N_O \dot{O} \\ &= N_O \left[-\frac{v^2}{2} \frac{\partial O}{\partial x} + \frac{\partial O}{\partial v} \dot{v} + \frac{\partial O}{\partial t} + \frac{1}{2} \frac{\partial^2 O}{\partial x^2} v + \frac{\partial^2 O}{\partial x \partial v} \rho \epsilon v + \frac{1}{2} \frac{\partial^2 O}{\partial v^2} \epsilon^2 v + \dots \right]. \end{aligned} \quad (20.475)$$

As before in Eq. (20.409), the noise in \dot{x} has disappeared. In contrast to the single-variable treatment, however, the noise variable η_v remains in the equation. It can only be removed if we trade a financial asset V whose price is equal to the variance directly on the markets. Then we can build a *riskfree portfolio* containing four assets

$$W(t) = N_S(t)S(t) + N_O(t)O(S, t) + N_V(t)V(t) + N_B(t)B(t), \quad (20.476)$$

instead of (20.396). Indeed, by adjusting

$$\frac{N_V(t)}{N_O(t)} = -\frac{\partial O(S(t), v(t), t)}{\partial v(t)}, \quad (20.477)$$

we could cancel the term \dot{v} in Eq. (20.475). There is definitely need to establish trading in such an asset. Without this, we can only reach an approximate freedom of risk by ignoring the noise $\eta_v(t)$ in the term \dot{v} and replacing \dot{v} by the deterministic first term in the stochastic differential equation (20.308):

$$\dot{v}(t) \longrightarrow -\gamma[v(t) - \bar{v}]. \quad (20.478)$$

In addition, we can account for the fact that the option price rises with the variance as in the Black-Scholes formula by adding on the right hand side of (20.478) a phenomenological correction term $-\lambda v$ called *price of volatility risk* [78, 11]. Such a term has simply the effect of renormalizing the parameters γ and \bar{v} to

$$\gamma^* = \gamma + \lambda, \quad \text{and} \quad \bar{v}^* = \gamma \bar{v} / \gamma^*. \quad (20.479)$$

Thus we find the Fokker-Planck-like differential equation [compare (20.417)]

$$\frac{\partial O}{\partial t} = r_W O - \left(r_W - \frac{v}{2} \right) \frac{\partial O}{\partial x} + \gamma^* [v(t) - \bar{v}^*] \frac{\partial O}{\partial v} - \frac{v}{2} \frac{\partial^2 O}{\partial x^2} - \rho \epsilon v \frac{\partial^2 O}{\partial x \partial v} - \frac{\epsilon^2 v}{2} \frac{\partial^2 O}{\partial v^2}. \quad (20.480)$$

On the right-hand side we recognize the Hamiltonian operator (20.319), with γ and \bar{v} replaced by γ^* and \bar{v}^* , in terms of which we can write

$$\frac{\partial O}{\partial t} = r_W (O - \partial_x O) + \left(\hat{H}^* + \gamma^* + \rho \epsilon \partial_x + \epsilon^2 \partial_v \right) O. \quad (20.481)$$

The solution of this equation can easily be expressed as a slight modification of

the solution $P(x_b, v_b, t_b | x_a v_a t_a)$ in Eq. (20.340) of the differential equation (20.318). Since it contains only additional first-order derivatives with respect to (20.318), we simply find, with $x \equiv x_a$ and $t \equiv t_a$, the solution $P^v(x_b, v_b, t_b | x_a v_a t_a)$ satisfying the initial condition

$$P^v(x_b, v_b, t_b | x_a v_a t_a) = \delta(x_b - x_a) \delta(v_b - v_a) \quad (20.482)$$

as follows:

$$P^v(x_b, v_b, t_b | x_a v_a t_a) = e^{-(r_W + \gamma^*) \Delta t} P_{\text{sh}}(x_b, v_b, t_b | x_a v_a t_a), \quad (20.483)$$

where the subscript sh indicates that the arguments $x_b - x_a$ and $v_b - v_a$ are shifted:

$$x_b - x_a \rightarrow x_b - x_a - (r_W - \rho \epsilon), \quad v_b - v_a \rightarrow v_b - v_a - \epsilon^2. \quad (20.484)$$

The distribution (20.482) may be inserted into an equation of the type (20.425) to find the option price at the time t_a from the price (20.423) at the expiration date t_b . If we assume the variance v_a to be equal to \bar{v} , and the remaining parameters to be

$$\gamma^* = 2, \quad \bar{v} = 0.01, \quad \epsilon = 0.1, \quad r_W = 0, \quad (20.485)$$

the price of an option with strike price $E = 100$ one half year before expiration with the stock price $S = E$ (this is called an option *at-the-money*) is 2.83 US\$ for $\rho = -0.5$ and 2.81 US\$ for $\rho = 0.5$. The difference with respect to the Black-Scholes price is shown in Fig. 20.31.

Figure 20.31 Difference between option price $O(S, v, t)$ with fluctuating volatility and Black-Scholes price $O_{\text{BS}}(S, t)$ with $\sigma^2 = \bar{v}$ for option of strike price 100 US\$. The parameters are given in Eq. (20.485). The noise correlation parameter is once $\rho = -0.5$ and once $\rho = 0.5$. For an at-the-money option the absolute value is 2.83 US\$ for $\rho = -0.5$ and 2.81 US\$ for $\rho = 0.5$ (after Ref. [78]).

20.7.8 Perturbation Expansion and Smile

A perturbative treatment of any non-Gaussian distributions $\tilde{D}(x)$, which we assume to be symmetric, for simplicity, starts from the expansion

$$D(p) = \left[1 + \frac{a_4}{4!}p^4 - \frac{a_6}{6!}p^6 + \frac{c_8}{8!}p^8 - \dots - \dots \right] e^{-\sigma^2 p^2/2}, \tag{20.486}$$

where

$$a_4 = c_4, \quad a_6 = c_6, \quad a_8 = c_8 + 35c_4^2, \quad a_{10} = c_{10} + 210c_4c_6, \dots, \tag{20.487}$$

which can also be expressed as a series

$$D(p) = \left[1 + \frac{a_4}{4!}2^2 \left(\frac{\partial}{\partial \sigma^2} \right)^2 + \frac{a_6}{6!}2^3 \left(\frac{\partial}{\partial \sigma^2} \right)^3 + \frac{a_8}{8!}2^4 \left(\frac{\partial}{\partial \sigma^2} \right)^4 + \dots \right] e^{-\sigma^2 p^2/2}. \tag{20.488}$$

By taking the Fourier transform we obtain the expansion of the distributions in x -space

$$\begin{aligned} \tilde{D}(x) &= \left[1 + \frac{a_4}{4!}2^2 \left(\frac{\partial}{\partial \sigma^2} \right)^2 + \frac{a_6}{6!}2^3 \left(\frac{\partial}{\partial \sigma^2} \right)^3 + \frac{a_8}{8!}2^4 \left(\frac{\partial}{\partial \sigma^2} \right)^4 + \dots \right] \frac{e^{-x^2/2\sigma^2}}{\sqrt{2\pi\sigma^2}} \\ &= \left[1 + \frac{\bar{c}_4}{8} - \frac{\bar{c}_6}{48} + \frac{35\bar{c}_4^2}{384} + \frac{\bar{c}_8}{384} + \frac{x^2}{\sigma^2} \left(-\frac{\bar{c}_4}{4} + \frac{\bar{c}_6}{16} - \frac{35\bar{c}_4^2}{96} - \frac{\bar{c}_8}{96} \right) \right. \\ &\quad + \frac{x^4}{\sigma^4} \left(\frac{\bar{c}_4}{24} - \frac{\bar{c}_6}{48} + \frac{35\bar{c}_4^2}{192} + \frac{\bar{c}_8}{192} \right) + \frac{x^6}{\sigma^6} \left(\frac{\bar{c}_6}{720} - \frac{35\bar{c}_4^2}{1440} - \frac{\bar{c}_8}{1440} \right) \\ &\quad \left. + \frac{x^8}{\sigma^8} \left(\frac{35\bar{c}_4^2}{40320} + \frac{\bar{c}_8}{40320} \right) + \dots \right] \frac{e^{-x^2/2\sigma^2}}{\sqrt{2\pi\sigma^2}}. \end{aligned} \tag{20.489}$$

The quantities \bar{c}_n contain the kurtosis κ , in the case of a truncated Lévy distribution with the powers $\varepsilon^{n/2-1}$. If the distribution is close to a Gaussian, we may re-expand all expressions in powers of the higher cumulants. In the case of a truncated Lévy distribution, we may keep systematically all terms up to a certain maximal power of ε and find

$$\begin{aligned} \tilde{D}(x) &= \left\{ 1 - \frac{x^2}{2\sigma^2} \left(\frac{\bar{c}_4}{2} - \frac{\bar{c}_6}{8} + \frac{2\bar{c}_4^2}{3} + \frac{\bar{c}_8}{48} + \frac{5\bar{c}_4\bar{c}_6}{192} - \frac{33\bar{c}_4^3}{256} \right) \right. \\ &\quad + \frac{x^4}{\sigma^4} \left(\frac{\bar{c}_4}{24} - \frac{\bar{c}_6}{48} + \frac{17\bar{c}_4^2}{96} + \frac{\bar{c}_8}{192} + \frac{\bar{c}_4\bar{c}_6}{288} - \frac{239\bar{c}_4^3}{9216} \right) \\ &\quad + \frac{x^6}{\sigma^6} \left(\frac{\bar{c}_6}{720} - \frac{7\bar{c}_4^2}{288} - \frac{\bar{c}_8}{1440} - \frac{\bar{c}_4\bar{c}_6}{5760} + \frac{7\bar{c}_4^3}{2304} \right) \\ &\quad \left. + \frac{x^8}{\sigma^8} \left(\frac{\bar{c}_4^2}{1152} + \frac{\bar{c}_8}{40320} - \frac{\bar{c}_4^3}{9216} \right) + \dots \right\} \frac{e^{-x^2/2\sigma^2}}{\sqrt{2\pi\sigma_1^2}}, \end{aligned} \tag{20.490}$$

where we have introduced the modified width

$$\tilde{\sigma}_1^2 \equiv \sigma^2 \left(1 - \frac{\bar{c}_4}{4} + \frac{\bar{c}_6}{24} - \frac{13\bar{c}_4^2}{96} - \frac{\bar{c}_8}{192} - \frac{\bar{c}_4\bar{c}_6}{64} - \frac{31\bar{c}_4^3}{512} + \dots \right). \tag{20.491}$$

The prefactor can be taken into the exponent yielding

$$\begin{aligned} \tilde{D}(x) &= \exp \left\{ -\frac{x^2}{2\sigma^2} \left(1 + \frac{\bar{c}_4}{2} + \frac{2\bar{c}_4^2}{3} - \frac{33\bar{c}_4^3}{256} - \frac{\bar{c}_6}{8} + \frac{5\bar{c}_4\bar{c}_6}{192} + \frac{\bar{c}_8}{48} \right) \right. \\ &\quad + \frac{x^4}{\sigma^4} \left(\frac{\bar{c}_4}{24} + \frac{7\bar{c}_4^2}{48} - \frac{1007\bar{c}_4^3}{9216} - \frac{\bar{c}_6}{48} + \frac{11\bar{c}_4\bar{c}_6}{576} + \frac{\bar{c}_8}{192} \right) \\ &\quad + \frac{x^6}{\sigma^6} \left(-\frac{\bar{c}_4^2}{72} + \frac{43\bar{c}_4^3}{768} + \frac{\bar{c}_6}{720} - \frac{23\bar{c}_4\bar{c}_6}{2880} - \frac{\bar{c}_8}{1440} \right) \\ &\quad \left. + \frac{x^8}{\sigma^8} \left(-\frac{101\bar{c}_4^3}{9216} + \frac{7\bar{c}_4\bar{c}_6}{5760} + \frac{\bar{c}_8}{40320} \right) + \dots \right\} \frac{1}{\sqrt{2\pi\sigma_1^2}}. \end{aligned} \tag{20.492}$$

Introducing a second modified width

$$\tilde{\sigma}_2^2 \equiv \sigma^2 \left(1 - \frac{\bar{c}_4}{2} + \frac{\bar{c}_6}{8} - \frac{5\bar{c}_4^2}{12} - \frac{\bar{c}_8}{48} - \frac{29\bar{c}_4\bar{c}_6}{192} + \frac{515\bar{c}_4^3}{768} + \dots \right), \tag{20.493}$$

the exponential can be brought to the form

$$\begin{aligned} \tilde{D}(x) = & \exp \left\{ -\frac{x^2}{\tilde{\sigma}_2^2} + \frac{x^4}{\tilde{\sigma}_2^4} \left(\frac{\bar{c}_4}{24} - \frac{\bar{c}_6}{48} + \frac{5\bar{c}_4^2}{48} + \frac{\bar{c}_8}{192} + \frac{29\bar{c}_4\bar{c}_6}{576} - \frac{2576\bar{c}_4^3}{9216} \right) \right. \\ & + \frac{x^6}{\tilde{\sigma}_2^6} \left(\frac{\bar{c}_6}{720} - \frac{\bar{c}_4^2}{72} - \frac{8\bar{c}_8}{1440} - \frac{29\bar{c}_4\bar{c}_6}{2880} + \frac{59\bar{c}_4^3}{768} \right) \\ & \left. + \frac{x^8}{\tilde{\sigma}_2^8} \left(\frac{\bar{c}_8}{40320} + \frac{7\bar{c}_4\bar{c}_6}{5760} - \frac{101\bar{c}_4^3}{9216} \right) + \dots \right\} \frac{1}{\sqrt{2\pi\tilde{\sigma}_1^2}}. \end{aligned} \tag{20.494}$$

The exponential can be re-expressed compactly in the quasi-Gaussian form

$$\tilde{D}(x) = \frac{1}{\sqrt{2\pi\tilde{\sigma}_1^2}} \exp \left[-\frac{x^2}{2\Sigma^2(x)} \right], \tag{20.495}$$

where we have defined an x -dependent width

$$\begin{aligned} \tilde{\Sigma}(x) \equiv & \sigma^2 \left[1 + \frac{x^2}{\sigma^2} \left(\frac{\bar{c}_4}{12} + \frac{5\bar{c}_4^2}{24} - \frac{2575\bar{c}_4^3}{4608} - \frac{\bar{c}_6}{24} + \frac{29\bar{c}_4\bar{c}_6}{288} + \frac{\bar{c}_8}{96} \right) \right. \\ & + \frac{x^4}{\sigma^4} \left(\frac{-\bar{c}_4^2}{48} + \frac{217\bar{c}_4^3}{1152} - \frac{1375\bar{c}_4^4}{27648} + \frac{\bar{c}_6}{360} - \frac{13\bar{c}_4\bar{c}_6}{480} - \frac{\bar{c}_4^2\bar{c}_6}{1728} + \frac{\bar{c}_6^2}{576} - \frac{\bar{c}_8}{720} + \frac{\bar{c}_4\bar{c}_8}{576} \right) \\ & \left. + \frac{x^6}{\sigma^6} \left(-\frac{359\bar{c}_4^3}{13824} + \frac{127\bar{c}_4^4}{6912} + \frac{5\bar{c}_4\bar{c}_6}{1728} - \frac{13\bar{c}_4^2\bar{c}_6}{17280} - \frac{\bar{c}_6^2}{4320} + \frac{\bar{c}_8}{20160} - \frac{\bar{c}_4\bar{c}_8}{4320} \right) + \dots \right]. \end{aligned} \tag{20.496}$$

For small x the deviation of $\Sigma^2(x)$ from a constant σ^2 is dominated by the quadratic term. If one plots the fluctuation width $\Sigma(x)$ for the logarithms of the observed option prices one finds the smile parabola shown before in Fig. 20.29. On the basis of the expansion (20.488) it is possible to derive an approximate option price formula for assets fluctuating according to the truncated Lévy distribution. We simply apply the differential operator in front of the Gaussian distribution

$$\mathcal{O} \equiv \left[1 + \frac{a_4}{4!} 2^2 \left(\frac{\partial}{\partial \sigma^2} \right)^2 + \frac{a_6}{6!} 2^3 \left(\frac{\partial}{\partial \sigma^2} \right)^3 + \frac{a_8}{8!} 2^4 \left(\frac{\partial}{\partial \sigma^2} \right)^4 + \dots \right] \tag{20.497}$$

to the Gaussian distribution (20.421). For $\lambda = 3/2$, the coefficients are

$$\begin{aligned} a_4 &= \frac{\varepsilon}{M^2}, \quad a_6 = \frac{5 \cdot 7 \varepsilon^2}{3M^3}, \quad a_8 = \frac{5 \cdot 7 \cdot 11 \varepsilon^2}{M^4} + \frac{5 \cdot 7 \varepsilon^2}{M^4}, \\ a_{10} &= \frac{5^2 \cdot 7 \cdot 11 \cdot 13 \varepsilon^4}{3M^5} + \frac{2^2 \cdot 5 \cdot 7 \cdot 17 \varepsilon^4}{3M^5}, \dots \end{aligned} \tag{20.498}$$

The operator \mathcal{O} winds up in front of the Black-Scholes expression (20.438), such that we obtain the formal result

$$O^L(x_a, t_a) = \mathcal{O}O(x_a, t_a) = \mathcal{O} \left[S(t_a)N(y_+) - e^{-(r_{xv} + \sigma^2/2)(t_b - t_a)} E N(y_-) \right], \tag{20.499}$$

where we have used (20.418) to exhibit the full σ -dependence on the right-hand side. This expression may now be expanded in powers of the kurtosis κ . The term proportional to a_4 yields a first correction to the Black-Scholes formula, linear in ε ,

$$\begin{aligned} O_1(x_a, t_a) = & -\frac{\varepsilon}{12M^2} \left\{ \left(S e^{-y_+^2/2} - e^{-r_{xv}(t_b - t_a)} E e^{-y_-^2/2} \right) \frac{y_m}{\sqrt{2\pi\sigma^2}} \right. \\ & \left. - e^{-r_{xv}(t_b - t_a)} (t_b - t_a) EN(y_-) \right\}. \end{aligned} \tag{20.500}$$

The term proportional to a_6 adds a correction proportional to ε^2 :

$$O_2(x_a, t_a) = \frac{35\varepsilon^2}{3M^3} \frac{1}{2^3 \cdot 3^2 \cdot 5} \left\{ \left[Se^{-y_+^2/2} (y_+ y_-^2 - 3y_+ + 4\sqrt{\sigma^2(t_b - t_a)}) \right. \right. \\ \left. \left. - e^{-r_w(t_b - t_a)} Ee^{-y_-^2/2} (y_-^3 - 3y_- - 2\sigma^2(t_b - t_a)y_-) \right] \frac{1}{\sqrt{2\pi\sigma^4}} \right. \\ \left. + e^{-r_w(t_b - t_a)} (t_b - t_a)^2 EN(y_-) \right\}. \tag{20.501}$$

The next term proportional to a_8 adds corrections proportional to ε^2 and ε^3 :

$$O_3(x_a, t_a) = \frac{385\varepsilon^3 + 35\varepsilon^2}{M^4} \frac{1}{2^6 \cdot 3^2 \cdot 5 \cdot 7} \\ \times \left\{ \left[Se^{-y_+^2/2} (-y_-^3 y_+^2 + 9y_- y_+^2 + y_-^3 - 15y_+ + 18 + \sqrt{\sigma^2(t_b - t_a)}(12y_- y_+ + 18)) \right. \right. \\ \left. \left. - e^{-r_w(t_b - t_a)} Ee^{-y_-^2/2} (y_-^5 - 10y_-^3 + 15y_- + \sigma^2(t_b - t_a)(3y_-^3 - 9y_-) \right. \right. \\ \left. \left. + \sigma^4(t_b - t_a)^2 3y_-) \right] \frac{1}{\sqrt{2\pi\sigma^6}} + e^{-r_w(t_b - t_a)} (t_b - t_a)^3 EN(y_-) \right\}. \tag{20.502}$$

Since the expansion is asymptotic, an efficient resummation scheme will be needed for practical applications.

Appendix 20A Large- x Behavior of Truncated Lévy Distribution

Here we derive the divergent asymptotic expansion in the large- x regime. Using the variable $y \equiv p/\alpha$ and the constant $a \equiv -s\alpha^\lambda$, we may write the Fourier integral (20.24) as

$$\tilde{L}_{\sigma^2}^{(\lambda, \alpha)}(x) = \alpha e^{-2a} \int_{-\infty}^{\infty} \frac{dy}{2\pi} e^{i\alpha y x} e^{a[(1-iy)^\lambda + (1+iy)^\lambda]}. \tag{20A.1}$$

Expanding the last exponential in a Taylor series, we obtain

$$\tilde{L}_{\sigma^2}^{(\lambda, \alpha)}(x) = \alpha e^{-2a} \int_{-\infty}^{\infty} \frac{dy}{2\pi} e^{iy\alpha x} \sum_{n=0}^{\infty} \frac{a^n}{n!} [(1-iy)^\lambda + (1+iy)^\lambda]^n = \\ = \alpha e^{-2a} \int_{-\infty}^{\infty} \frac{dy}{2\pi} e^{i\alpha xy} \sum_{n=0}^{\infty} \frac{a^n}{n!} \sum_{m=0}^n \binom{n}{m} (1-iy)^{\lambda(n-m)} (1+iy)^{\lambda m} \tag{20A.2}$$

containing binominal coefficients. Changing the order of summations yields

$$\tilde{L}_{\sigma^2}^{(\lambda, \alpha)}(x) = \alpha e^{-2a} \sum_{n=0}^{\infty} \frac{a^n}{n!} \sum_{m=0}^n \binom{n}{m} \int_{-\infty}^{\infty} \frac{dy}{2\pi} e^{i\alpha xy} (1-iy)^{\lambda(n-m)} (1+iy)^{\lambda m}. \tag{20A.3}$$

This can be written with the help of the Whittaker functions (20.30) as

$$\tilde{L}_{\sigma^2}^{(\lambda, \alpha)}(x) = \alpha e^{-2a} \sum_{n=0}^{\infty} \frac{a^n}{n!} \sum_{m=0}^n \binom{n}{m} \frac{(\alpha x)^{-1-\lambda n/2} 2^{\lambda n/2}}{\Gamma(-\lambda m)} W_{\lambda n/2 - \lambda m, (\lambda n + 1)/2}(2\alpha x). \tag{20A.4}$$

After converting the Gamma functions of negative arguments into those of positive arguments, this becomes

$$\tilde{L}_{\sigma^2}^{(\lambda, \alpha)}(x) = -\frac{\alpha}{\pi} e^{-2a} \sum_{n=1}^{\infty} a^n \sum_{m=0}^n \frac{2^{\lambda n/2} \Gamma(1 + \lambda m) \sin(\pi \lambda m)}{(\alpha x)^{1 + \lambda n/2} m! (n - m)!} W_{\lambda n/2 - \lambda m, (\lambda n + 1)/2}(2\alpha x). \tag{20A.5}$$

The Whittaker functions $W_{\lambda, \gamma}(x)$ have the following asymptotic expansion

$$W_{\lambda, \gamma}(x) = e^{-x/2} x^\lambda \left\{ 1 + \sum_{k=1}^{\infty} \frac{1}{k! x^k} \prod_{j=1}^k [\gamma^2 - (\lambda - j + 1/2)^2] \right\}. \tag{20A.6}$$

For $\gamma \equiv (\lambda n + 1)/2$ and $\lambda \equiv \lambda(n - 2m)/2$, the product takes the form

$$\begin{aligned} \prod_{j=1}^k [\gamma^2 - (\lambda - j + 1/2)^2] &= \prod_{j=1}^k \left\{ \left(\frac{\lambda n + 1}{2} \right)^2 - \left[\frac{\lambda(n - 2m)}{2} - j + \frac{1}{2} \right]^2 \right\} \\ &= \prod_{j=1}^k (\lambda m + j)(\lambda n + 1 - \lambda m - j). \end{aligned} \tag{20A.7}$$

Inserting this into (20A.6) and the result into (20A.5), we obtain the asymptotic expansion for large x :

$$\begin{aligned} \tilde{L}_{\sigma^2}^{(\lambda, \alpha)}(x) &= -\frac{1}{\pi} e^{-2a} \frac{e^{-\alpha x}}{x} \sum_{n=1}^{\infty} a^n 2^{\lambda n} \sum_{m=1}^n \frac{\Gamma(1 + \lambda m) \sin(\pi \lambda m)}{m! (n - m)!} (2\alpha x)^{-\lambda m} \\ &\quad \times \left[1 + \sum_{k=1}^{\infty} \frac{\prod_{j=1}^k (\lambda m + j)(\lambda n + 1 - \lambda m - j)}{k! (2\alpha x)^k} \right]. \end{aligned} \tag{20A.8}$$

We have raised the initial value of the index of summation m by one unit since $\sin(\pi \lambda m)$ vanishes for $m = 0$. If we define a product of the form $\prod_{j=1}^0 \dots$ to be equal to unity, we can write the term in the last bracket as

$$\sum_{k=0}^{\infty} \frac{1}{k! (2\alpha x)^k} \prod_{j=1}^k (j + \lambda m)(1 - \lambda m - j + \lambda n). \tag{20A.9}$$

Rearranging the double sum in (20A.8), we write $\tilde{L}_{\sigma^2}^{(\lambda, \alpha)}(x)$ as

$$\begin{aligned} \tilde{L}_{\sigma^2}^{(\lambda, \alpha)}(x) &= -\frac{1}{\pi} e^{-2a} \frac{e^{-\alpha x}}{x} \sum_{m=1}^{\infty} \frac{\Gamma(1 + \lambda m) \sin(\pi \lambda m)}{m! (2\alpha x)^{\lambda m}} \sum_{n=m}^{\infty} \frac{a^n 2^{\lambda n}}{(n - m)!} \\ &\quad \times \sum_{k=0}^{\infty} \frac{1}{k! (2\alpha x)^k} \prod_{j=1}^k (j + \lambda m)(1 - \lambda m - j + \lambda n), \end{aligned} \tag{20A.10}$$

and further as

$$\begin{aligned} \tilde{L}_{\sigma^2}^{(\lambda, \alpha)}(x) &= -\frac{1}{\pi} e^{-2a} \frac{e^{-\alpha x}}{x} \sum_{m=1}^{\infty} \frac{\Gamma(1 + \lambda m) \sin(\pi \lambda m)}{m!} (2\alpha x)^{-\lambda m} \\ &\quad \times \sum_{n=0}^{\infty} (2\lambda a)^{n+m} \frac{1}{n!} \sum_{k=0}^{\infty} \frac{1}{k! (2\alpha x)^k} \prod_{j=1}^k (j + \lambda m)(1 - j + \lambda n) = \end{aligned}$$

$$\begin{aligned}
 &= -\frac{1}{\pi} e^{-2a} \frac{e^{-\alpha x}}{x} \sum_{k=0}^{\infty} \frac{1}{k!(2\alpha x)^k} \sum_{m=1}^{\infty} \frac{\Gamma(1 + \lambda m) \sin(\pi \lambda m) (2^\lambda a)^m}{(2\alpha x)^{\lambda m} m!} \\
 &\quad \times \prod_{j'=1}^k (j' + \lambda m) \sum_{n=0}^{\infty} \frac{(2^\lambda a)^n}{n!} \prod_{j=1}^k (\lambda n + 1 - j). \tag{20A.11}
 \end{aligned}$$

The last sum over n in this expression can be re-expressed more efficiently with the help of a generating function

$$f^{(k)}(y^\lambda) \equiv \frac{d^k}{dy^k} e^{y^\lambda}, \tag{20A.12}$$

whose Taylor series is

$$f^{(k)}(y^\lambda) = \frac{d^k}{dy^k} \sum_{n=0}^{\infty} \frac{y^{\lambda n}}{n!} = \sum_{n=0}^{\infty} \frac{1}{n!} \prod_{j=1}^k (\lambda n - j + 1) y^{\lambda n - k}, \tag{20A.13}$$

leading to

$$\begin{aligned}
 \tilde{L}_{\sigma^2}^{(\lambda, \alpha)}(x) &= \frac{1}{\pi} e^{-2a} \frac{e^{-\alpha x}}{x} \sum_{k=0}^{\infty} \frac{a^{k/\lambda} 2^k f^{(k)}(2^\lambda a)}{k!(2\alpha x)^k} \\
 &\quad \times \sum_{m=1}^{\infty} \frac{\Gamma(1 + \lambda m) \sin(\pi \lambda m) (2^\lambda a)^m}{m!} (2\alpha x)^{-\lambda m} \prod_{j=1}^k (\lambda m + j). \tag{20A.14}
 \end{aligned}$$

This can be rearranged to

$$\begin{aligned}
 \tilde{L}_{\sigma^2}^{(\lambda, \alpha)}(x) &= -\frac{e^{-2a}}{\pi} e^{-\alpha x} \sum_{k=0}^{\infty} \frac{(-s)^{k/\lambda} f^{(k)}(-s(2\alpha)^\lambda)}{k!} \\
 &\quad \times \sum_{m=1}^{\infty} \frac{\Gamma(1 + \lambda m + k) \sin(\pi \lambda m) (-s)^m}{m! x^{1+\lambda m+k}}. \tag{20A.15}
 \end{aligned}$$

Thus we obtain the asymptotic expansion

Figure 20.32 Comparison of large- x expansions containing different numbers of terms (with $K = 0, 1, 2, 3, 4, 5$, with increasing dash length) with the tails of the truncated Lévy distribution for $\lambda = \sqrt{2}$, $\sigma = 0.5$, $\alpha = 1$.

$$\tilde{L}_{\sigma^2}^{(\lambda,\alpha)}(x) = -\frac{e^{-2a}}{\pi} \frac{e^{-\alpha x}}{x} \sum_{k=0}^{\infty} A_k \sum_{m=1}^{\infty} B_{km} \frac{(-s)^m}{x^{\lambda m+k}}, \tag{20A.16}$$

where

$$A_k = \frac{(-s)^{k/\lambda} f^{(k)}(-s(2\alpha)^\lambda)}{k!}, \quad B_{km} = \frac{\Gamma(1 + \lambda m + k) \sin(\pi \lambda m)}{m!}. \tag{20A.17}$$

We shall denote by $\tilde{L}_{\sigma^2}^{(\lambda,\alpha)(K)}(x)$ the approximants in which the sums over K are truncated after the K th term. To have a definite smallest power in $|x|$, the sum over m is truncated after the smallest integer larger than $(K - k + \lambda)/\lambda$. The leading term is

$$\begin{aligned} \tilde{L}_{\sigma^2}^{(\lambda,\alpha)(0)}(x) &= -\frac{e^{-2a}}{\pi} e^{-\alpha x} f^{(0)}(-s(2\alpha)^\lambda) \frac{\Gamma(1 + \lambda) \sin(\pi \lambda) (-s)}{x^{1+\lambda}} \\ &= s \frac{e^{\alpha^\lambda s(2-2^\lambda)}}{\pi} \frac{\Gamma(1 + \lambda) \sin(\pi \lambda)}{x^{1+\lambda}} e^{-\alpha x}. \end{aligned} \tag{20A.18}$$

The large- x approximations $\tilde{L}_{\sigma^2}^{(\lambda,\alpha)(0)}(x)$ are compared with the numerically calculated truncated Lévy distribution in Fig. 20.32.

Appendix 20B Gaussian Weight

For simplicity, let us study the Gaussian content in the final distribution (20.347) only for the simpler case $\rho = 0$. Then we shift the contour of integration in (20.347) to run along $p + i/2$, and we study the Fourier integral

$$P(xt | x_a t_a) = e^{-\Delta x/2} \int_{-\infty}^{+\infty} \frac{dp}{2\pi} e^{ip\Delta x - \bar{H}(p, \Delta t)}, \tag{20B.1}$$

where

$$\bar{H}(p, \Delta t) = -\frac{\gamma^2 \bar{v} t}{\kappa^2} + \frac{2\gamma \bar{v}}{\kappa^2} \ln \left[\cosh \frac{\Omega t}{2} + \frac{\Omega^2 + \gamma^2}{2\gamma \Omega} \sinh \frac{\Omega t}{2} \right], \tag{20B.2}$$

and

$$\Omega = \sqrt{\gamma^2 + \kappa^2(p^2 + 1/4)}. \tag{20B.3}$$

The function $\bar{H}(p, \Delta t)$ is real and symmetric in p . The integral (20B.1) is therefore a symmetric function of Δx . The only source of asymmetry of $P(xt | x_a t_a)$ in Δx is the exponential prefactor in (20B.1).

Let us expand the integral in (20B.1) for small Δx :

$$P(xt | x_a t_a) \approx e^{-\Delta x/2} \left[\mu_0 - \frac{1}{2} \mu_2 (\Delta x)^2 \right] \approx \mu_0 e^{-\Delta x/2} e^{-\mu_2 (\Delta x)^2 / 2\mu_0}, \tag{20B.4}$$

where the coefficients are the first and the second moments of $\exp[\bar{H}(p, \Delta t)]$

$$\mu_0(\Delta t) = \int_{-\infty}^{+\infty} \frac{dp}{2\pi} e^{-\bar{H}(p, \Delta t)}, \quad \mu_2(\Delta t) = \int_{-\infty}^{+\infty} \frac{dp}{2\pi} p^2 e^{-\bar{H}(p, \Delta t)}. \tag{20B.5}$$

If we ignore the existence of semi-heavy tails and extrapolate the Gaussian expression on the right-hand side to $\Delta x \in (-\infty, \infty)$, the total probability contained in such a Gaussian extrapolation will be the fraction

$$f(\Delta t) = \int_{-\infty}^{+\infty} d\Delta x \mu_0 e^{-\Delta x/2 - \mu_2 \Delta x^2 / 2\mu_0} = \sqrt{\frac{2\pi \mu_0^3}{\mu_2}} e^{\mu_0 / 8\mu_2}. \tag{20B.6}$$

This is always less than 1 since the integral (20B.6) ignores the probability contained in the semi-heavy tails. The difference $1 - f(\Delta t)$ measures the relative contribution of the semi-heavy tails. The parameters $\mu_0(\Delta t)$ and $\mu_2(\Delta t)$ are calculated numerically and the resulting fraction $f(\Delta t)$ is plotted in Fig. 20.25 as a function of Δt . For $\Delta t \rightarrow \infty$, the distribution becomes Gaussian, whereas for small Δt , it becomes a broad function of p .

Appendix 20C Comparison with Dow-Jones Data

For the comparison of the theory in Section 20.4 with actual financial data shown in Fig. 20.22, the authors of Ref. [79] downloaded the daily closing values of the Dow-Jones industrial index for the period of 20 years from 1 January 1982 to 31 December 2001 from the Web site of Yahoo [110]. The data set contained 5049 points $S(t_n)$, where the discrete time variable t_n parametrizes the days. Short days before holidays were ignored. For each t_n , they compiled the log-returns $\Delta x(t_n) = \ln S(t_{n+1})/S(t_n)$. Then they partitioned the x -axis into equally spaced intervals of width Δx and counted the number of log-returns $\Delta x(t_n)$ falling into each interval. They omitted all intervals with occupation numbers less than five, which they considered as too few to rely on. Only less than 1% of the entire data set was omitted in this way. Dividing the occupation number of each bin by Δr and by the total occupation number of all bins, they obtained the probability density for a given time interval $\Delta t = 1$ day. From this they found $P^{(DJ)}(xt|x_at_a)$ by replacing $\Delta x \rightarrow \Delta x - r_S \Delta t$.

Assuming that the system is ergodic, so that ensemble averaging is equivalent to time averaging, they compared $P^{(DJ)}(xt|x_at_a)$ with the calculated $P(xt|x_at_a)$ in Eq. (20.347). The parameters of the model were determined by minimizing the mean-square deviation $\sum_{\Delta x, \Delta t} |\log P^{(DJ)}(xt|x_at_a) - \log P(xt|x_at_a)|^2$, with the sum taken over all available Δx and over $\Delta t = 1, 5, 20, 40$, and 250 days. These values of Δt were selected because they represent different regimes: $\gamma \Delta t \ll 1$ for $t = 1$ and 5 days, $\gamma \Delta t \approx 1$ for $t = 20$ days, and $\gamma \Delta t \gg 1$ for $t = 40$ and 250 days. As Figs. 20.22 and 20.23 illustrate, the probability density $P(xt|x_at_a)$ calculate from the Fourier integral (20.347) with components (20.348) agrees with the data very well, not only for the selected five values of time t , but for the whole time interval from 1 to 250 trading days. The comparison cannot be extended to Δt longer than 250 days, which is approximately 1/20 of the entire range of the data set, because it is impossible to reliably extract $P^{(DJ)}(xt|x_at_a)$ from the data when Δt is too long.

The best fits for the four parameters $\gamma, \bar{v}, \varepsilon, \mu$ are given in Table 20.1. Within the scattering of the data, there are no discernible differences between the fits with the correlation coefficient ρ being zero or slightly different from zero. Thus the correlation parameter ρ between the noise terms for stock price and variance in Eq. (20.310) is practically zero. This conclusion is in contrast with the value $\rho = -0.58$ found in [111] by fitting the leverage correlation function introduced in [112]. Further study is necessary to understand this discrepancy. All theoretical curves shown in the above figures are calculated for $\rho = 0$, and fit the data very well.

The parameters $\gamma, \bar{v}, \varepsilon, \mu$ have the dimensionality of 1/time. One row in Table 20.1 gives their values in units of 1/day, as originally determined in our fit. The other row shows the annualized values of the parameters in units of 1/year, where one year is here equal to the average number of 252.5 trading days per calendar year. The relaxation time of variance is equal to $1/\gamma = 22.2$ trading days = 4.4 weeks ≈ 1 month, where 1 week = 5 trading days. Thus one finds that the variance has a rather long relaxation time, of the order of one month, which is in agreement with an earlier conclusion in Ref. [111].

Using the numbers given in Table 20.1, the value of the parameter $\varepsilon^2/2\gamma\bar{v}$ is ≈ 0.772 thus satisfying the smallness condition Eq. (20.322) ensuring that v never reaches negative values.

The stock prices have an apparent growth rate determined by the position $x_m(t)$ where the probability density is maximal. Adding this to the initially subtracted growth rate r_S we find that the apparent growth rate is $\bar{r}_S = r_S - \gamma\bar{v}/2\omega_0 = 13\%$ per year. This number coincides with the apparent average growth rate of the Dow-Jones index obtained by a simple fit of the data points S_{t_n} with an exponential function of t_n . The apparent growth rate \bar{r}_S is comparable to the

Table 20.1 Parameters of equations with fluctuating variance obtained from fits to Dow-Jones data. The fit yields $\rho \approx 0$ for the correlation coefficient and $1/\gamma = 22.2$ trading days for the relaxation time of variance.

Units	γ	\bar{v}	ε	μ
1/day	4.50×10^{-2}	8.62×10^{-5}	2.45×10^{-3}	5.67×10^{-4}
1/year	11.35	0.022	0.618	0.143

average stock volatility after one year $\sigma = \sqrt{\bar{v}} = 14.7\%$. Moreover, the parameter (20.328) which characterizes the width of the stationary distribution of variance is equal to $v_{\max}/w = 0.54$. This means that the distribution of variance is broad, and variance can easily fluctuate to a value twice greater than the average value \bar{v} . As a consequence, even though the average growth rate of the stock index is positive, there is a substantial probability of $\int_{-\infty}^0 d\Delta x P(xt|x_a t_a) \approx 17.7\%$ to have negative growth for $\Delta t = 1$ year.

According to (20.368), the asymmetry between the slopes of exponential tails for positive and negative Δx is given by the parameter p_0 , which is equal to $1/2$ when $\rho = 0$ [see also the discussion of Eq. (20B.1) in Appendix 20B]. The origin of this asymmetry can be traced back to the transformation from $\dot{S}(t)/S(t)$ to $\dot{x}(t)$ using Itô's formula. This produces a term $v(t)/2$ in Eq. (20.306), which leads to the first term in the Hamiltonian operator (20.319). For $\rho = 0$ this is the only source of asymmetry in Δx of $P(xt|x_a t_a)$. In practice, the asymmetry of the slopes $p_0 = 1/2$ is quite small (about 2.7%) compared to the average slope $q_*^\pm \approx \omega_0/\varepsilon = 18.4$.

Notes and References

Option pricing beyond Black and Scholes via path integrals was discussed in Ref. [113], where strategies are devised to minimize risks in the presence of extreme fluctuations, as occur on real markets. See also Ref. [114].

Recently, a generalization of path integrals to functional integrals over surfaces has been proposed in Ref. [115] as an alternative to the Heath-Jarrow-Morton approach of modeling yield curves (see <http://risk.ifci.ch/00011661.htm>). Applications of the Duru-Kleinert transformation to financial markets are described in Ref. [21] of Chapter 14.
